### Revision history<sup>1</sup>

- Version 0.1 – July 2008 to September 2008 (initial development)
- Version 0.2 – released September 29, 2008 for Fall quarter student use (SafeCreative registration code 0810111072182)
- Version 0.4 – released January 12, 2009 for Winter quarter student use (SafeCreative registration code 0901122394919)
- Version 0.6 – released April 21, 2009 for public use (SafeCreative registration code 0904213106101)
- Version 0.8 – released September 8, 2009 for public use (SafeCreative registration code 0909094400980)
- Version 1.0 – released September 28, 2009 for public use (SafeCreative registration code 0909284601913)
- Version 1.2 – released January 12, 2010 for public use (SafeCreative registration code 1001125303242)
- Version 1.4 – released April 11, 2010 for public use (SafeCreative registration code 1004125976416)
- Version 1.6 – released May 4, 2010 for public use (SafeCreative registration code 1005046194859)
- Version 1.8 – released June 1, 2010 for public use (SafeCreative registration code 1006016477958)
- Version 1.10 – released June 28, 2010 for public use (SafeCreative registration code 1006286691573)
- Version 1.12 – released September 20, 2010 for public use (SafeCreative registration code 1009217397803)

---

<sup>1</sup>Version numbers ending in odd digits are developmental (e.g. 0.7, 1.23, 4.5), with only the latest revision made accessible to the public. Version numbers ending in even digits (e.g. 0.6, 1.0, 2.14) are considered “public-release” and will be archived. Version numbers beginning with zero (e.g. 0.1, 0.2, etc.) represent early editions that were substantially incomplete.

- Version 1.14 – released January 11, 2011 for public use (SafeCreative registration code 1101118240391)
- Version 1.16 – released April 11, 2011 for public use (SafeCreative registration code 1104118950581)
- Version 1.18 – released July 4, 2011 for public use (SafeCreative registration code 1107069618739)
- Version 1.20 – released September 19, 2011 for public use (SafeCreative registration code 1109190093232)
- Version 1.22 – released January 8, 2012 for public use (SafeCreative registration code 1201090880285)
- Version 1.24 – released April 8, 2012 for public use (SafeCreative registration code 1204091446627)
- Version 1.26 – released June 30, 2012 for public use
- Version 1.28 – released September 18, 2012 for public use
- Version 1.30 – released January 5, 2013 for public use
- Version 1.32 – released April 1, 2013 for public use
- Version 1.34 – released July 1, 2013 for public use
- Version 1.36 – released September 23, 2013 for public use
- Version 2.00 – released January 12, 2014 for public use
- Version 2.02 – released April 14, 2014 for public use
- Version 2.04 – released August 8, 2014 for public use
- Version 2.06 – released September 22, 2014 for public use
- Version 2.08 – released January 12, 2015 for public use
- Version 2.10 – released April 7, 2015 for public use
- Version 2.12 – released June 29, 2015 for public use
- Version 2.14 – released September 21, 2015 for public use
- Version 2.16 – released January 1, 2016 for public use
- Version 2.18 – released April 11, 2016 for public use
- Version 2.20 – released September 16, 2016 for public use
- Version 2.22 – released April 8, 2017 for public use

- Version 2.24 – released July 4, 2017 for public use
- Version 2.26 – released September 25, 2017 for public use
- Version 2.28 – released April 1, 2018 for public use

# Contents

<b>Preface</b>	<b>1</b>
<b>1 Calculus</b>	<b>5</b>
1.1 Introduction to calculus . . . . .	6
1.2 The concept of differentiation . . . . .	9
1.3 The concept of integration . . . . .	14
1.4 How derivatives and integrals relate to one another . . . . .	23
1.5 Symbolic versus numerical calculus . . . . .	27
1.6 Numerical differentiation . . . . .	31
1.7 Numerical integration . . . . .	41
<b>2 Physics</b>	<b>55</b>
2.1 Terms and Definitions . . . . .	56
2.2 Metric prefixes . . . . .	57
2.3 Areas and volumes . . . . .	57
2.3.1 Common geometric shapes . . . . .	58
2.4 Unit conversions and physical constants . . . . .	60
2.4.1 Unity fractions . . . . .	61
2.4.2 Conversion formulae for temperature . . . . .	64
2.4.3 Conversion factors for distance . . . . .	65
2.4.4 Conversion factors for volume . . . . .	65
2.4.5 Conversion factors for velocity . . . . .	65
2.4.6 Conversion factors for mass . . . . .	65
2.4.7 Conversion factors for force . . . . .	65
2.4.8 Conversion factors for area . . . . .	65
2.4.9 Conversion factors for pressure (either all gauge or all absolute) . . . . .	66
2.4.10 Conversion factors for pressure (absolute pressure units only) . . . . .	66
2.4.11 Conversion factors for energy or work . . . . .	66
2.4.12 Conversion factors for power . . . . .	66
2.4.13 Terrestrial constants . . . . .	67
2.4.14 Properties of water . . . . .	67
2.4.15 Miscellaneous physical constants . . . . .	68
2.4.16 Weight densities of common materials . . . . .	69
2.5 Dimensional analysis . . . . .	71

2.6	The International System of Units . . . . .	72
2.7	Conservation Laws . . . . .	73
2.8	Classical mechanics . . . . .	73
2.8.1	Newton's Laws of Motion . . . . .	74
2.8.2	Work, energy, and power . . . . .	75
2.8.3	Mechanical springs . . . . .	91
2.8.4	Rotational motion . . . . .	93
2.9	Simple machines . . . . .	99
2.9.1	Levers . . . . .	99
2.9.2	Pulleys . . . . .	101
2.9.3	Inclined planes . . . . .	104
2.9.4	Gears . . . . .	106
2.9.5	Belt drives . . . . .	117
2.9.6	Chain drives . . . . .	120
2.10	Elementary thermodynamics . . . . .	121
2.10.1	Heat versus Temperature . . . . .	122
2.10.2	Temperature . . . . .	123
2.10.3	Heat . . . . .	125
2.10.4	Heat transfer . . . . .	126
2.10.5	Specific heat and enthalpy . . . . .	137
2.10.6	Phase changes . . . . .	144
2.10.7	Phase diagrams and critical points . . . . .	152
2.10.8	Saturated steam table . . . . .	155
2.10.9	Thermodynamic degrees of freedom . . . . .	158
2.10.10	Applications of phase changes . . . . .	159
2.11	Fluid mechanics . . . . .	170
2.11.1	Pressure . . . . .	170
2.11.2	Pascal's Principle and hydrostatic pressure . . . . .	175
2.11.3	Fluid density expressions . . . . .	180
2.11.4	Manometers . . . . .	182
2.11.5	Systems of pressure measurement . . . . .	186
2.11.6	Negative pressure . . . . .	189
2.11.7	Buoyancy . . . . .	191
2.11.8	Gas Laws . . . . .	197
2.11.9	Fluid viscosity . . . . .	199
2.11.10	Reynolds number . . . . .	201
2.11.11	Law of Continuity . . . . .	205
2.11.12	Viscous flow . . . . .	207
2.11.13	Bernoulli's equation . . . . .	208
2.11.14	Torricelli's equation . . . . .	218
2.11.15	Flow through a venturi tube . . . . .	219

<b>3</b>	<b>Chemistry</b>	<b>225</b>
3.1	Terms and Definitions . . . . .	228
3.2	Atomic theory and chemical symbols . . . . .	230
3.3	Periodic table of the elements . . . . .	236
3.4	Electronic structure . . . . .	241
3.5	Spectroscopy . . . . .	249
3.5.1	Emission spectroscopy . . . . .	253
3.5.2	Absorption spectroscopy . . . . .	256
3.6	Formulae for common chemical compounds . . . . .	258
3.7	Molecular quantities . . . . .	262
3.8	Stoichiometry . . . . .	265
3.8.1	Balancing chemical equations by trial-and-error . . . . .	266
3.8.2	Balancing chemical equations using algebra . . . . .	268
3.8.3	Stoichiometric ratios . . . . .	271
3.9	Energy in chemical reactions . . . . .	273
3.9.1	Heats of reaction and activation energy . . . . .	274
3.9.2	Heats of formation and Hess's Law . . . . .	278
3.10	Periodic table of the ions . . . . .	281
3.11	Ions in liquid solutions . . . . .	282
3.12	pH . . . . .	284
<b>4</b>	<b>DC electricity</b>	<b>291</b>
4.1	Electrical voltage . . . . .	292
4.2	Electrical current . . . . .	298
4.2.1	Electron versus conventional flow . . . . .	301
4.3	Electrical sources and loads . . . . .	306
4.4	Electrical power . . . . .	312
4.5	Electrical resistance and Ohm's Law . . . . .	313
4.6	Series versus parallel circuits . . . . .	316
4.7	Kirchhoff's Laws . . . . .	320
4.8	Circuit fault analysis . . . . .	324
4.9	Bridge circuits . . . . .	327
4.9.1	Component measurement . . . . .	328
4.9.2	Sensor signal conditioning . . . . .	330
4.10	Null-balance voltage measurement . . . . .	336
4.11	Electromagnetism . . . . .	340
4.12	Capacitors . . . . .	346
4.13	Inductors . . . . .	350
<b>5</b>	<b>AC electricity</b>	<b>355</b>
5.1	RMS quantities . . . . .	356
5.2	Resistance, Reactance, and Impedance . . . . .	360
5.3	Series and parallel circuits . . . . .	361
5.4	Transformers . . . . .	361
5.4.1	Basic principles . . . . .	362
5.4.2	Loading effects . . . . .	365

5.4.3	Step ratios	367
5.4.4	Transformer impedance	369
5.5	Phasors	371
5.5.1	Circles, sine waves, and cosine waves	372
5.5.2	Phasor expressions of phase shifts	377
5.5.3	Phasor expressions of impedance	386
5.5.4	Phasor arithmetic	390
5.5.5	Phasors and circuit measurements	394
5.6	The $s$ variable	402
5.6.1	Meaning of the $s$ variable	403
5.6.2	Impedance expressed using the $s$ variable	406
5.7	Transfer function analysis	411
5.7.1	Example: LR low-pass filter circuit	412
5.7.2	Example: RC high-pass filter circuit	418
5.7.3	Example: LC “tank” circuit	423
5.7.4	Example: RLC band-pass filter circuit	428
5.7.5	Summary of transfer function analysis	437
5.8	Polyphase AC power	439
5.8.1	Delta and Wye configurations	447
5.8.2	Power in three-phase circuits	451
5.8.3	Grounded three-phase circuits	454
5.8.4	Symmetrical components	457
5.9	Phasor analysis of transformer circuits	466
5.9.1	Phasors in single-phase transformer circuits	468
5.9.2	Phasors in three-phase transformer circuits	474
5.10	Transmission lines	475
5.10.1	Open-ended transmission lines	477
5.10.2	Shorted transmission lines	479
5.10.3	Properly terminated transmission lines	481
5.10.4	Discontinuities	483
5.10.5	Velocity factor	483
5.10.6	Cable losses	484
5.11	Antennas	485
5.11.1	Maxwell and Hertz	489
5.11.2	Antenna size	491
5.11.3	Antenna orientation and directionality	492
<b>6</b>	<b>Introduction to industrial instrumentation</b>	<b>497</b>
6.1	Example: boiler water level control system	500
6.2	Example: wastewater disinfection	505
6.3	Example: chemical reactor temperature control	507
6.4	Other types of instruments	510
6.4.1	Indicators	511
6.4.2	Recorders	514
6.4.3	Process switches and alarms	520
6.5	Summary	529

6.6	Review of fundamental principles . . . . .	530
<b>7</b>	<b>Instrumentation documents</b>	<b>531</b>
7.1	Process Flow Diagrams . . . . .	533
7.2	Process and Instrument Diagrams . . . . .	535
7.3	Loop diagrams . . . . .	537
7.4	Functional diagrams . . . . .	540
7.5	Instrument and process equipment symbols . . . . .	543
7.5.1	Line types . . . . .	544
7.5.2	Process/Instrument line connections . . . . .	545
7.5.3	Instrument bubbles . . . . .	545
7.5.4	Process valve types . . . . .	546
7.5.5	Valve actuator types . . . . .	547
7.5.6	Valve failure mode . . . . .	548
7.5.7	Liquid level measurement devices . . . . .	549
7.5.8	Flow measurement devices (flowing left-to-right) . . . . .	550
7.5.9	Process equipment . . . . .	552
7.5.10	Functional diagram symbols . . . . .	553
7.5.11	Single-line electrical diagram symbols . . . . .	554
7.5.12	Fluid power diagram symbols . . . . .	556
7.6	Instrument identification tags . . . . .	558
<b>8</b>	<b>Instrument connections</b>	<b>563</b>
8.1	Pipe and pipe fittings . . . . .	563
8.1.1	Flanged pipe fittings . . . . .	564
8.1.2	Tapered thread pipe fittings . . . . .	571
8.1.3	Parallel thread pipe fittings . . . . .	574
8.1.4	Sanitary pipe fittings . . . . .	575
8.2	Tube and tube fittings . . . . .	579
8.2.1	Compression tube fittings . . . . .	580
8.2.2	Common tube fitting types and names . . . . .	585
8.2.3	Bending instrument tubing . . . . .	588
8.2.4	Special tubing tools . . . . .	590
8.3	Electrical signal and control wiring . . . . .	592
8.3.1	Connections and wire terminations . . . . .	593
8.3.2	DIN rail . . . . .	602
8.3.3	Cable routing . . . . .	605
8.3.4	Signal coupling and cable separation . . . . .	613
8.3.5	Electric field (capacitive) de-coupling . . . . .	617
8.3.6	Magnetic field (inductive) de-coupling . . . . .	623
8.3.7	High-frequency signal cables . . . . .	626
8.4	Fiber optics . . . . .	627
8.4.1	Fiber optic data communication . . . . .	628
8.4.2	Fiber optic sensing applications . . . . .	631
8.4.3	Fiber optic cable construction . . . . .	636
8.4.4	Multi-mode and single-mode optical fibers . . . . .	639

8.4.5	Fiber optic cable connectors, routing, and safety . . . . .	641
8.4.6	Fiber optic cable testing . . . . .	644
8.5	Review of fundamental principles . . . . .	650
<b>9</b>	<b>Discrete process measurement</b>	<b>653</b>
9.1	“Normal” status of a switch . . . . .	654
9.2	Hand switches . . . . .	659
9.3	Limit switches . . . . .	661
9.4	Proximity switches . . . . .	663
9.5	Pressure switches . . . . .	668
9.6	Level switches . . . . .	673
9.6.1	Float-type level switches . . . . .	674
9.6.2	Tuning fork level switches . . . . .	676
9.6.3	Paddle-wheel level switches . . . . .	677
9.6.4	Ultrasonic level switches . . . . .	678
9.6.5	Capacitive level switches . . . . .	679
9.6.6	Conductive level switches . . . . .	680
9.7	Temperature switches . . . . .	682
9.8	Flow switches . . . . .	686
9.9	Review of fundamental principles . . . . .	688
<b>10</b>	<b>Discrete control elements</b>	<b>689</b>
10.1	On/off valves . . . . .	690
10.2	Fluid power systems . . . . .	692
10.3	Solenoid valves . . . . .	702
10.3.1	2-way solenoid valves . . . . .	703
10.3.2	3-way solenoid valves . . . . .	706
10.3.3	4-way solenoid valves . . . . .	710
10.3.4	Normal energization states . . . . .	715
10.4	On/off electric motor control circuits . . . . .	718
10.4.1	AC induction motors . . . . .	719
10.4.2	Motor contactors . . . . .	728
10.4.3	Motor protection . . . . .	730
10.4.4	Motor control circuit wiring . . . . .	738
10.5	Review of fundamental principles . . . . .	745
<b>11</b>	<b>Relay control systems</b>	<b>747</b>
11.1	Control relays . . . . .	749
11.2	Relay circuits . . . . .	753
11.3	Interposing relays . . . . .	760
11.4	Review of fundamental principles . . . . .	763

<b>12 Programmable Logic Controllers</b>	<b>765</b>
12.1 PLC examples	766
12.2 Input/Output (I/O) capabilities	775
12.2.1 Discrete I/O	777
12.2.2 Analog I/O	784
12.2.3 Network I/O	786
12.3 Logic programming	787
12.3.1 Relating I/O status to virtual elements	788
12.3.2 Memory maps and I/O addressing	796
12.4 Ladder Diagram (LD) programming	802
12.4.1 Contacts and coils	804
12.4.2 Counters	822
12.4.3 Timers	827
12.4.4 Data comparison instructions	832
12.4.5 Math instructions	835
12.4.6 Sequencers	838
12.5 Structured Text (ST) programming	848
12.6 Instruction List (IL) programming	848
12.7 Function Block Diagram (FBD) programming	848
12.8 Sequential Function Chart (SFC) programming	848
12.9 Human-Machine Interfaces	849
12.10 How to teach yourself PLC programming	855
12.11 Review of fundamental principles	858
<b>13 Analog electronic instrumentation</b>	<b>861</b>
13.1 4 to 20 mA analog current signals	861
13.2 Relating 4 to 20 mA signals to instrument variables	865
13.2.1 Example calculation: controller output to valve	868
13.2.2 Example calculation: flow transmitter	869
13.2.3 Example calculation: temperature transmitter	871
13.2.4 Example calculation: pH transmitter	874
13.2.5 Example calculation: reverse-acting I/P transducer signal	876
13.2.6 Example calculation: PLC analog input scaling	878
13.2.7 Graphical interpretation of signal ranges	881
13.2.8 Thinking in terms of per unit quantities	883
13.3 Controller output current loops	886
13.4 4-wire (“self-powered”) transmitter current loops	889
13.5 2-wire (“loop-powered”) transmitter current loops	891
13.6 4-wire “passive” versus “active” output transmitters	893
13.7 Troubleshooting current loops	894
13.7.1 Using a standard milliammeter to measure loop current	896
13.7.2 Using a clamp-on milliammeter to measure loop current	898
13.7.3 Using “test” diodes to measure loop current	899
13.7.4 Using shunt resistors to measure loop current	901
13.7.5 Troubleshooting current loops with voltage measurements	902
13.7.6 Using loop calibrators	906

13.7.7 NAMUR signal levels . . . . .	913
13.8 Review of fundamental principles . . . . .	914
<b>14 Pneumatic instrumentation</b>	<b>915</b>
14.1 Pneumatic sensing elements . . . . .	921
14.2 Self-balancing pneumatic instrument principles . . . . .	923
14.3 Pilot valves and pneumatic amplifying relays . . . . .	928
14.4 Analogy to opamp circuits . . . . .	938
14.5 Analysis of practical pneumatic instruments . . . . .	950
14.5.1 Foxboro model 13A differential pressure transmitter . . . . .	951
14.5.2 Foxboro model E69 “I/P” electro-pneumatic transducer . . . . .	956
14.5.3 Fisher model 546 “I/P” electro-pneumatic transducer . . . . .	961
14.5.4 Fisher-Rosemount model 846 “I/P” electro-pneumatic transducer . . . . .	966
14.6 Proper care and feeding of pneumatic instruments . . . . .	969
14.7 Advantages and disadvantages of pneumatic instruments . . . . .	970
14.8 Review of fundamental principles . . . . .	971
<b>15 Digital data acquisition and networks</b>	<b>973</b>
15.1 Digital representation of numerical data . . . . .	977
15.1.1 Integer number formats . . . . .	978
15.1.2 Fixed-point number formats . . . . .	981
15.1.3 Floating-point number formats . . . . .	982
15.1.4 Example of industrial number formats . . . . .	984
15.2 Digital representation of text . . . . .	987
15.2.1 Morse and Baudot codes . . . . .	988
15.2.2 EBCDIC and ASCII . . . . .	989
15.2.3 Unicode . . . . .	991
15.3 Analog-digital conversion . . . . .	991
15.3.1 Converter resolution . . . . .	992
15.3.2 Converter sampling rate and aliasing . . . . .	996
15.4 Analog signal conditioning and referencing . . . . .	999
15.4.1 Instrumentation amplifiers . . . . .	1000
15.4.2 Analog input references and connections . . . . .	1009
15.5 Digital data communication theory . . . . .	1022
15.5.1 Serial communication principles . . . . .	1024
15.5.2 Physical encoding of bits . . . . .	1027
15.5.3 Communication speed . . . . .	1030
15.5.4 Data frames . . . . .	1032

# Preface

I did not want to write this book . . . honestly.

My first book project began in 1998, titled *Lessons In Electric Circuits*, and I didn't call "quit" until six volumes and five years later. Even then it was not complete, but being an open-source project it gained traction on the Internet to the point where other people took over its development and it grew fine without me. The impetus for writing this first tome was a general dissatisfaction with available electronics textbooks. Plenty of textbooks exist to describe things, but few really *explain* things well for students, and the field of electronics is no exception. I wanted my book(s) to be different, and so they were. No one told me how time-consuming it was going to be to write them, though!

The next few years' worth of my spare time went to developing a set of question-and-answer worksheets designed to teach electronics theory in a Socratic, active-engagement style. This project proved quite successful in my professional life as an instructor of electronics. In the summer of 2006, my job changed from teaching electronics to teaching industrial instrumentation, and I decided to continue the Socratic mode of instruction with another set of question-and-answer worksheets.

However, the field of industrial instrumentation is not as well-represented as general electronics, and thus the array of available textbooks is not as vast. I began to re-discover the drudgery of trying to teach with inadequate texts as source material. The basis of my active teaching style was that students would spend time researching the material on their own, then engage in Socratic-style discussion with me on the subject matter when they arrived for class. This teaching technique functions in direct proportion to the quality and quantity of the research sources at the students' disposal. Despite much searching, I was unable to find a textbook adequately addressing my students' learning needs. Many textbooks I found were written in a shallow, "math-phobic" style well below the level I intended to teach to. Some reference books I found contained great information, but were often written for degreed engineers with lots of Laplace transforms and other mathematical techniques well above the level I intended to teach to. Few on either side of the spectrum actually made an effort to explain certain concepts students generally struggle to understand. I needed a text giving good, practical information and theoretical coverage at the same time.

In a futile effort to provide my students with enough information to study outside of class, I scoured the Internet for free tutorials written by others. While some manufacturer's tutorials were nearly perfect for my needs, others were just as shallow as the textbooks I had found, and/or were little more than sales brochures. I found myself starting to write my own tutorials on specific topics to "plug the gaps," but then another problem arose: it became troublesome for students to navigate through dozens of tutorials in an effort to find the information they needed in their studies. What my students really needed was a *book*, not a smorgasbord of tutorials.

So here I am again, writing another textbook. This time around I have the advantage of wisdom gained from the first textbook project. For this project, I will *not*:

- . . . attempt to maintain a parallel book in HTML markup (for direct viewing on the Internet). I had to go to the trouble of inventing my own quasi-XML markup language last time in an effort to generate multiple format versions of the book from the same source code. Instead, this time I will use stock L<sup>A</sup>T<sub>E</sub>X as the source code format and regular Adobe PDF format for the final output, which anyone may read thanks to its ubiquity. If anyone else desires the book in a different format, I will gladly let them deal with issues of source code translation. Not that this should be a terrible problem for anyone technically competent in markup languages, as L<sup>A</sup>T<sub>E</sub>X source is rather easy to work with.
- . . . use a GNU GPL-style copyleft license. Instead, I will use the Creative Commons Attribution-only license, which is far more permissive for anyone wishing to incorporate my work into derivative works. My interest is maximum flexibility for those who may adapt my material to their own needs, not the imposition of certain philosophical ideals.
- . . . start from a conceptual state of “ground zero.” I will assume the reader has certain familiarity with electronics and mathematics, which I will build on. If a reader finds they need to learn more about electronics, they should go read *Lessons In Electric Circuits*.
- . . . avoid using calculus to help explain certain concepts. Not all my readers will understand these parts, and so I will be sure to explain what I can without using calculus. However, I want to give my more mathematically adept students an opportunity to see the power of calculus applied to instrumentation where appropriate. By occasionally applying calculus and explaining my steps, I also hope this text will serve as a practical guide for students who might wish to learn calculus, so they can see its utility and function in a context that interests them.

There do exist many fine references on the subject of industrial instrumentation. I only wish I could condense their best parts into a single volume for my students. Being able to do so would certainly save me from having to write my own! Listed here are some of the best books I can recommend for those wishing to explore instrumentation outside of my own presentation:

- *Instrument Engineers’ Handbook* series (Volumes I, II, and III), edited by Béla Lipták – by far my favorite modern references on the subject. Unfortunately, there is a fair amount of material within that lies well beyond my students’ grasp (Laplace transforms, etc.), and the volumes are incredibly bulky and expensive (nearly 2000 pages, and at a cost of nearly \$200.00, *apiece!*). These texts also lack some of the basic content my students do need, and I don’t have the heart to tell them to buy yet *another* textbook to fill the gaps.
- *Handbook of Instrumentation and Controls*, by Howard P. Kallen. Perhaps the best-written textbook on general instrumentation I have ever encountered. Too bad it is both long out of print – my copy dates 1961 – and technologically dated. Like most American textbooks written during the years immediately following Sputnik, it is a masterpiece of practical content and conceptual clarity. I consider books like this useful for their presentations of “first principles,” which of course are timeless.
- *Industrial Instrumentation Fundamentals*, by Austin E. Fribance. Another great post-Sputnik textbook – my copy dates 1962.

- *Instrumentation for Process Measurement and Control*, by Norman A. Anderson. An inspiring effort by someone who knows the art of teaching as well as the craft of instrumentation. Too bad the content doesn't seem to have been updated since 1980.
- *Applied Instrumentation in the Process Industries* (Volume I), edited by William G. Andrew. A very clear and fairly comprehensive overview of industrial instrumentation. Sadly, this fine book is out of print, and much of the material is dated (second edition written in 1979).
- Practically anything written by Francis Greg Shinskey.

Whether or not I achieve my goal of writing a better textbook is a judgment left for others to make. One decided advantage my book will have over all the others is its *openness*. If you don't like anything you see in these pages, you have the right to modify it to your liking! Delete content, add content, modify content – it's all fair game thanks to the Creative Commons licensing. My only conditions are declared in the license: you must give me credit for my original authorship, include a copyright notice, and also include the full text of the Creative Commons license informing readers of their rights (see Section 3(a)(1) of the License for more detail). What you do with it beyond that is wholly up to you<sup>2</sup>. This way, perhaps I can spare someone else from having to write their own textbook from scratch!

---

<sup>2</sup>This includes selling copies of it, either electronic or print. Of course, you must include the Creative Commons license as part of the text you sell, which means anyone will be able to tell it is an open text and can probably figure out how to download an electronic copy off the Internet for free. The only way you're going to make significant money selling this text is to add your own value to it, either in the form of expansions or bundled product (e.g. simulation software, learning exercises, etc.), which of course is perfectly fair – you must profit from your *own* labors. All my work does for you is give you a starting point.

# Chapter 1

## Calculus

Mathematics is the investigation of an artificial world: a universe populated by abstract entities and rigid rules governing those entities. Mathematicians devoted to the study and advancement of pure mathematics have an extremely well-developed respect for these rules, for the integrity of this artificial world depends on them. In order to preserve the integrity of their artificial world, their collective work must be *rigorous*, never allowing for sloppy handling of the rules or allowing intuitive leaps to be left unproven.

However, many of the tools and techniques developed by mathematicians for their artificial world happen to be extremely useful for understanding the real world in which we live and work, and therein lies a problem. In applying mathematical rules to the study of real-world phenomena, we often take a far more pragmatic approach than any mathematician would feel comfortable with.

The tension between pure mathematicians and those who apply math to real-world problems is not unlike the tension between linguists and those who use language in everyday life. All human languages have rules (though none as rigid as in mathematics!), and linguists are the guardians of those rules, but the vast majority of human beings play fast and loose with the rules as they use language to describe and understand the world around them. Whether or not this “sloppy” adherence to rules is good depends on which camp you are in. To the purist, it is offensive; to the pragmatist, it is convenient.

I like to tell my students that mathematics is very much like a language. The more you understand mathematics, the larger “vocabulary” you will possess to describe principles and phenomena you encounter in the world around you. Proficiency in mathematics also empowers you to grasp relationships between different things, which is a powerful tool in learning new concepts.

This book is not written for (or by!) mathematicians. Rather, it is written for people wishing to make sense of industrial process measurement and control. This chapter of the book is devoted to a very pragmatic coverage of certain mathematical concepts, for the express purpose of applying these concepts to real-world systems.

Mathematicians, cover your eyes for the rest of this chapter!

## 1.1 Introduction to calculus

Few areas of mathematics are as powerfully useful in describing and analyzing the physical world as calculus: the mathematical study of *changes*. Calculus also happens to be tremendously confusing to most students first encountering it. A great deal of this confusion stems from mathematicians' insistence on rigor<sup>1</sup> and denial of intuition.

Look around you right now. Do you see any mathematicians? If not, good – you can proceed in safety. If so, find another location to begin reading the rest of this chapter. I will frequently appeal to practical example and intuition in describing the basic principles of single-variable calculus, for the purpose of expanding your mathematical “vocabulary” to be able to describe and better understand phenomena of change related to instrumentation.

Silvanus P. Thompson, in his wonderful book *Calculus Made Simple* originally published in 1910, began his text with a short chapter entitled, “To Deliver You From The Preliminary Terrors<sup>2</sup>.” I will follow his lead by similarly introducing you to some of the notations frequently used in calculus, along with very simple (though not mathematically rigorous) definitions.

When we wish to speak of a change in some variable's value (let's say  $x$ ), it is common to precede the variable with the capital Greek letter “delta” as such:

$$\Delta x = \text{“Change in } x\text{”}$$

An alternative interpretation of the “delta” symbol ( $\Delta$ ) is to think of it as denoting a *difference* between two values of the same variable. Thus,  $\Delta x$  could be taken to mean “the difference between two values of  $x$ ”. The cause of this difference is not important right now: it may be the difference between the value of  $x$  at one point in time versus another point in time, it may be the difference between the value of  $x$  at one point in space versus another point in space, or it may simply be the difference between values of  $x$  as it relates to some other variable (e.g.  $y$ ) in a mathematical function. If we have some variable such as  $x$  that is known to change value relative to some other variable (e.g. time, space,  $y$ ), it is nice to be able to express that change using precise mathematical symbols, and this is what the “delta” symbol does for us.

---

<sup>1</sup>In mathematics, the term *rigor* refers to a meticulous attention to detail and insistence that each and every step within a chain of mathematical reasoning be thoroughly justified by deductive logic, not intuition or analogy.

<sup>2</sup>The book's subtitle happens to be, *Being a very-simplest introduction to those beautiful methods of reckoning which are generally called by the terrifying names of the differential calculus and the integral calculus*. Not only did Thompson recognize the anti-pragmatic tone with which calculus is too often taught, but he also infused no small amount of humor in his work.

For example, if the temperature of a furnace ( $T$ ) increases over time, we might wish to describe that change in temperature as  $\Delta T$ :

The value of  $\Delta T$  is nothing more than the difference (subtraction) between the recent temperature and the older temperature. A rising temperature over time thus yields a positive value for  $\Delta T$ , while a falling temperature over time yields a negative value for  $\Delta T$ .

We could also describe differences between the temperature of two *locations* (rather than a difference of temperature between two *times*) by the notation  $\Delta T$ , such as this example of heat transfer through a heat-conducting wall where one side of the wall is hotter than the other:

Once again,  $\Delta T$  is calculated by subtracting one temperature from another. Here, the sign (positive or negative) of  $\Delta T$  denotes the *direction* of heat flow through the thickness of the wall.

One of the major concerns of calculus is changes or differences between variable values lying *very*

*close to each other.* In the context of a heating furnace, this could mean increases in temperature over miniscule time periods. In the context of heat flowing through a wall, this could mean differences in temperature sampled between points within the wall immediately adjacent each other. If our desire is to express the change in a variable between neighboring points along a continuum rather than over some discrete period, we may use a different notation than the capital Greek letter delta ( $\Delta$ ); instead, we use a lower-case Roman letter  $d$  (or in some cases, the lower-case Greek letter delta:  $\delta$ ).

Thus, a change in furnace temperature from one instant in time to the next could be expressed as  $dT$  (or  $\delta T$ ), and likewise a difference in temperature between two adjacent positions within the heat-conducting wall could also be expressed as  $dT$  (or  $\delta T$ ). Just as with the “delta” ( $\Delta$ ) symbol, the changes references by either  $d$  or  $\delta$  may occur over a variety of different domains.

We even have a unique name for this concept of extremely small differences: whereas  $\Delta T$  is called a *difference* in temperature,  $dT$  is called a *differential* of temperature. The concept of a differential may seem redundant to you right now, but they are actually quite powerful for describing *continuous changes*, especially when one differential is related to another differential by ratio (something we call a *derivative*).

Another major concern in calculus is how quantities accumulate, especially how differential quantities add up to form a larger whole. A furnace’s temperature rise since start-up ( $\Delta T_{total}$ ), for example, could be expressed as the accumulation (sum) of many temperature differences ( $\Delta T$ ) measured periodically. The total furnace temperature rise calculated from a sampling of temperature once every minute from 9:45 to 10:32 AM could be written as:

$$\Delta T_{total} = \Delta T_{9:45} + \Delta T_{9:46} + \cdots \Delta T_{10:32} = \text{Total temperature rise over time, from 9:45 to 10:32}$$

A more sophisticated expression of this series uses the capital Greek letter sigma (meaning “sum of” in mathematics) with notations specifying which temperature differences to sum:

$$\Delta T_{total} = \sum_{n=9:45}^{10:32} \Delta T_n = \text{Total temperature rise over time, from 9:45 to 10:32}$$

However, if our furnace temperature monitor scans at an infinite pace, measuring temperature *differentials* ( $dT$ ) and summing them in rapid succession, we may express the same accumulated temperature rise as an *infinite* sum of *infinitesimal* (infinitely small) changes, rather than as a finite sum of temperature changes measured once every minute. Just as we introduced a unique mathematical symbol to represent differentials ( $d$ ) over a continuum instead of differences ( $\Delta$ ) over discrete periods, we will introduce a unique mathematical symbol to represent the summation of differentials ( $\int$ ) instead of the summation of differences ( $\sum$ ):

$$\Delta T_{total} = \int_{9:45}^{10:32} dT = \text{Total temperature rise over time, from 9:45 to 10:32}$$

This summation of infinitesimal quantities is called *integration*, and the elongated “S” symbol ( $\int$ ) is the *integral* symbol.

These are the two major ideas and notations of calculus: *differentials* (tiny changes represented by  $d$  or  $\delta$ ) and *integrals* (accumulations represented by  $\int$ ). Now that wasn’t so frightening, was it?

## 1.2 The concept of differentiation

Suppose we wished to measure the rate of propane gas flow through a hose to a torch:

Flowmeters appropriate for measuring low flow rates of any gas are typically very expensive, making it impractical to directly measure the flow rate of propane fuel gas consumed by this torch at any given moment. We could, however, *indirectly* measure the flow rate of propane by placing the tank on a scale where its mass ( $m$ ) could be monitored over time. By taking measurements of mass over short time periods ( $\Delta t$ ), we could calculate the corresponding differences in mass ( $\Delta m$ ), then calculate the ratio of mass lost over time to calculate average mass flow rate ( $\overline{W}$ ):

$$\overline{W} = \frac{\Delta m}{\Delta t} = \text{Average mass flow rate}$$

Where,

$\overline{W}$  = Average mass flow rate within each time period (kilograms per minute)

$\Delta m$  = Measured mass difference over time period (kilograms)

$\Delta t$  = Time period of mass measurement sample (minutes)

Note that flow rate is a ratio (quotient) of mass change over time change. The units used to express flow even reflect this process of division: kilograms *per* minute.

$$\overline{W} = \frac{[\text{kg}]}{[\text{min}]} = \text{Average mass flow rate} = \left[ \frac{\text{kg}}{\text{min}} \right]$$

Graphed as a function over time, the tank's mass will be seen to decrease as time elapses. Each dot represents a mass and time measurement coordinate pair (e.g. 20 kilograms at 7:38, 18.6 kilograms at 7:51, etc.):

We should recall from basic geometry that the slope of a line or line segment is defined as its *rise* (vertical height) divided by its *run* (horizontal width). Thus, the average mass flow rate calculated within each time period may be represented as the pitch (slope) of the line segments connecting dots, since mass flow rate is defined as a change in mass per (divided by) change in time.

Periods of high propane flow (large flame from the torch) show up on the graph as steeply-pitched line segments. Periods of no propane flow reveal themselves as flat portions on the graph (no rise or fall over time).

If the determination of average flow rates between significant gaps in time is good enough for our application, we need not do anything more. However, if we wish to detect mass flow rate at any particular *instant* in time, we need to perform the same measurements of mass loss, time elapse, and division of the two at an infinitely fast rate.

Supposing such a thing were possible, what we would end up with is a smooth graph showing mass consumed over time. Instead of a few line segments roughly approximating a curve, we would have an *infinite* number of infinitely short line segments connected together to form a seamless curve. The flow rate at any particular point in time would be the ratio of the mass and time differentials (the slope of the infinitesimal line segment) at that point:

$$W = \frac{dm}{dt} = \text{Instantaneous mass flow rate}$$

Where,

$W$  = Instantaneous mass flow rate at a given time (kilograms per minute)

$dm$  = Mass differential at a single point in time (kilograms)

$dt$  = Time differential at a single point in time (minutes)

Flow is calculated just the same as before: a quotient of mass and time differences, except here the differences are infinitesimal in magnitude. The unit of flow measurement reflects this process of division, just as before, with mass flow rate expressed in units of kilograms *per* minute. Also, just as before, the rate of flow is graphically represented by the *slope* of the graph: steeply-sloped points on the graph represent moments of high flow rate, while shallow-sloped points on the graph represent moments of low flow rate.

Such a ratio of differential quantities is called a *derivative* in calculus<sup>3</sup>. Derivatives – especially time-based derivatives such as flow rate – find many applications in instrumentation as well as the general sciences. Some of the most common time-based derivative functions include the relationships between *position* ( $x$ ), *velocity* ( $v$ ), and *acceleration* ( $a$ ).

Velocity ( $v$ ) is the rate at which an object changes position over time. Since position is typically denoted by the variable  $x$  and time by the variable  $t$ , the derivative of position with respect to time may be written as such:

$$v = \frac{dx}{dt} \quad [\text{meters/second}] = \frac{[\text{meters}]}{[\text{seconds}]}$$

The metric units of measurement<sup>4</sup> for velocity (meters per second, miles per hour, etc.) betray this process of division: a differential of position (meters) divided by a differential of time (second).

Acceleration ( $a$ ) is the rate at which an object changes velocity over time. Thus, we may express acceleration as the time-derivative of velocity, just as velocity was expressed as the time-derivative of position:

$$a = \frac{dv}{dt} \quad [\text{meters/second}^2] = \frac{[\text{meters/second}]}{[\text{seconds}]}$$

We may even express acceleration as a function of position ( $x$ ), since it is the rate of change of the rate of change in position over time. This is known as a *second derivative*, since it is applying the process of “differentiation” twice:

$$a = \frac{d}{dt} \left( \frac{dx}{dt} \right) = \frac{d^2x}{dt^2} \quad [\text{meters/second}^2] = \frac{[\text{meters}]}{[\text{seconds}^2]}$$

As with velocity, the units of measurement for acceleration (meters per second squared, or alternatively meters per second per second) suggest a compounded quotient.

---

<sup>3</sup>Isaac Newton referred to derivatives as *fluxions*, and in Silvanus Thompson’s day they were known as *differential coefficients*.

<sup>4</sup>British units of measurement for velocity indicate this same process of division: the number of feet traveled in a time period of seconds yields a velocity in feet per second. There is nothing unique about metric units in this regard.

It is also possible to express rates of change between different variables not involving time. A common example in the engineering realm is the concept of *gain*, generally defined as the ratio of output change to input change. An electronic amplifier, for example, with an input signal of 2 volts (peak-to-peak) and an output signal of 8.6 volts (peak-to-peak), would be said to have a gain of 4.3, since the change in output measured in peak-to-peak volts is 4.3 times larger than the corresponding change in input voltage:

This gain may be expressed as a quotient of differences ( $\frac{\Delta V_{out}}{\Delta V_{in}}$ ), or it may be expressed as a derivative instead:

$$\text{Gain} = \frac{dV_{out}}{dV_{in}}$$

If the amplifier's behavior is perfectly linear, there will be no difference between gain calculated using differences and gain calculated using differentials (the derivative), since the average slope of a straight line is the same as the instantaneous slope at any point along that line. If, however, the amplifier does not behave in a perfectly linear fashion, gain calculated from large changes in voltage ( $\frac{\Delta V_{out}}{\Delta V_{in}}$ ) will not be the same as gain calculated from infinitesimal changes at different points along the amplifier's operating voltage range.

### 1.3 The concept of integration

Suppose we wished to measure the consumption of propane over time for a large propane storage tank supplying a building with heating fuel, because the tank lacked a level indicator to show how much fuel was left at any given time. The flow rate is sufficiently large, and the task sufficiently important, to justify the installation of a mass flowmeter<sup>5</sup>, which registers flow rate at an indicator inside the building:

By measuring true mass flow rate, it should be possible to indirectly measure how much propane has been used at any time following the most recent filling of the tank. For example, if the mass flow rate of propane out of the tank happened to be a constant 5 kilograms per hour for 30 hours straight, it would be a simple matter of multiplication to calculate the consumed mass:

$$\left(\frac{5 \text{ kg}}{\text{hr}}\right) \left(\frac{30 \text{ hrs}}{1}\right) = 150 \text{ kg of propane consumed}$$

Expressing this mathematically as a function of differences in mass and differences in time, we may write the following equation:

$$\Delta m = \bar{W} \Delta t$$

Where,

$\bar{W}$  = Average mass flow rate within the time period (kilograms per hour)

$\Delta m$  = Mass difference over time period (kilograms)

$\Delta t$  = Time period of flow measurement sample (hours)

It is easy to see how this is just a variation of the quotient-of-differences equation used previously in this chapter to define mass flow rate:

$$\bar{W} = \frac{\Delta m}{\Delta t} = \text{Average mass flow rate}$$

Inferring mass flow rate from changes in mass over time periods is a process of *division*. Inferring changes in mass from flow rate over time periods is a process of *multiplication*. The units of measurement used to express each of the variables makes this quite clear.

<sup>5</sup>Most likely a thermal mass flowmeter or a Coriolis flowmeter.

As we learned previously, the process of differentiation is really just a matter of determining the *slope* of a graph. A graph of propane fuel mass ( $m$ ) plotted over discrete points in time ( $t$ ) has a slope corresponding to mass flow rate ( $W = \frac{\Delta m}{\Delta t}$ ). Here, we are attempting to do the opposite: the data reported by the sensing instrument is propane mass flow rate ( $W$ ), and our goal is to determine total mass lost ( $\Delta m$ ) as the propane is consumed from the storage tank over a period of time ( $\Delta t$ ). This operation is fundamentally distinct from differentiation, which means its graphical interpretation will not be the same. Instead of calculating the slope of the graph, we will have to do something else.

Using the previous example of the propane flowmeter sensing a constant mass flow rate ( $W$ ) of 5 kilograms of propane per hour for 30 hours (for a total consumption of 150 kilograms), we may plot a trend graph showing flow rate (vertical) as a function of time (horizontal). We know the consumed propane quantity is the simple product (multiplication) of constant flow rate and time, which relates to the geometric *area* enclosed by the graph, since the area of any rectangle is height times width:

To summarize: the height of this graph represents the rate at which propane exits the storage tank, the width of the graph represents the length of time propane has been consumed from the storage tank, and the geometric area enclosed by these two boundaries represents the total mass of propane consumed during that time.

The task of inferring lost mass over time becomes more complicated if the propane flow rate is not constant over time. Consider the following graph, showing periods of increased and decreased flow rate due to different gas-fired appliances turning on and off inside the building:

Here, the propane gas flow rate does not stay constant throughout the entire time interval covered by the graph. This graph is obviously more challenging to analyze than the previous example where the propane flow rate was constant. From that previous example, though, we have learned that the geometric area enclosed by the boundaries of the graph's height (flow rate) and width (time duration) has physical meaning, representing the total quantity of propane passed through the flowmeter. Despite the fact that the graph's area is now more complex to calculate, the basic principle remains the same as before: the enclosed area represents the amount of propane consumed.

In order to accurately calculate the amount of propane mass consumed by the building over time, we must treat each period of constant flow as its own propane quantity, calculating the mass lost during each period, then summing those mass differences to arrive at a total mass loss for the entire time interval covered by the graph. Since we know the difference (loss) in mass over a time period is equal to the average flow rate for that period multiplied by the period's duration ( $\Delta m = W \Delta t$ ), we may calculate each period's mass as an *area* underneath the graph line, each rectangular area being equal to height ( $W$ ) times width ( $\Delta t$ ):

Each rectangular area underneath the flow line on the graph ( $W_n \Delta t_n$ ) represents a quantity of propane gas consumed during that time period. To find the total amount of propane consumed in the time represented by the entire graph, we must sum these mass quantities together:

$$\Delta m = (W_1 \Delta t_1) + (W_2 \Delta t_2) + (W_3 \Delta t_3) + (W_4 \Delta t_4) + (W_5 \Delta t_5) + (W_6 \Delta t_6) + (W_7 \Delta t_7) + (W_8 \Delta t_8)$$

A “shorthand” notation for this sum uses the capital Greek letter sigma to represent a series of repeated products (multiplication) of mass flow and time periods for the eight rectangular areas enclosed by the graph:

$$\Delta m = \sum_{n=1}^8 W_n \Delta t_n$$

While  $W_n \Delta t_n$  represents the area of just one of the rectangular periods,  $\sum_{n=1}^8 W_n \Delta t_n$  represents the total combined areas, which in this example represents the total mass of propane consumed over the eight time periods shown on the graph.

The task of inferring total propane mass consumed over time becomes even more complicated if the flow does not vary in stair-step fashion as it did in the previous example. Suppose the building were equipped with *throttling* gas appliances instead of on/off gas appliances, thus creating a continuously variable flow rate demand over time. A typical flow rate graph might look something like this:

The physics of gas flow and gas mass over time has not changed: total propane mass consumed over time will still be the area enclosed beneath the flow curve. The only difference between this example and the two previous examples is the complexity of actually calculating that enclosed area.

We can, however, *approximate* the area underneath this curve by overlaying a series of rectangles, the area of each rectangle being height ( $W$ ) times width ( $\Delta t$ ):

It should be intuitively obvious that this strategy of approximating the area underneath a curve improves with the number of rectangles used. Each rectangle still has an area  $W\Delta t$ , but since the  $\Delta t$  periods are shorter, it is easier to fit the rectangles to the curve of the graph. The summation of a series of rectangular areas intended to approximate the area enclosed by a graphed function is commonly referred to as a *Riemann Sum* in honor of the mathematician Bernhard Riemann:

Taking this idea to its ultimate realization, we could imagine a super-computer sampling mass flow rates at an infinite speed, then calculating the rectangular area covered by each flow rate ( $W$ ) times each infinitesimal increment of time ( $dt$ ). With time increments of negligible width, the “approximation” of area underneath the graph found by the sum of all these rectangles would be perfect – indeed, it would not be an approximation at all, but rather an exact match:

If we represent infinitesimal time increments using the notation “ $dt$ ” as opposed to the notation “ $\Delta t$ ” used to represent discrete time periods, we must also use different notation to represent the mathematical sum of those quantities. Thus, we will replace the “sigma” symbol ( $\sum$ ) used for summation and replace it with the integral symbol ( $\int$ ), which means a *continuous* summation of infinitesimal quantities:

$$\Delta m = \sum_{n=0}^x W \Delta t_n \quad \text{Summing discrete quantities of } W \Delta t$$

$$\Delta m = \int_0^x W dt \quad \text{Summing continuous quantities of } W dt$$

This last equation tells us the total change in mass ( $\Delta m$ ) from time 0 to time  $x$  is equal to the continuous sum of mass quantities found by multiplying mass flow rate measurements ( $W$ ) over corresponding increments of time ( $dt$ ). We refer to this summation of infinitesimal quantities as *integration* in calculus. Graphically, the *integral* of a function is the geometric area enclosed by the function over a specified interval.

An important detail to note is that this process of integration (multiplying flow rates by infinitesimal time increments, then summing those products) only tells us how much propane mass was consumed – it does *not* tell us how much propane remains in the tank, which was the purpose of installing the mass flowmeter and performing all this math! The integral of mass flow and time ( $\int W dt$ ) will always be a negative<sup>6</sup> quantity in this example, because a flow of propane gas out of the tank represents a *loss* of propane mass within the tank. In order to calculate the amount of propane mass left in the tank, we would need to know the initial value of propane in the tank before any of it flowed to the building, then we would add this initial mass quantity ( $m_0$ ) to the negative mass loss calculated by integration.

Thus, we would mathematically express the propane mass inside the tank at time  $x$  as such<sup>7</sup>:

$$m_x = \int_0^x W dt + m_0$$

This initial value must always be considered in problems of integration if we attempt to absolutely define some integral quantity. Otherwise, all the integral will yield is a relative quantity (how much something has *changed* over an interval).

---

<sup>6</sup>Although we will measure time, and differentials of time, as positive quantities, the mass flowmeter should be configured to show a negative flow rate ( $W$ ) when propane flows from the tank to the building. This way, the *integrand* (the product “inside” the integration symbol;  $W dt$ ) will be a negative quantity, and thus the integral over a positive time interval (from 0 to  $x$ ) will likewise be a negative quantity.

<sup>7</sup>According to calculus convention, the differential  $dt$  represents the end of the integrand. It is safe to regard the long “S” symbol and the differential ( $dx$ ,  $dt$ , etc.) as complementary *grouping symbols* declaring the beginning and end of the integrand. This tells us  $m_0$  is not part of the integrand, but rather comes after it. Using parentheses to explicitly declare the boundaries of the integrand, we may re-write the expression as  $m_x = (\int_0^x W dt) + m_0$

The problem of initial values is very easy to relate to common experience. Consider the *odometer* indication in an automobile. This is an example of an integral function, the distance traveled ( $x$ ) being the time-integral<sup>8</sup> of speed (or velocity,  $v$ ):

$$\Delta x = \int v \, dt$$

Although the odometer does accumulate to larger and larger values as you drive the automobile, its indication does not necessarily tell me how many miles *you* have driven it. If, for example, you purchased the automobile with 32411.6 miles on the odometer, its current indication of 52704.8 miles means that you have driven it 20293.2 miles. The automobile's *total* distance traveled since manufacture is equal to the distance you have accumulated while driving it ( $\int v \, dt$ ) *plus* the initial mileage accumulated at the time you took ownership of it ( $x_0$ ):

$$x_{total} = \int v \, dt + x_0$$

---

<sup>8</sup>Recall from the previous section (“The Concept of Differentiation”) that velocity could be defined as the time-derivative of position:  $v = \frac{dx}{dt}$ . All we have done here is algebraically solved for changes in  $x$  by first multiplying both sides of the equation by  $dt$  to arrive at  $dx = v \, dt$ . Next, we integrate both sides of the equation in order to “un-do” the differential ( $d$ ) applied to  $x$ :  $\int dx = \int v \, dt$ . Since accumulations ( $\int$ ) of any differential ( $dx$ ) yields a discrete change for that variable, we may substitute  $\Delta x$  for  $\int dx$  and get our final answer of  $\Delta x = \int v \, dt$ .

## 1.4 How derivatives and integrals relate to one another

First, let us review some of the properties of *differentials* and *derivatives*, referencing the expression and graph shown below:

- A *differential* is an infinitesimal increment of change (difference) in some continuously-changing variable, represented either by a lower-case Roman letter  $d$  or a lower-case Greek letter “delta” ( $\delta$ ). Such a change in time would be represented as  $dt$ ; a similar change in temperature as  $dT$ ; a similar change in the variable  $x$  as  $dx$ .
- A derivative is always a *quotient of differences*: a process of subtraction (to calculate the amount each variable changed) followed by division (to calculate the *rate* of one change to another change).
- The units of measurement for a derivative reflect this final process of division: one unit divided by some other unit (e.g. gallons *per* minute, feet *per* second).
- Geometrically, the derivative of a function is its graphical *slope* (its “rise over run”).
- When computing the value of a derivative, we must specify a single point along the function where the slope is to be calculated.
- The *tangent line* matching the slope at that point has a “rise over run” value equal to the derivative of the function at that point.

Next, let us review some of the properties of *integrals*, referencing the expression and graph shown below:

- An integral is always a *sum of products*: a process of multiplication (to calculate the product of two variables) followed by addition (to sum those quantities into a whole).
- The units of measurement for an integral reflect this initial process of multiplication: one unit times some other unit (e.g. kilowatt-hours, foot-pounds, volt-seconds).
- When computing the value of an integral, we must specify both the starting and ending points along the function defining the interval of integration ( $a$  and  $b$ ).
- Geometrically, the integral of a function is the graphical *area* enclosed by the function and the interval boundaries.
- The area enclosed by the function may be thought of as an infinite sum of extremely narrow rectangles, each rectangle having a height equal to one variable ( $y$ ) and a width equal to the differential of another variable ( $dx$ ).

Just as division and multiplication are *inverse* mathematical functions (i.e. one “un-does” the other), differentiation and integration are also inverse mathematical functions. The two examples of propane gas flow and mass measurement highlighted in the previous sections illustrates this complementary relationship. We may use differentiation with respect to time to convert a mass measurement ( $m$ ) into a mass flow measurement ( $W$ , or  $\frac{dm}{dt}$ ). Conversely, we may use integration with respect to time to convert a mass flow measurement ( $W$ , or  $\frac{dm}{dt}$ ) into a measurement of mass gained or lost ( $\Delta m$ ).

Likewise, the common examples of position ( $x$ ), velocity ( $v$ ), and acceleration ( $a$ ) used to illustrate the principle of differentiation are also related to one another by the process of integration. Reviewing the derivative relationships:

$$v = \frac{dx}{dt} \quad \text{Velocity is the derivative of position with respect to time}$$

$$a = \frac{dv}{dt} \quad \text{Acceleration is the derivative of velocity with respect to time}$$

Now, expressing position and velocity as *integrals* of velocity and acceleration, respectively<sup>9</sup>:

$$x = \int v \, dt \quad \text{Position is the integral of velocity with respect to time}$$

$$v = \int a \, dt \quad \text{Velocity is the integral of acceleration with respect to time}$$

Differentiation and integration may be thought of as processes transforming these quantities into one another. Note the transformation of units with each operation – differentiation always divides while integration always multiplies:

<sup>9</sup>To be perfectly accurate, we must also include initial values for position and velocity. In other words,  $x = \int v \, dt + x_0$  and  $v = \int a \, dt + v_0$

The inverse nature of these two calculus operations is codified in mathematics as the *Fundamental Theorem of Calculus*, shown here:

$$\frac{d}{dx} \left[ \int_a^b f(x) dx \right] = f(x)$$

What this equation tells us is that the derivative of the integral of any continuous function is that original function. In other words, we can take any mathematical function of a variable that we know to be continuous over a certain range – shown here as  $f(x)$ , with the range of integration starting at  $a$  and ending at  $b$  – integrate that function over that range, then take the derivative of that result and end up with the original function. By analogy, we can take the *square-root* of any quantity, then *square* the result and end up with the original quantity, because these are inverse functions as well.

A feature of this book which may be helpful to your understanding of derivatives, integrals, and their relation to each other is found in an Appendix section (Appendix [A.4](#) beginning on page [2906](#)). In this section, a series of illustrations provides a simple form of animation you may “flip” through to view the filling and emptying of a water storage tank, with graphs showing stored volume ( $V$ ) and volumetric flow rate ( $Q$ ). Since flow rate is the time-derivative of volume ( $Q = \frac{dV}{dt}$ ) and volume change is the time-integral of volumetric flow rate ( $\Delta V = \int Q dt$ ), the animation demonstrates both concepts in action.

## 1.5 Symbolic versus numerical calculus

Calculus has a reputation for being difficult to learn, and with good reason. The traditional approach to teaching calculus is based on manipulating symbols (variables) in equations, learning how different types of mathematical functions become transformed by the calculus operations of differentiation and integration.

For example, suppose a first-semester calculus student were given the following function to differentiate. The function is expressed as  $y$  in terms of  $x$ :

$$y = \frac{3x^2 - 2x + 5}{x^2 - 8}$$

A calculus student would first apply two basic rules of symbolic differentiation (namely, the *Power Rule* and the *Quotient Rule*) followed by algebraic distribution and combination of like terms to arrive at the derivative of  $y$  with respect to  $x$  (written as  $\frac{dy}{dx}$ ) in terms of  $x$ :

$$\begin{aligned}\frac{dy}{dx} &= \frac{(x^2 - 8)(6x - 2) - (3x^2 - 2x + 5)(2x)}{(x^2 - 8)^2} \\ \frac{dy}{dx} &= \frac{6x^3 - 2x^2 - 48x + 16 - (6x^3 - 4x^2 + 10x)}{x^4 - 16x^2 + 64} \\ \frac{dy}{dx} &= \frac{2x^2 - 58x + 16}{x^4 - 16x^2 + 64}\end{aligned}$$

The resulting derivative expresses the rate-of-change of  $y$  with respect to  $x$  of the original function for any value of  $x$ . In other words, anyone can now plug any arbitrary value of  $x$  they wish into the derivative equation, and the result ( $\frac{dy}{dx}$ ) will tell them *how steep the slope is* of the original function at that same  $x$  value<sup>10</sup>.

Rules such as the Power Rule and even the Quotient Rule are not difficult to memorize, but they are far from intuitive. Although it is possible to formally prove each one of them from more fundamental principles of algebra, doing so is tedious, and so most students simply resign themselves to memorizing all the calculus rules of differentiation and integration. There are many such rules to memorize in symbolic calculus.

Symbolic integration is even more difficult to learn than symbolic differentiation. Most calculus textbooks reserve pages at the very end listing the general rules of differentiation and integration. Whereas a table of derivatives might occupy a single page in a calculus text, tables of integrals may fill five or more pages!

The next logical topic in the sequence of a calculus curriculum is *differential equations*. A “differential equation” is a function relating some variable to one or more of its own derivatives. To use the variables  $y$  and  $x$ , a differential equation would be one containing both  $y$  and at least one derivative of  $y$  ( $\frac{dy}{dx}$ ,  $\frac{d^2y}{dx^2}$ ,  $\frac{d^3y}{dx^3}$ , etc.).  $\frac{dV}{dt} = -kV$  is an example of a simple differential equation. The various forms and solution techniques for different kinds of differential equations are numerous and complex.

---

<sup>10</sup>For instance, at  $x = 1$ , the original function tells us that  $y$  will be equal to  $-\frac{6}{7}$ . If we plug this same value of 1 into  $x$  of the derivative function, the result  $\frac{dy}{dx} = -\frac{40}{49}$  tells us the original function  $y = f(x)$  has a slope of  $-\frac{40}{49}$  when  $x = 1$ .

It has been said that the laws of the universe are written in the language of calculus. This is immediately evident in the study of physics, but it is also true for chemistry, biology, astronomy, and other “hard sciences.” Areas of applied science including engineering (chemical, electrical, mechanical, and civil) as well as economics, statistics, and genetics would be impoverished if not for the many practical applications of symbolic calculus. To be able to express a function of real-life quantities as a set of symbols, then apply the rules of calculus to those symbols to transform them into functions relating rates of change and accumulations of those real-life quantities, is an incredibly powerful tool.

Two significant problems exist with symbolic calculus, however. The first problem with symbolic calculus is its complexity, which acts as a barrier to many people trying to learn it. It is quite common for students to drop out of calculus or to change their major of study in college because they find the subject so confusing and/or frustrating. This is a shame, not only because those students end up missing out on the experience of being able to see the world around them in a new way, but also because mastery of calculus is an absolute requirement of entry into many professions. One cannot become a licensed engineer in the United States, for example, without passing a series of calculus courses in an accredited university and demonstrating mastery of those calculus concepts on a challenging exam.

The second significant problem with symbolic calculus is its limitation to a certain class of mathematical functions. In order to be able to symbolically differentiate a function (e.g.  $y = f(x)$ ) to determine its derivative ( $\frac{dy}{dx}$ ), we must first have a function written in mathematical symbols to differentiate. This rather obvious fact becomes a barrier when the data we have from a real-life application defies symbolic expression. It is trivial for a first-semester calculus student to determine the derivative of the function  $V = 2t^2 - 4t + 9$ , but what if  $V$  and  $t$  only exist as recorded values in a table, or as a trend drawn by a process recorder? Without a mathematical formula showing  $V$  as a function of  $t$ , none of the rules learned in a calculus course for manipulating those symbols directly apply. The problem is even worse for differential equations, where a great many examples exist that have so far defied solution by the greatest mathematicians.

Such is the case when we apply calculus to recorded values of process variable, setpoint, and controller output in real-world automated processes. A trend showing a PV over time *never* comes complete with a formula showing you  $PV = f(t)$ . We must approach these practical applications from some perspective other than symbolic manipulation if we are to understand how calculus relates. Students of instrumentation face this problem when learning PID control: the most fundamental algorithm of feedback control, used in the vast majority of industrial processes to regulate process variables to their setpoint values.

An alternative approach to calculus exists which is easily understood by anyone with the ability to perform basic arithmetic (addition, subtraction, multiplication, and division) and sketching (drawing lines and points on a graph). Numerical calculus uses simple *arithmetic* to approximate derivatives and integrals on real-world data. The results are not as precise as with symbolic calculus, but the technique works on *any* data as well as most mathematical functions written in symbolic form. Furthermore, the simplicity of these techniques opens a door to those people who might otherwise be scared away by the mathematical rigor of symbolic calculus. Any way we can find to showcase the beauty and practicality of calculus principles to more people is a good thing!

Suppose we needed to calculate the derivative of some real-world function, such as the volume of liquid contained in a storage vessel. The derivative of volume ( $V$ ) with respect to time ( $t$ ) is *volumetric flow rate* ( $\frac{dV}{dt}$ ), thus the time-derivative of the vessel's volume function at any specified point in time will be the net flow rate into (or out of) that vessel at that point in time.

To numerically determine the derivative of volume from raw data, we could follow these steps:

- Choose two values of volume both near the point in time we're interested in calculating flow rate.
- Subtract the two volume values: this will be  $\Delta V$ .
- Subtract the two time values corresponding to those volume values: this will be  $\Delta t$ .
- Divide  $\Delta V$  by  $\Delta t$  to approximate  $\frac{dV}{dt}$  between those two points in time.

A slightly different approach to numerical differentiation follows these steps:

- Sketch a graph of the volume versus time data for this vessel (if this has not already been done for you by a trend recorder).
- Locate the point in time on this graph you are interested in, and sketch a tangent line to that point (a straight line having the same slope as the graphed data at that point).
- Estimate the rise-over-run slope of this tangent line to approximate  $\frac{dV}{dt}$  at this point.

An illustration is a helpful reminder of what differentiation means for any graphed function: the *slope* of that function at a specified point:

Suppose we needed to calculate the integral of some real-world function, such as the flow rate of liquid through a pipe. The integral of volumetric flow ( $Q$ ) with respect to time ( $t$ ) is *total volume* ( $V$ ), thus the time-integral of the flow rate over any specified time interval will be the total volume of liquid that passed by over that time.

To numerically determine the integral of flow from raw data, we could follow these steps:

- Identify the time interval over which we intend to calculate volume, and the duration of each measured data point within that interval.
- Multiply each measured value of flow by the duration of that measurement (the interval between that measurement and the next one) to obtain a volume over each duration.
- Repeat the last step for each and every flow data point up to the end of the interval we're interested in.
- Add all these volume values together – the result will be the approximate liquid volume passed through the pipe over the specified time interval.

A slightly different approach to numerical integration follows these steps:

- Sketch a graph of the flow versus time data for this pipe (if this has not already been done for you by a trend recorder).
- Mark the time interval over which we intend to calculate volume (two straight vertical lines on the graph).
- Use any geometrical means available to estimate the area bounded by the graph and the two vertical time markers – the result will be the approximate liquid volume passed through the pipe over the specified time interval.

An illustration is a helpful reminder of what integration means for any graphed function: the *area* enclosed by that function within a specified set of boundaries:

The next sections of this chapter delve into more specific details of numerical differentiation and integration, with realistic examples to illustrate.

## 1.6 Numerical differentiation

As we have seen, the concept of *differentiation* is finding the rate-of-change of one variable compared to another (related) variable. In this section, we will explore the practical application of this concept to real-world data, where actual numerical values of variables are used to calculate relative rates of change.

In industrial instrumentation, for example, we are often interested in knowing the rate of change of some process variable (pressure, level, temperature, flow, etc.) over time, and so we may use computers to calculate those rates of change, either after the fact (from recorded data) or in real time (as the data is being received by sensors and acquired by the computer). We may be similarly interested in calculating the rate at which one process variable changes with respect to another process variable, both of which measured and recorded as tables of data by instruments.

Numerical (data-based) differentiation is fundamentally a two-step arithmetic process. First, we must use *subtraction* to calculate the change in a variable between two different points. Actually, we perform this step twice to determine the change in *two variables* which we will later compare. Then, we must use *division* to calculate the ratio of the two variables' changes, one to the other (i.e. the “rise-over-run” steepness of the function's graph).

For example, let us consider the application of pressure measurement for a pipeline. One of the diagnostic indicators of a burst pipeline is that the measured pressure rapidly drops. It is not the existence of low pressure in and of itself that suggests a breach, but rather the *rate* at which the pressure falls that reveals a burst pipe. For this reason, pipeline control systems may be equipped with automatic shut-down systems triggered by rate-of-change pressure calculations.

The association of rapid pressure drop with pipeline ruptures is nothing new to pipeline operations. Here is an illustration taken from page 566 of volume 8 of *Cassier's Magazine* published in the year 1895, showing water pressure measurements taken by a paper strip chart recorder on a city water main line. The pressure drop created by a burst in that 36-inch pipe is clearly seen and commented on the recording:

FIG. 5. CHART SHOWING THE BURSTING OF A WATER MAIN.

An example of a modern<sup>11</sup> pressure-trend recording during a pipeline rupture is shown here:

While it may seem surprising that pipeline pressure should recover after the low point immediately following the pipe's rupture, it is important to bear in mind that many pipelines are *pressure-controlled* processes. After a pipeline ruptures, the pumping equipment will attempt to compensate for the reduced pressure automatically, which is why the pressure jumps back up (although not to its previous level) after the initial drop.

This phenomenon helps explain why pressure rate-of-change is a more reliable diagnostic indicator of a ruptured pipe than pressure magnitude alone: any automatic rupture-detection scheme based on a simple comparison of pipeline pressure against a pre-set threshold may fail to reliably detect a rupture if the pressure-regulating equipment is able to quickly restore pipeline pressure following the rupture. A rate-of-change system, on the other hand, will still detect the rupture based on the sharp pressure decrease following the break, even if the pressure quickly recovers.

<sup>11</sup>Unlike the recording shown from *Cassier's Magazine*, which runs chronologically from right to left, modern chart recordings all run from left to right.

A computer tasked with calculating the pressure's rate of change over time ( $\frac{dP}{dt}$ ) would have to continuously sample the pressure value over short time periods, then calculate the quotient of pressure changes over time changes. Given a sample rate of once every 5 minutes, we see how the computer would tabulate the pressure data over time:

Pressure	Time
217.5 PSI	1 hour, 20 minutes
215.0 PSI	1 hour, 25 minutes
222.5 PSI	1 hour, 30 minutes
226.3 PSI	1 hour, 35 minutes
150.0 PSI	1 hour, 40 minutes
150.0 PSI	1 hour, 45 minutes
151.3 PSI	1 hour, 50 minutes
148.8 PSI	1 hour, 55 minutes
145.0 PSI	2 hours, 0 minutes
145.0 PSI	2 hours, 5 minutes

To calculate the rate of pressure change over time in each of these periods, the computer would subtract the two adjacent pressure values, subtract the two corresponding adjacent time values, and then divide those two differences to arrive at a figure in units of PSI per minute. Taking the first two data coordinates in the table as an example:

$$\frac{\Delta P}{\Delta t} = \frac{215.0 \text{ PSI} - 217.5 \text{ PSI}}{1:25 - 1:20} = \frac{-2.5 \text{ PSI}}{5 \text{ min}} = -0.5 \frac{\text{PSI}}{\text{min}}$$

The sample period where the computer would detect the pipeline rupture lies between 1:35 and 1:40. Calculating this rate of pressure change:

$$\frac{\Delta P}{\Delta t} = \frac{150.0 \text{ PSI} - 226.3 \text{ PSI}}{1:40 - 1:35} = \frac{-76.3 \text{ PSI}}{5 \text{ min}} = -15.26 \frac{\text{PSI}}{\text{min}}$$

Clearly, a pressure drop rate of  $-15.26$  PSI per minute is far greater than a typical drop of  $-0.5$  PSI per minute, thus signaling a pipeline rupture.

As you can see, the pipeline monitoring computer is not technically calculating *derivatives* ( $\frac{dP}{dt}$ ), but rather *difference quotients* ( $\frac{\Delta P}{\Delta t}$ ). Being a digital device, the best it can ever do is perform calculations at discrete points in real time. It is evident that calculating rates of change over 5-minute period misses a lot of detail<sup>12</sup>. The actual rate of change at the steepest point of the pressure drop *far* exceeds  $-15.26$  PSI per minute.

It is possible for us to calculate the instantaneous rate-of-change of pressure ( $\frac{dP}{dt}$ ) at the moment of the rupture by examining the graph and sketching a straight line called a *tangent line* matching the slope where the graph is steepest. Our goal is to calculate the exact slope of that single (steepest) point on that graph, rather than an estimate of slope between two points as the computer did. In essence, the computer “drew” short line segments between pairs of points and calculated the slopes (rise-over-run) of those line segments. The slope of each line segment<sup>13</sup> is a difference quotient:  $\frac{\Delta P}{\Delta t}$ . The slope of a tangent line matching the slope at a single point on the function graph, however, is a derivative:  $\frac{dP}{dt}$ .

---

<sup>12</sup>Not only does a 5-minute rate calculation period miss a lot of detail, but it also results in a time delay of (up to) 5 minutes detecting a pipeline rupture.

<sup>13</sup>The technical term for a line passing through a pair of points on a curve is called a *secant line*.

First we sketch a tangent line (by hand) matching the steepest portion of the pressure trend graph. Then, we calculate the slope of a tangent line by marking convenient points<sup>14</sup> where the line intersects major division marks on the graph's graduated scale, then calculating rise over run:

$$\frac{dP}{dt} = \frac{150.0 \text{ PSI} - 340.0 \text{ PSI}}{1:40:00 - 1:37:30} = \frac{-190.0 \text{ PSI}}{2.5 \text{ min}} = -76.0 \frac{\text{PSI}}{\text{min}}$$

This distinction between calculating difference quotients ( $\frac{\Delta P}{\Delta t}$ ) and calculating true derivative values ( $\frac{dP}{dt}$ ) becomes less and less significant as the calculation period shortens. If the computer could sample and calculate at infinite speed, it *would* generate true derivative values instead of approximate derivative values.

<sup>14</sup>Please note that the pipeline pressure is *not* actually 340.0 PSI at a time of 1:37:30. This is simply a coordinate convenient to mark because it how it lines up with the divisions on the trend display. We choose coordinate points on the tangent line easy to visually discern, then calculate the tangent line's slope using those coordinates.

An algorithm applicable to calculating rates of change in a digital computer is shown here, using a notation called *pseudocode*<sup>15</sup>. For more information on pseudocode, refer to section 29.15.1 beginning on page 2388. Each line of text in this listing represents a command for the digital computer to follow, one by one, in order from top to bottom. The LOOP and ENDLOOP markers represent the boundaries of a program *loop*, where the same set of encapsulated commands are executed over and over again in cyclic fashion:

#### Pseudocode listing

```

LOOP
  SET x = analog_input_N      // Update x with the latest measured input
  SET t = system_time         // Sample the system clock

  SET delta_x = x - last_x     // Calculate change in x
  SET delta_t = t - last_t     // Calculate change in t (time)

  SET rate = (delta_x / delta_t) // Calculate ratio of changes

  SET last_x = x               // Update last_x value for next program cycle
  SET last_t = t               // Update last_t value for next program cycle
ENDLOOP

```

Each SET command tells the computer to assign a numerical value to the variable on the left-hand side of the equals sign (=), according to the value of the variable or expression on the right-hand side of the equals sign. Text following the double-dash marks (//) are *comments*, included only to help human readers interpret the code, not for the computer's benefit.

This computer program uses two variables to “remember” the values of the input ( $x$ ) and time ( $t$ ) from the previous scan, named `last_x` and `last_t`, respectively. These values are subtracted from the current values for  $x$  and  $t$  to yield differences (`delta_x` and `delta_t`, respectively), which are subsequently divided to yield a difference quotient. This quotient (`rate`) may be sampled in some other portion of the computer's program to trigger an alarm, a shutdown action, or simply display and/or record the rate value for a human operator's benefit.

The time period ( $\Delta t$ ) for this program's difference quotient calculation is simply how often this algorithm “loops,” or repeats itself. For a modern digital microprocessor, this could be many thousands of times per second.

---

<sup>15</sup>“Pseudocode” is a name given to any imaginary computer language used for the purpose of illustrating some procedure or concept without having to make reference to any particular (real) computer programming language. I could have just as well shown you the same algorithm using BASIC, C, or Java code, but pseudocode does just as well without the burden of introducing unfamiliar syntax to the reader.

If a nearly-instantaneous calculation is required for a rate-of-change variable, we may turn to an older technology using analog electronic circuitry. Such a *differentiator* circuit uses the natural behavior of a capacitor to generate an output voltage proportional to the instantaneous rate-of-change of the input voltage:

$$V_{out} = -RC \frac{dV_{in}}{dt}$$

The negative feedback of the operational amplifier forms a *virtual ground* at the node where the capacitor, resistor, and inverting input connect. This means the capacitor “sees” the full input voltage ( $V_{in}$ ) at all times. Current through a capacitor is a direct function of the voltage’s time-derivative:

$$I = C \frac{dV}{dt}$$

This current finds its way through the feedback resistor, developing a voltage drop that becomes the output signal ( $V_{out}$ ). Thus, the output voltage of this analog differentiator circuit is directly proportional to the time-derivative of the input voltage (i.e. the input voltage’s rate-of-change).

It is indeed impressive that such a simple circuit, possessing far fewer components than a microprocessor, is actually able to do a *better* job at calculating the real-time derivative of a changing signal than modern digital technology. The only real limitations to this device are accuracy (tolerances of the components used) and the bandwidth of the operational amplifier.

It would be a mistake, though, to think that an analog differentiator circuit is better suited to industrial applications of rate calculation than a digital computer, even if it does a superior job differentiating live signals. A very good argument for favoring difference quotients over actual derivatives is the presence of *noise* in the measured signal. A true differentiator, calculating the actual time-derivative of a live signal, will pick up on *any* rise or fall of the signal over time, no matter how brief. This is a serious problem when differentiating real-world signals, because noise (small amounts of “jittering” in the signal caused by any number of phenomena) will be interpreted by a perfect differentiator as very large rates of change over time.

A close look at the previous pipeline pressure trend illustrates this problem. Note the areas circled (in red) on the graph, representing relatively small increases and decreases in signal occurring over very short periods of time:

Although each “step” in pressure at these circled locations is small in amplitude, each one occurs over an extremely brief time increment. Thus, each of these steps has a nearly *infinite* rate of change (i.e. a vertical slope). Any rate-of-change sensing system able to apply true differentiation to the pressure signal would falsely declare an alarm (high rate-of-change) condition every time it encountered one of these “steps” in the signal. This means that even under perfectly normal operating conditions the rate-detection system would periodically declare an alarm (or perhaps shut the pipeline down!) given the inevitable presence of small noise-induced<sup>16</sup> “jitters” in the signal.

The best solution to this problem is to use a digital computer to calculate rates of change, setting the calculation period time slow enough that these small “jitters” will be averaged to very low values, yet fast enough that any serious pressure rate-of-change will be detected if it occurs. Back in the days when analog electronic circuits were the *only* practical option for calculating rates of signal change, the solution to this problem was to place a low-pass filter before the differentiator circuit to block such noise from ever reaching the differentiator.

Differentiation with respect to *time* has many applications, but there are other applications of differentiation in industrial measurement and control that are not time-based. For example, we may

<sup>16</sup>Another source of trouble for differentiation of live signals is when the signal originates from a digital sensor. Digital devices, by their very nature, break analog signals into a series of discrete amplitude steps. As a digital process transmitter encounters a steadily increasing or decreasing process variable, its output rises or falls in discrete “jumps” rather than continuously as a fully analog transmitter would. Now, each of these jumps is quite small, but since each one occurs almost instantly it still translates into an extremely large rate-of-change when detected by a differentiator sampling over small time increments or sampling continuously (as in the case of an analog differentiator circuit). This means the problem of false rates-of-change exists *even in perfectly noiseless systems*, when the detection device (and/or the information channel to the monitoring system) is digital rather than analog.

use differentiation to express the *sensitivity* of a non-linear device in terms of the rate-of-change of output over input.

One such application is the sensitivity of a mechanism called a *baffle/nozzle* assembly used in many pneumatic instruments to convert a small physical motion ( $x$ ) into an air pressure signal ( $P$ ). This very simple mechanism uses a flat piece of sheet metal (the baffle) to restrict air flow out of a small nozzle, causing a variable “backpressure” at the nozzle to develop as the baffle-to-nozzle clearance changes:

The graph expressing the relationship between  $P$  and  $x$  is clearly non-linear, having different slopes ( $\frac{dP}{dx}$ ) at different points along its range. When used as part of the feedback mechanism for a self-balancing instrument, the purpose of the baffle/nozzle assembly is to detect baffle motion as sensitively as possible: that is, to generate the greatest change in pressure ( $\Delta P$ ) for the least change in motion ( $\Delta x$ ). This means the designer of the pneumatic instrument should design it in such a way that the normal baffle/nozzle clearance gap rests at a point of maximum slope (maximum  $\frac{dP}{dx}$ ) on the graph.

Sketching a tangent line near the point of maximum slope (maximum “steepness” on the graph) allows us to approximate the rate of change at that point:

Choosing convenient points<sup>17</sup> on this tangent line aligning with major divisions on the graph’s scales, we find two coordinates we may use to calculate the derivative of the curve at its steepest point:

$$\frac{dP}{dx} = \frac{0 \text{ PSI} - 18 \text{ PSI}}{0.0025 \text{ inch} - 0.001 \text{ inch}} = \frac{-18 \text{ PSI}}{0.0015 \text{ inch}} = -12000 \text{ PSI per inch}$$

The phenomenally large value of  $-12000$  PSI per inch is a *rate* of pressure change to clearance (baffle-nozzle gap) change. Do not mistakenly think that this value suggests the mechanism could ever develop a pressure of 12000 PSI – it is simply describing the extreme sensitivity of the mechanism in terms of PSI change per unit change of baffle motion. By analogy, just because an automobile travels at a *speed* of 70 miles per hour does not mean it must travel 70 miles in *distance*!

It should be clear from an examination of the graph that this high sensitivity extends approximately between the pressure values of 9 and 14 PSI. Outside of those pressure values, the graph’s slope begins to decrease. While still sensitive, the baffle/nozzle mechanism will not be as sensitive to baffle motion outside those pressure values as it is within.

<sup>17</sup>Once gain, we are looking for points where the tangent line happens to intersect with major divisions on the graph’s scale. This makes it relatively easy to calculate the line’s slope, since the pressure and distance values for those coordinates are easy to read.

## 1.7 Numerical integration

As we have seen, the concept of *integration* is finding the accumulation of one variable multiplied by another (related) variable. In this section, we will explore the practical application of this concept to real-world data, where actual numerical values of variables are used to calculate accumulated sums.

In industrial instrumentation, for example, we are often interested in calculating the accumulation of some process fluid based on a measured flow *rate* of that fluid. The rate is, of course, expressed in either mass or volume units per unit time (e.g. gallons per minute), but the total accumulated quantity will be expressed plainly in either mass or volume units (e.g. gallons). We may use computers to calculate those accumulated quantities, either after the fact (from recorded data) or in real time.

Numerical (data-based) integration is fundamentally a two-step arithmetic process. First, we must use *multiplication* to calculate the product of a variable and a small increment of another variable (a change in the second variable between two different points). Then, we must use *addition* to calculate the accumulated sum of the products.

To illustrate, we will first focus on the integration of a flow measurement signal with respect to time. The flow rate of any fluid is always expressed in units of volume or mass *per unit time*. Common volumetric flow units are gallons *per minute*, liters *per second*, cubic feet *per day*, etc. Common mass flow units are pounds *per hour*, kilograms *per minute*, slugs *per second*, etc. If we desire to calculate the volume or mass of fluid passed through a pipe – representing fluid added to or removed from a system – over some interval of time, we may do so by integrating flow rate with respect to time:

$$\Delta V = \int_a^b Q \, dt$$

$$\Delta m = \int_a^b W \, dt$$

Where,

$\Delta V$  = Volume of fluid added or removed

$Q$  = Volumetric flow rate of fluid

$\Delta m$  = Mass of fluid added or removed

$W$  = Mass flow rate of fluid

$a$  = Starting point of integration interval

$b$  = Ending point of integration interval

$t$  = Time

As always, integration is fundamentally a matter of *multiplying* one variable by small increments of another variable. If a flow rate is integrated with respect to time, the result is that the unit for time becomes eliminated. Gallons per minute, for example, becomes gallons after integration; kilograms per second becomes kilograms; etc.

The elimination of time units is also evident if we re-write the integrands in the previous equations to show volumetric and mass flow rates ( $Q$  and  $W$ , respectively) as the rates of change they are ( $Q = \frac{dV}{dt}$  and  $W = \frac{dm}{dt}$ ):

$$\Delta V = \int_a^b \frac{dV}{dt} dt$$

$$\Delta m = \int_a^b \frac{dm}{dt} dt$$

It should be clear that the time differentials ( $dt$ ) cancel in each integrand, leaving:

$$\Delta V = \int_a^b dV$$

$$\Delta m = \int_a^b dm$$

Since we know the integral symbol ( $\int$ ) simply means the “continuous sum of” whatever follows it, we may conclude in each case that the continuous sum of infinitesimal increments of a variable is simply a larger change of that same variable. The continuous summation of  $dV$  is simply the total change in  $V$  over the interval beginning at time  $a$  and ending at time  $b$ ; likewise, the continuous summation of  $dm$  is simply the total change in  $m$  over the interval beginning at time  $a$  and ending at time  $b$ .

A flowmeter measuring the flow rate of a fluid outputs a signal representing either volume or mass units passing by per unit time. Integrating that signal with respect to time yields a value representing the total volume or mass passed through the pipe over a specific interval. A physical device designed to perform this task of integrating a signal with respect to time is called an *integrator* or a *totalizer*:

An example of a flow integrator, or flow totalizer, made for pneumatic instrument systems is the Foxboro model 14. A view of this instrument's front face shows an odometer-style display, in this particular case showing the total number of pounds (lb) of fluid passed through the pipe, with a multiplying factor of 10:

The fact that this instrument's display resembles the odometer of an automobile is no coincidence. Odometers are really just another form of mechanical integrator, “totalizing” the distance traveled by a vehicle. If the speedometer of a vehicle registers speed ( $v$ ) in units of miles per hour, then the odometer will accumulate a distance ( $\Delta x$ ) in units of miles, since distance (miles) is the time-integral of speed (miles per hour):

$$\Delta x = \int_a^b v \, dt \quad . . . \text{ or } . . . \quad \Delta x = \int_a^b \frac{dx}{dt} \, dt$$

$$[\text{miles}] = \int_a^b \left( \left[ \frac{\text{miles}}{\text{hour}} \right] [\text{hours}] \right)$$

In this particular case, where the flowmeter measures pounds per hour, and the integrator registers accumulated mass in pounds, the integration of units is as follows:

$$\Delta m = \int_a^b W \, dt \quad . . . \text{ or } . . . \quad \Delta m = \int_a^b \frac{dm}{dt} \, dt$$

$$[\text{pounds}] = \int_a^b \left( \left[ \frac{\text{pounds}}{\text{hour}} \right] [\text{hours}] \right)$$

The Foxboro model 14 used a turbine wheel driven by a jet of compressed air from a nozzle. The wheel's speed was made proportional to the process fluid flow rate sensed by a pneumatic DP transmitter. As process flow rate increased, the wheel spun faster. This spinning wheel drove a gear-reduction mechanism to slowly turn the odometer-style numerals, registering total fluid quantity passed through the flowmeter:

As pneumatic signal pressure (3-15 PSI) from a pneumatic flow transmitter entered the brass bellows of this instrument, it pressed down on a lever, forcing a baffle toward a nozzle. As nozzle backpressure rose, amplified air pressure spun the turbine wheel to drive the integrating “odometer” display. Mounted on the turbine wheel was a set of fly-weights, which under the influence of centrifugal force would press upward on the lever to re-establish a condition of force-balance to maintain a (relatively) constant baffle-nozzle gap. Thus, the force-balance mechanism worked to establish an accurate and repeatable relationship<sup>18</sup> between instrument signal pressure and integration rate.

---

<sup>18</sup>The Foxboro model 14 totalizer’s design was quite ingenious, since centrifugal force varies with the *square* of angular velocity. This had the effect of naturally performing the *square-root* characterization required of most pneumatic flow-measuring instruments due to the quadratic nature of most primary flow-sensing elements (e.g. orifice plate, venturi tubes, pitot tubes, etc.).

A very different style of integrator appears here, as part of the controller for a ball mill used to crush limestone into small pieces for the manufacturing of concrete. Limestone is fed into the ball mill on a device called a *weighfeeder*, which measures the mass of limestone as it passes over a conveyor belt. The controller maintains a limestone “flow rate” at a setpoint specified in tons per hour (mass flow of solid material). The red LED digital display shows the total number of tons passed through the mill:

The units involved in the integration of limestone “flow” into the ball mill are slightly different from the example shown with the Foxboro model 14 totalizer, but the concept is the same:

$$\Delta m = \int_a^b W \, dt$$

$$[\text{tons}] = \int_a^b \left( \left[ \frac{\text{tons}}{\text{hour}} \right] [\text{hours}] \right)$$

As with all cases of numerical integration, an essential piece of information to know when “totalizing” any rate is the initial quantity at the start of the totalization interval. This is the *constant of integration* mentioned previously. For flow totalization, this constant would be the initial volume of fluid recorded at the starting time. For an automobile’s odometer, this constant is the initial “mileage” accumulated prior to driving on a trip<sup>19</sup>.

<sup>19</sup>Vehicles equipped with a *trip odometer* allow the driver to reset this integration constant to zero at will, thus

An algorithm applicable to integrating real signals with respect to time in a digital computer is shown here, once again using “pseudocode” as the computer language. Each line of text in this listing represents a command for the digital computer to follow, one by one, in order from top to bottom. The LOOP and ENDLOOP markers represent the boundaries of a program *loop*, where the same set of encapsulated commands are executed over and over again in cyclic fashion:

#### Pseudocode listing

```

LOOP
  SET x = analog_input_N    // Update x with the latest measured input
  SET t = system_time        // Sample the system clock

  SET delta_t = t - last_t    // Calculate change in t (time)

  SET product = x * delta_t    // Calculate product (integrand)
  SET total = total + product  // Update the running total

  SET last_t = t              // Update last_t value for next program cycle
ENDLOOP

```

This computer program uses a variable to “remember” the value of time ( $t$ ) from the previous scan, named `last_t`. This value is subtracted from the current value for  $t$  to yield a difference (`delta_t`), which is subsequently multiplied by the input value  $x$  to form a product. This product is then added to an accumulating total (named `total`), representing the integrated value. This “total” value may be sampled in some other portion of the computer’s program to trigger an alarm, a shutdown action, or simply display and/or record the totalized value for a human operator’s benefit.

The time period ( $\Delta t$ ) for this program’s difference quotient calculation is simply how often this algorithm “loops,” or repeats itself. For a modern digital microprocessor, this could be upwards of many thousands of times per second. Unlike differentiation, where an excessive sampling rate may cause trouble by interpreting noise as extremely high rates of change, there is no danger of excessive sampling when performing numerical integration. The computer may integrate as fast as it can with no ill effect.

One of the fundamental characteristics of integration is that it *ignores* noise, which is a very good quality for industrial signal processing. Small “jittering” in the signal tends to be random, which means for every “up” spike of noise, one may expect a comparable “down” spike (or collection of “down” spikes having comparable weight) at some later time. Thus, noise tends to cancel itself out when integrated over time.

As with differentiation, applications exist for integration that are not time-based. One such application is the calculation of mechanical *work*, defined as the product of force and displacement (distance moved). In mechanical systems where there is no energy dissipated due to friction, work results in a change in the energy possessed by an object.

---

allowing the tracking of mileage for individual trips instead of over the life of the automobile.

For example, if we use a hoist to lift a mass weighing 700 pounds straight up against gravity a distance of 3 feet, we will have done 2100 foot-pounds of work. The work done on the mass increases its potential energy ( $\Delta E$ ) by 2100 foot-pounds:

$$\Delta E = Fx$$

Where,

$\Delta E$  = Change in potential energy resulting from work, in joules (metric) or foot-pounds (British)

$F$  = Force doing the work, in newtons (metric) or pounds (British)

$x$  = Displacement over which the work was done, in meters (metric) or feet (British)

We may also express this change in potential energy as an integral of force ( $F$ ) multiplied by infinitesimal increments in displacement ( $dx$ ) over some interval (from  $a$  to  $b$ ), since we know integration is nothing more than a sophisticated way to multiply quantities:

$$\Delta E = \int_a^b F dx$$

Like any other integral, the energy change effected by lifting this mass a vertical distance may be represented graphically as the *area* enclosed by the graph. In this case, the area is very simple to calculate, being a simple rectangle (height times width):

Lifting the mass vertically constitutes a *positive* change in potential energy for this object, because each displacement differential ( $dx$ ) is a positive quantity as we move from a height of 0 feet to a height of 3 feet:

$$2100 \text{ ft-lbs} = \int_{0 \text{ ft}}^{3 \text{ ft}} (700 \text{ lbs}) dx$$

A natural question to ask at this point is, *what would the resulting change in energy be if we lowered the mass from its height of 3 feet back down to 0 feet?* Doing so would cover the exact same distance (3 feet) while exerting the exact same amount of suspending force (700 lbs), and so we can safely conclude the work will have an absolute magnitude of 2100 ft-lbs. However, if we lower the mass, each displacement differential ( $dx$ ) will be a negative quantity<sup>20</sup> as we move from a greater height to a lesser height. This makes the work – and the resulting energy change – a negative quantity as well:

$$-2100 \text{ ft-lbs} = \int_{3ft}^{0ft} (700 \text{ lbs}) dx$$

This means if we raise the mass to a height of 3 feet, then lower it back to its original starting height of 0 feet, the total change in potential energy will be zero:

$$0 \text{ ft-lbs} = \int_{0ft}^{3ft} (700 \text{ lbs}) dx + \int_{3ft}^{0ft} (700 \text{ lbs}) dx$$

This is true for any integral having an interval of zero (same starting and ending values), regardless of the integrand's value at any point in time:

$$0 \text{ ft-lbs} = \int_a^a F dx$$

---

<sup>20</sup>As we lower the mass to ground level, height ( $x$ ) goes from being a positive value to zero. This means each differential (infinitesimal change in value) for  $x$  will be negative, thus causing the integrand  $F dx$  to have a negative value and thus causing the integrated total (work) to be negative as well.

The integration of force and displacement to calculate potential energy change really shows its utility when the force changes as a function of displacement. A classic example of this is the compression of a mechanical spring, described in section 2.8.3 beginning on page 91.

One practical example of this sort of calculation is the determination of energy stored in an archer's bow when drawn to a certain displacement. The so-called *force-draw curve* of a longbow is nearly ideal for a theoretical spring, with force increasing linearly as the string is drawn back by the archer. The force-draw curve for a compound bow<sup>21</sup> is quite nonlinear, with a much lesser holding force required to maintain the bow at full draw:

The force required to draw a compound bow rises sharply during the first few inches of draw, peaks during the region where the archer's arms are ideally angled for maximum pulling strength, then "lets off" toward the end where the archer's drawing arm is weakest in the "holding" position. The result is a bow that requires substantial force to draw, but is relatively easy to hold in fully-drawn position.

---

<sup>21</sup>While a longbow is really nothing more than a long and flexible stick with a straight string drawn across it, a compound bow is a sophisticated machine with multiple passes of string and cam-shaped pulleys providing the nonlinear force-draw relationship.

While the compound bow may be easier to hold at full draw than the longbow, for any given holding force the compound bow stores *much* more energy than the longbow, owing to the far greater *area* (force-displacement integral) enclosed by the curve:

This is why a compound bow is so much more powerful than a longbow or a “recurve” bow with the same holding force: the energy represented by the greater area underneath the force-draw curve equates to greater energy imparted to the arrow when released, and therefore greater kinetic energy in the arrow during flight.

Like any other form of mechanical work, the energy invested into the bow by the archer is readily calculated and expressed in units of force  $\times$  displacement, typically newton-meters (joules) in metric units and foot-pounds in British units. This stands to reason, since we know integration is fundamentally a matter of *multiplying* quantities together, in this case force (pull) and displacement (draw).

To actually calculate the amount of energy stored in a fully-drawn bow, we could measure both force and displacement with sensors as the archer draws the bow, with a computer numerically integrating force over increments of draw in real time. Another method would be to simply graph force versus draw as we have done here, then use geometric methods<sup>22</sup> to approximate the area underneath the curve.

---

<sup>22</sup>One simple way to do this is to cover the entire integration area using nothing but rectangles and triangles, then measuring all the sketched shapes to totalize their areas.

A more sophisticated example of numerical integration used to calculate work is that of a heat engine, where a piston compresses an enclosed gas:

As the piston is pushed farther into the cylinder, the gas becomes compressed, exerting more force on the piston. This requires an ever-increasing application of force to continue the piston's motion. Unlike the example where a mass of constant weight was lifted against the pull of gravity, here the force is a dynamically changing variable instead of a constant. The graph shows this relationship between piston displacement and piston force.

If we push the piston into the cylinder, the force increases as the displacement decreases. The change in energy is described by the integral of force with respect to displacement, graphically equivalent to the area underneath the force curve:

$$\Delta E = \int_a^b F dx$$

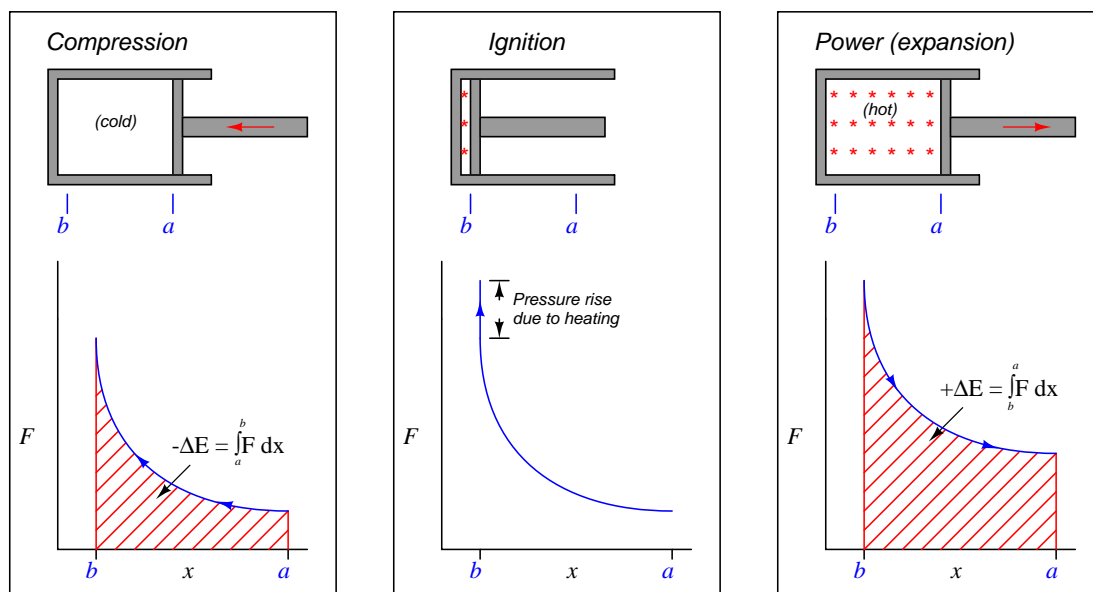

If we slowly allow the piston to return to its original position (letting the pressure of the enclosed gas push it back out), the piston's force decreases as displacement increases. The force/displacement relationship is the same as before, the only difference being the direction of travel is opposite. This means the change in energy is happening over the same interval, in reverse direction (from  $b$  to  $a$  now instead of from  $a$  to  $b$ ). Expressed as an integral:

$$\Delta E = \int_b^a F dx$$

As we have already learned, a reversal of direction means the sign of the integral will be opposite. If pushing the piston farther inside the cylinder represented work being done on the enclosed gas by the applied force, now the gas will be doing work on the source of the applied force as the piston returns to its extended position.

This means we will have done zero net work by pushing the piston into the cylinder and then letting it spring back out to its original position, just as we performed zero net work by lifting a mass 3 feet in the air and then letting it back down.

In order that this piston/cylinder mechanism might function as an engine, we must have some way of making the energy change greater in one direction than the other. This is done by *heating* the enclosed gas at the point of greatest compression. In a spark-ignition engine, the gas is actually a mixture of air and fuel, ignited by an electric spark. In a compression-ignition (diesel) engine, the gas is pure air, with fuel injected at the last moment to initiate combustion. The addition of heat (from combustion) will cause the gas pressure to rise, exerting more force on the piston than what it took to compress the gas when cold. This increased force will result in a *greater* energy change with the piston moving out of the cylinder than with the piston moving in:

Representing the work done by the hot gas as the area enclosed by the curve makes this clear: more mechanical energy is being released as the piston travels from  $b$  to  $a$  during the “power stroke” than the amount of energy invested in compressing the gas as the piston traveled from  $a$  to  $b$  during the “compression stroke.” Thus, an internal combustion engine produces mechanical power by repeatedly compressing a cold gas, heating that gas to a greater temperature, and then expanding that hot gas to extract energy from it.

At the conclusion of the power stroke, a valve opens to exhaust the hot gas and another valve opens to introduce cold gas. This places the piston and cylinder in the original condition, ready for another set of compression, ignition, and power strokes. This cycle is sometimes represented as a closed “loop” on the force/displacement graph, like this:

The amount of net energy output by the engine at the conclusion of each cycle is equivalent to the area enclosed by the loop. This is the difference in areas (integrals) between the “compression” and “power” strokes. Any design change to the engine resulting in a greater “loop” area (i.e. less energy required to compress the gas, and/or more energy extracted from its expansion) results in a more powerful engine. This is why heat engines output the most power when the difference in temperatures (cold gas versus heated gas) is greatest: a greater temperature shift results in the two curves being farther apart vertically, thus increasing the area enclosed by the “loop.”

## Chapter 2

# Physics

**Everything there is to know about physics** – excerpted from “Everything you need to know about school” in the September 16, 2008 edition of the Seattle periodical *The Stranger*:

If stuff is still, it doesn’t like to move; if stuff is moving, it doesn’t like to stop. The more stuff you are trying to move, the more you need to push it to speed it up. When you push on stuff, it pushes back on you. Stuff likes other stuff, from a distance at least. Stuff likes becoming more chaotic, but cannot be created or destroyed; stuff can be rearranged. (All that is Isaac Newton.) Energy, like stuff, cannot be created or destroyed, only changed from one kind to another. Energy can be stored in movement, bonds between stuff, and many other places. Changes in how energy is stored allow us to do things – like bake, drive, get up tall buildings, and kill each other. (That’s Sadi Carnot.) Also, stuff *is* energy. Stuff is a lot of energy. (That’s Albert Einstein.) Compress plutonium with explosives and the atoms fission, releasing the energy stored in stuff. When the energy is released in downtown Nagasaki, you kill about 40,000 people right away and another 40,000 over time. (Thanks, Enrico Fermi!)

There is a lot of truth to this quote, despite its sarcastic tone. Physics really is the study of matter and energy, and of the laws governing the interactions of both. The movement of matter largely follows the laws described by Isaac Newton (so much so that this category of physics is often referred to as *Newtonian physics*). The flow and transformation of energy is a category called *thermodynamics*. Albert Einstein went on to equate matter with energy through his famous equation  $E = mc^2$  which helped usher in the age of nuclear physics.

Physics is important to the study of industrial instrumentation because its laws describe and explain so many applications of measurement and control. As a teacher, one of the things I like to tell students is that their chosen field is really nothing more than applied physics. Granted, there aren’t too many applications of macroscopic projectile motion in industrial measurement and control, but on a microscopic level this is what all moving fluids are: an extremely large collection of independent molecules obeying Newtonian laws of motion. Physics is the study of *stuff*, while instrumentation is the discipline of measuring and controlling stuff. The better you understand stuff, the better you will be able to measure and control that stuff. Enjoy!

## 2.1 Terms and Definitions

*Mass* ( $m$ ) is the opposition an object has to acceleration (changes in velocity). *Weight* is the force ( $F$ ) imposed on a mass by a gravitational field. Mass is an intrinsic property of an object, regardless of the environment. Weight, on the other hand, depends on the strength of the gravitational field in which the object resides. A 20 kilogram slug of metal has the exact same mass whether it rests on Earth, or in the zero-gravity environment of outer space, or on the surface of the planet Jupiter. However, the *weight* of that mass depends on gravity: zero weight in outer space (where there is no gravity to act upon it), some weight on Earth, and a much greater amount of weight on the planet Jupiter (due to the much stronger gravitational field of that planet).

Since mass is the opposition of an object to changes in velocity (acceleration), it stands to reason force, mass, and acceleration for any particular object are directly related to one another:

$$F = ma$$

Where,

$F$  = Force in newtons (metric) or pounds (British)

$m$  = Mass in kilograms (metric) or slugs (British)

$a$  = Acceleration in meters per second squared (metric) or feet per second squared (British)

If the force in question is the weight of the object, then the acceleration ( $a$ ) in question is the acceleration constant of the gravitational field where the object resides. For Earth at sea level,  $a_{gravity}$  is approximately 9.81 meters per second squared, or 32.2 feet per second squared. Earth's gravitational acceleration constant is usually represented in equations by the variable letter  $g$  instead of the more generic  $a$ .

Since acceleration is nothing more than the rate of velocity change with respect to time, the force/mass equation may be expressed using the calculus notation of the first derivative:

$$F = m \frac{dv}{dt}$$

Where,

$F$  = Force in newtons (metric) or pounds (British)

$m$  = Mass in kilograms (metric) or slugs (British)

$v$  = Velocity in meters per second (metric) or feet per second (British)

$t$  = Time in seconds

Since velocity is nothing more than the rate of position change with respect to time, the force/mass equation may be expressed using the calculus notation of the second derivative (acceleration being the derivative of velocity, which in turn is the derivative of position):

$$F = m \frac{d^2x}{dt^2}$$

Where,

$F$  = Force in newtons (metric) or pounds (British)

$m$  = Mass in kilograms (metric) or slugs (British)

$x$  = Position in meters (metric) or feet (British)

$t$  = Time in seconds

*Mass density* ( $\rho$ ) for any substance is the proportion of mass to volume. *Weight density* ( $\gamma$ ) for any substance is the proportion of weight to volume.

Just as weight and mass are related to each other by gravitational acceleration, weight density and mass density are also related to each other by gravity:

$$F_{weight} = mg \quad \text{Weight and Mass}$$

$$\gamma = \rho g \quad \text{Weight density and Mass density}$$

## 2.2 Metric prefixes

## 2.3 Areas and volumes

*Area* refers to the size of two-dimensional surface. *Volume* refers to the size of a three-dimensional space. To put both these measures into context; the question of how much paint will be required to adequately cover a house is one of area, while the question of how much water will be required to fill a pond is one of volume.

Some units of measurement for area and volume are nothing more than compounded linear units. Ten *centimeters* is an expression of distance, while ten *square centimeters* ( $\text{cm}^2$ ) is an expression of area, and ten *cubic centimeters* ( $\text{cm}^3$ ) is an expression of volume. It is important to note that the modifiers “square” and “cubic” do not in any way imply the object in question is square or cubic in shape. It is perfectly reasonable to measure the area of a *circle*, for instance, using the unit of *square centimeters*.

Other units of spatial measurement are specific to area or to volume. The *acre*, for example, is a unit of area measurement developed for the purpose of quantifying the size of land plots, one acre being equivalent to 43560 square feet. An example of a unit specifically devoted to volume measurement is the *liter*, equivalent to 1000 cubic centimeters.

## 2.3.1 Common geometric shapes

**Triangle**

$$\text{Area } A = \frac{1}{2} b h$$

**Trapezoid**

$$\text{Area } A = \frac{1}{2} (b + B) h$$

**Rectangle**

$$\text{Perimeter } P = 2x + 2y$$

$$\text{Area } A = xy$$

**Rectangular solid**

$$\text{Surface area } A = 2xy + 2yz + 2xz$$

$$\text{Volume } V = xyz$$

**Circle**

$$\text{Circumference } C = \pi D = 2\pi r$$

$$\text{Area } A = \pi r^2$$

**Sphere**

$$\text{Surface area } A = 4\pi r^2$$

$$\text{Volume } V = \frac{4}{3} \pi r^3$$

**Right circular cylinder**

Surface area  $A = 2\pi r^2 + 2\pi rh$

Volume  $V = \pi r^2 h$

**Cone**

Surface area  $A = \pi r \sqrt{r^2 + h^2} + \pi r^2$

Volume  $V = \frac{1}{3} \pi r^2 h$

Note: the volume of any pyramid or cone is one-third the product of its height ( $h$ ) and the area of its base.

**Tetrahedron**

Volume  $V = \frac{1}{3} xyh$

## 2.4 Unit conversions and physical constants

Converting between disparate units of measurement is the bane of many science students. The problem is worse for students in the United States of America, who must work with British (“Customary”) units such as the pound, the foot, the gallon, etc. World-wide adoption of the metric system would go a long way toward alleviating this problem, but until then it is important for students to master the art of unit conversions<sup>1</sup>.

It is possible to convert from one unit of measurement to another by use of tables designed expressly for this purpose. Such tables usually have a column of units on the left-hand side and an identical row of units along the top, whereby one can look up the conversion factor to multiply by to convert from any listed unit to any other listed unit. While such tables are undeniably simple to use, they are practically impossible to memorize.

A better way to convert between different units is shown in the next subsection.

---

<sup>1</sup>An interesting point to make here is the United States did get something right when they designed their monetary system of dollars and cents. This is essentially a *metric* system of measurement, with 100 cents per dollar. The founders of the USA wisely decided to avoid the utterly confusing denominations of the British, with their pounds, pence, farthings, shillings, etc. The denominations of penny, dime, dollar, and eagle (\$10 gold coin) comprised a simple power-of-ten system for money. Credit goes to France for first adopting a metric system of general weights and measures as their national standard.

### 2.4.1 Unity fractions

An important principle in the physical sciences is to closely track all units of measurement when performing calculations of physical quantities. This practice is generally referred to as *dimensional analysis*. A brief example of dimensional analysis is shown here, used to analyze the simple formula  $P = IV$  which describes the amount of power dissipated by an electrical load ( $P$ ) given its current ( $I$ ) and voltage drop ( $V$ ):

$$P = IV$$

Substituting units of measurement for each variable in this formula (i.e. Watts for power, Amperes for current, and Volts for voltage), using bracket symbols to denote these as unit abbreviations rather than variables, we get this result:

$$[\text{Watts}] = [\text{Amperes}] \times [\text{Volts}] \quad \text{or} \quad [\text{W}] = [\text{A}][\text{V}]$$

If we happen to know that “watts” is equivalent to joules of energy dissipated per second, and that “amperes” is equivalent to coulombs of charge motion per second, and that “volts” is equivalent to joules of energy per coulomb of electrical charge, we may substitute these units of measurement into the formula and see that the unit of “coulomb” cancels just like identical variables in the numerator and denominator of multiplied fractions:

$$\left[ \frac{\text{Joules}}{\text{Seconds}} \right] = \left[ \frac{\text{Coulombs}}{\text{Seconds}} \right] \times \left[ \frac{\text{Joules}}{\text{Coulombs}} \right] \quad \text{or} \quad \left[ \frac{\text{J}}{\text{s}} \right] = \left[ \frac{\text{C}}{\text{s}} \right] \left[ \frac{\text{J}}{\text{C}} \right]$$

As it so happens, dimensional analysis may be employed in a similar manner to convert between different units of measurement via a technique I like to call *unity fractions*.

This technique involves setting up the original quantity as a fraction, then multiplying by a series of fractions having *physical* values of unity (1) so that by multiplication the original value does not change, but the units do. Let’s take for example the conversion of quarts into gallons, an example of a fluid volume conversion:

$$35 \text{ qt} = ??? \text{ gal}$$

Now, most people know there are four quarts in one gallon, and so it is tempting to simply divide the number 35 by four to arrive at the proper number of gallons. However, the purpose of this example is to show you how the technique of unity fractions works, not to get an answer to a problem.

To demonstrate the unity fraction technique, we will first write the original quantity as a fraction, in this case a fraction with 1 as the denominator:

$$\frac{35 \text{ qt}}{1}$$

Next, we will multiply this fraction by another fraction having a *physical* value of unity (1) so that we do not alter<sup>2</sup> the quantity. This means a fraction comprised of equal measures in the numerator and denominator, but having different units of measurement. This “unity” fraction must be arranged in such a way that the undesired unit cancels out and leaves only the desired unit(s) in the product. In this particular example, we wish to cancel out quarts and end up with gallons, so we must arrange a fraction consisting of quarts and gallons having equal quantities in numerator and denominator, such that quarts will cancel and gallons will remain:

$$\left(\frac{35 \text{ qt}}{1}\right) \left(\frac{1 \text{ gal}}{4 \text{ qt}}\right)$$

Now we see how the unit of “quarts” cancels from the numerator of the first fraction and the denominator of the second (“unity”) fraction, leaving only the unit of “gallons” left standing:

$$\left(\frac{35 \text{ ~~qt~~}}{1}\right) \left(\frac{1 \text{ gal}}{4 \text{ ~~qt~~}}\right) = 8.75 \text{ gal}$$

The reason this conversion technique is so powerful is it allows one to perform the largest range of unit conversions while memorizing the smallest possible set of conversion factors.

Here is a set of six equal volumes, each one expressed in a different unit of measurement:

$$1 \text{ gallon (gal)} = 231.0 \text{ cubic inches (in}^3\text{)} = 4 \text{ quarts (qt)} = 8 \text{ pints (pt)} = 128 \text{ fluid ounces (fl. oz.)} \\ = 3.7854 \text{ liters (l)}$$

Since all six of these quantities are physically equal, it is possible to build a “unity fraction” out of any two, to use in converting any of the represented volume units into any of the other represented volume units. Shown here are a few different volume unit conversion problems, using unity fractions built only from these factors (all canceled units shown using strike-out lines):

40 gallons converted into fluid ounces (using  $128 \text{ fl. oz.} = 1 \text{ gal}$  in the unity fraction):

$$\left(\frac{40 \text{ ~~gal~~}}{1}\right) \left(\frac{128 \text{ fl. oz.}}{1 \text{ ~~gal~~}}\right) = 5120 \text{ fl. oz}$$

5.5 pints converted into cubic inches (using  $231 \text{ in}^3 = 8 \text{ pt}$  in the unity fraction):

$$\left(\frac{5.5 \text{ ~~pt~~}}{1}\right) \left(\frac{231 \text{ in}^3}{8 \text{ ~~pt~~}}\right) = 158.8 \text{ in}^3$$

---

<sup>2</sup>A basic mathematical identity is that multiplication of any quantity by 1 does not change the value of that original quantity. If we multiply some quantity by a fraction having a physical value of 1, no matter how strange-looking that fraction may appear, the value of the original quantity will be left intact. The goal here is to judiciously choose a fraction with a physical value of 1 but with its units of measurement so arranged that we cancel out the original quantity’s unit(s) and replace them with the units we desire.

1170 liters converted into quarts:

$$\left(\frac{1170 \cancel{\text{L}}}{1}\right) \left(\frac{4 \text{ qt}}{3.7854 \cancel{\text{L}}}\right) = 1236 \text{ qt}$$

By contrast, if we were to try to memorize a  $6 \times 6$  table giving conversion factors between *any two* of six volume units, we would have to commit 30 different conversion factors to memory! Clearly, the ability to set up “unity fractions” is a much more memory-efficient and practical approach.

This economy of conversion factors is very useful, and may also be extended to cases where linear units are raised to powers to represent two- or three-dimensional quantities. To illustrate, suppose we wished to convert 5.5 pints into cubic *feet* instead of cubic *inches*: with no conversion equivalence between pints and cubic feet included in our string of six equalities, what do we do?

We should know the equality between inches and feet: there are exactly 12 inches in 1 foot. This simple fact may be applied by incorporating *another* unity fraction in the original problem to convert cubic inches into cubic feet. We will begin by including another unity fraction comprised of 12 inches and 1 foot, just to see how this might work:

5.5 pints converted into cubic feet (*our first attempt!*):

$$\left(\frac{5.5 \cancel{\text{pt}}}{1}\right) \left(\frac{231 \text{ in}^3}{8 \cancel{\text{pt}}}\right) \left(\frac{1 \text{ ft}}{12 \cancel{\text{in}}}\right) = 13.23 \text{ in}^2 \cdot \text{ft}$$

Unfortunately, this yields a non-sensical unit of square inch-feet. Even though  $\frac{1 \text{ ft}}{12 \text{ in}}$  is a valid unity fraction, it does not *completely* cancel out the unit of cubic inches in the numerator of the first unity fraction. Instead, the unit of “inches” in the denominator of the unity fraction merely cancels out one of the “inches” in the “cubic inches” of the previous fraction’s numerator, leaving square inches ( $\text{in}^2$ ). What we need for full cancellation of cubic inches is a unity fraction relating *cubic* feet to *cubic* inches. We can get this, though, simply by *cubing* the  $\frac{1 \text{ ft}}{12 \text{ in}}$  unity fraction:

5.5 pints converted into cubic feet (*our second attempt!*):

$$\left(\frac{5.5 \cancel{\text{pt}}}{1}\right) \left(\frac{231 \text{ in}^3}{8 \cancel{\text{pt}}}\right) \left(\frac{1 \text{ ft}}{12 \text{ in}}\right)^3$$

Distributing the third power to the interior terms of the last unity fraction:

$$\left(\frac{5.5 \cancel{\text{pt}}}{1}\right) \left(\frac{231 \text{ in}^3}{8 \cancel{\text{pt}}}\right) \left(\frac{1^3 \text{ ft}^3}{12^3 \cancel{\text{in}}^3}\right)$$

Calculating the values of  $1^3$  and  $12^3$  inside the last unity fraction, then canceling units and solving:

$$\left(\frac{5.5 \cancel{\text{pt}}}{1}\right) \left(\frac{231 \cancel{\text{in}}^3}{8 \cancel{\text{pt}}}\right) \left(\frac{1 \text{ ft}^3}{1728 \cancel{\text{in}}^3}\right) = 0.0919 \text{ ft}^3$$

Now the answer makes sense: a volume expressed in units of cubic feet.

Once again, this unit conversion technique shows its power by minimizing the number of conversion factors we must memorize. We need not memorize how many cubic inches are in a cubic foot, or how many square inches are in a square foot, if we know how many linear inches are in a linear foot and we simply let the fractions “tell” us whether a power is needed for unit cancellation.

Unity fractions are also useful when we need to convert more than one unit in a given quantity. For example, suppose a flowmeter at a wastewater treatment facility gave us a flow measurement of 205 cubic feet per minute but we needed to convert this expression of water flow into units of cubic yards per day. Observe the following unit-fraction conversion to see how unity fractions serve the purpose of converting cubic feet into cubic yards, and minutes into days (by way of minutes to hours, and hours to days):

$$\left(\frac{205 \text{ ft}^3}{\text{min}}\right) \left(\frac{1^3 \text{ yd}^3}{3^3 \text{ ft}^3}\right) \left(\frac{60 \text{ min}}{1 \text{ hr}}\right) \left(\frac{24 \text{ hr}}{1 \text{ day}}\right) = 10933.3 \text{ yd}^3/\text{day}$$

Note how the only units left un-canceled on the left-hand side of the “equals” symbol are cubic yards ( $\text{yd}^3$ ) and days, which therefore become the units of measurement for the final result.

A major caveat to this method of converting units is that the units must be *directly proportional* to one another, since this multiplicative conversion method is really nothing more than an exercise in mathematical proportions. Here are some examples (but not an exhaustive list!) of conversions that *cannot* be performed using the “unity fraction” method:

- Absolute / Gauge pressures, because one scale is *offset* from the other by 14.7 PSI (atmospheric pressure).
- Celsius / Fahrenheit, because one scale is *offset* from the other by 32 degrees.
- Wire diameter / gauge number, because gauge numbers grow smaller as wire diameter grows larger (inverse proportion rather than direct) and because there is no proportion relating the two.
- Power / decibels, because the relationship is logarithmic rather than proportional.

The following subsections give sets of physically equal quantities, which may be used to create unity fractions for unit conversion problems. Note that only those quantities shown in the same line (separated by = symbols) are truly equal to each other, not quantities appearing in different lines!

### 2.4.2 Conversion formulae for temperature

Note: all of the conversion factors given for temperature are *exact*, not approximations.

$$^{\circ}\text{F} = (^{\circ}\text{C})(9/5) + 32$$

$$^{\circ}\text{C} = (^{\circ}\text{F} - 32)(5/9)$$

$$^{\circ}\text{R} = ^{\circ}\text{F} + 459.67$$

$$\text{K} = ^{\circ}\text{C} + 273.15$$

### 2.4.3 Conversion factors for distance

Note: all of the conversion factors given for distance are *exact*, not approximations.

$$1 \text{ inch (in)} = 2.54 \text{ centimeters (cm)}$$

$$1 \text{ foot (ft)} = 12 \text{ inches (in)}$$

$$1 \text{ yard (yd)} = 3 \text{ feet (ft)}$$

$$1 \text{ mile (mi)} = 5280 \text{ feet (ft)}$$

### 2.4.4 Conversion factors for volume

Note: all conversion factors shown in **bold** type are *exact*, not approximations.

$$1 \text{ gallon (gal)} = 231.0 \text{ cubic inches (in}^3\text{)} = 4 \text{ quarts (qt)} = 8 \text{ pints (pt)} = 16 \text{ cups} = 128 \text{ fluid ounces (fl. oz.)} = 3.7854 \text{ liters (l)}$$

$$1 \text{ milliliter (ml)} = 1 \text{ cubic centimeter (cm}^3\text{)}$$

### 2.4.5 Conversion factors for velocity

Note: all conversion factors shown in **bold** type are *exact*, not approximations.

$$1 \text{ mile per hour (mi/h)} = 88 \text{ feet per minute (ft/m)} = 1.46667 \text{ feet per second (ft/s)} = 1.60934 \text{ kilometer per hour (km/h)} = 0.44704 \text{ meter per second (m/s)} = 0.868976 \text{ knot (knot - international)}$$

### 2.4.6 Conversion factors for mass

$$1 \text{ pound-mass (lbm)} = 0.4535924 \text{ kilogram (kg)} = 0.031081 \text{ slugs}$$

### 2.4.7 Conversion factors for force

$$1 \text{ pound-force (lbf)} = 4.448222 \text{ newtons (N)}$$

$$1 \text{ kilogram-force (kgf)} = 9.80665 \text{ newtons (N)}$$

### 2.4.8 Conversion factors for area

Note: all conversion factors shown in **bold** type are *exact*, not approximations.

$$1 \text{ acre} = 43560 \text{ square feet (ft}^2\text{)} = 4840 \text{ square yards (yd}^2\text{)} = 4046.86 \text{ square meters (m}^2\text{)}$$

### 2.4.9 Conversion factors for pressure (either all gauge or all absolute)

Note: all conversion factors shown in **bold** type are *exact*, not approximations.

1 pounds per square inch (PSI) = 2.03602 inches of mercury at 0 °C (in. Hg) = 27.6799 inches of water at 4 °C (in. W.C.) = 6.894757 kilopascals (kPa) = 0.06894757 bar

**1 bar = 100 kilopascals (kPa)** = 14.504 pounds per square inch (PSI)

**1 meter of water at 4 °C (m W.C.) = 9.80665 kilopascals (kPa)**

### 2.4.10 Conversion factors for pressure (absolute pressure units only)

Note: all conversion factors shown in **bold** type are *exact*, not approximations.

**1 standard atmosphere (Atm)** = 14.7 pounds per square inch absolute (PSIA) = **101.325 kilopascals absolute (kPaA)** = **1.01325 bar absolute** = 760 millimeters of mercury absolute (mmHgA) = 760 torr (torr)

### 2.4.11 Conversion factors for energy or work

1 British thermal unit (Btu – “International Table”) = 251.996 calories (cal – “International Table”) = 1055.06 joules (J) = 1055.06 watt-seconds (W-s) = 0.293071 watt-hour (W-hr) =  $1.05506 \times 10^{10}$  ergs (erg) = 778.169 foot-pound-force (ft-lbf)

### 2.4.12 Conversion factors for power

Note: all conversion factors shown in **bold** type are *exact*, not approximations.

**1 horsepower = 550 foot-pounds per second (ft-lbf/s)** = 745.7 watts (W) = 2544.43 British thermal units per hour (Btu/h) = 0.0760181 boiler horsepower (hp – boiler)

**2.4.13 Terrestrial constants**

Acceleration of gravity at sea level = 9.806650 meters per second per second ( $\text{m/s}^2$ ) = 32.1740 feet per second per second ( $\text{ft/s}^2$ )

Atmospheric pressure = 14.7 pounds per square inch absolute (PSIA) = 760 millimeters of mercury absolute (mmHgA) = 760 torr (torr) = 1.01325 bar (bar)

Atmospheric gas concentrations (by volume, not mass):

- Nitrogen = 78.084 %
- Oxygen = 20.946 %
- Argon = 0.934 %
- Carbon Dioxide ( $\text{CO}_2$ ) = 0.033 %
- Neon = 18.18 ppm
- Helium = 5.24 ppm
- Methane ( $\text{CH}_4$ ) = 2 ppm
- Krypton = 1.14 ppm
- Hydrogen = 0.5 ppm
- Nitrous Oxide ( $\text{N}_2\text{O}$ ) = 0.5 ppm
- Xenon = 0.087 ppm

Density of dry air at 20 °C and 760 torr =  $1.204 \text{ mg/cm}^3 = 1.204 \text{ kg/m}^3 = 0.075 \text{ lb/ft}^3 = 0.00235 \text{ slugs/ft}^3$

Absolute viscosity of dry air at 20 °C and 760 torr = 0.018 centipoise (cp) =  $1.8 \times 10^{-5}$  pascal-seconds (Pa·s)

**2.4.14 Properties of water**

Freezing point at sea level = 32 °F = 0 °C

Boiling point at sea level = 212 °F = 100 °C

Density of water at 4 °C =  $1000 \text{ kg/m}^3 = 1 \text{ g/cm}^3 = 1 \text{ kg/liter} = 62.428 \text{ lb/ft}^3 = 1.94 \text{ slugs/ft}^3$

Specific heat of water at 14 °C = 1.00002 calories/g·°C = 1 BTU/lb·°F = 4.1869 joules/g·°C

Specific heat of ice  $\approx 0.5$  calories/g·°C

Specific heat of steam  $\approx 0.48$  calories/g·°C

Absolute viscosity of water at 20 °C = 1.0019 centipoise (cp) = 0.0010019 pascal-seconds (Pa·s)

Surface tension of water (in contact with air) at 18 °C = 73.05 dynes/cm

pH of pure water at 25 °C = 7.0 (*pH scale = 0 to 14*)

### 2.4.15 Miscellaneous physical constants

Note: all constants shown in **bold** type are *exact*, not approximations. Parentheses show one standard deviation ( $\sigma$ ) of uncertainty in the last digits: for example, Avogadro's number given as  $6.02214179(30) \times 10^{23}$  means the center value ( $6.02214179 \times 10^{23}$ ) plus or minus  $0.00000030 \times 10^{23}$ .

Avogadro's number ( $N_A$ ) =  $6.02214179(30) \times 10^{23}$  per mole ( $\text{mol}^{-1}$ )

Boltzmann's constant ( $k$ ) =  $1.3806504(24) \times 10^{-23}$  joules per Kelvin (J/K)

Electronic charge ( $e$ ) =  $1.602176487(40) \times 10^{-19}$  Coulomb (C)

Faraday constant ( $F$ ) =  $9.64853399(24) \times 10^4$  Coulombs per mole (C/mol)

Gravitational constant ( $G$ ) =  $6.67428(67) \times 10^{-11}$  cubic meters per kilogram-seconds squared ( $\text{m}^3/\text{kg}\cdot\text{s}^2$ )

Molar gas constant ( $R$ ) =  $8.314472(15)$  joules per mole-Kelvin (J/mol-K) =  $0.08205746(14)$  liters-atmospheres per mole-Kelvin

Planck constant ( $h$ ) =  $6.62606896(33) \times 10^{-34}$  joule-seconds (J-s)

Stefan-Boltzmann constant ( $\sigma$ ) =  $5.670400(40) \times 10^{-8}$  Watts per square meter-Kelvin<sup>4</sup> ( $\text{W}/\text{m}^2\cdot\text{K}^4$ )

Speed of light in a vacuum ( $c$ ) = **299792458 meters per second** (m/s) = 186282.4 miles per second (mi/s)

All constants taken from NIST data "Fundamental Physical Constants – Extensive Listing", published 2006.

### 2.4.16 Weight densities of common materials

All density figures approximate for samples at standard temperature and pressure<sup>3</sup>.

#### Liquids:

- Acetone:  $\gamma = 49.4 \text{ lb/ft}^3$
- Alcohol, ethyl (ethanol):  $\gamma = 49.4 \text{ lb/ft}^3$
- Alcohol, methyl (methanol):  $\gamma = 50.5 \text{ lb/ft}^3$
- Benzene:  $\gamma = 56.1 \text{ lb/ft}^3$
- Butane (liquid):  $\gamma = 36.1 \text{ lb/ft}^3$
- Carbon disulfide:  $\gamma = 80.7 \text{ lb/ft}^3$
- Carbon tetrachloride:  $\gamma = 99.6 \text{ lb/ft}^3$
- Chloroform:  $\gamma = 93 \text{ lb/ft}^3$
- Ethylene glycol (ethanediol):  $\gamma = 69.22 \text{ lb/ft}^3$
- Gasoline:  $\gamma = 41 \text{ lb/ft}^3$  to  $43 \text{ lb/ft}^3$
- Glycerin:  $\gamma = 78.6 \text{ lb/ft}^3$
- Isobutane (liquid):  $\gamma = 34.8 \text{ lb/ft}^3$
- Kerosene:  $\gamma = 51.2 \text{ lb/ft}^3$
- Mercury:  $\gamma = 849 \text{ lb/ft}^3$
- Methanol (methyl alcohol):  $\gamma = 50.5 \text{ lb/ft}^3$
- Milk:  $\gamma = 64.2 \text{ lb/ft}^3$  to  $64.6 \text{ lb/ft}^3$
- Naphtha, petroleum:  $\gamma = 41.5 \text{ lb/ft}^3$
- Oil, castor:  $\gamma = 60.5 \text{ lb/ft}^3$
- Oil, coconut:  $\gamma = 57.7 \text{ lb/ft}^3$
- Oil, linseed (boiled):  $\gamma = 58.8 \text{ lb/ft}^3$
- Oil, olive:  $\gamma = 57.3 \text{ lb/ft}^3$
- Propane (liquid):  $\gamma = 31.2 \text{ lb/ft}^3$
- Toluene:  $\gamma = 54.1 \text{ lb/ft}^3$

---

<sup>3</sup>Density figures taken or derived from tables in the *CRC Handbook of Chemistry and Physics*, 64th Edition. Most liquid densities taken from table on page F-3 and solid densities taken from table on page F-1. Some liquid densities taken from tables on pages E-27 through E-31. All temperatures at or near 20 °C.

- Turpentine:  $\gamma = 54.3 \text{ lb/ft}^3$
- Water, heavy:  $\gamma = 68.97 \text{ lb/ft}^3$
- Water, light (normal):  $\gamma = 62.4 \text{ lb/ft}^3$
- Water, sea:  $\gamma = 63.99 \text{ lb/ft}^3$

**Solids:**

- Beryllium:  $\gamma = 115.37 \text{ lb/ft}^3$
- Brass:  $\gamma = 524.4 \text{ lb/ft}^3$
- Calcium:  $\gamma = 96.763 \text{ lb/ft}^3$
- Carbon (diamond):  $\gamma = 196.65 \text{ lb/ft}^3$  to  $220.37 \text{ lb/ft}^3$
- Cement (set):  $\gamma = 170 \text{ lb/ft}^3$  to  $190 \text{ lb/ft}^3$
- Chromium:  $\gamma = 448.86 \text{ lb/ft}^3$
- Copper:  $\gamma = 559.36 \text{ lb/ft}^3$
- Cork:  $\gamma = 14 \text{ lb/ft}^3$  to  $16 \text{ lb/ft}^3$
- Gold:  $\gamma = 1178.6 \text{ lb/ft}^3$
- Ice:  $\gamma = 57.2 \text{ lb/ft}^3$
- Iron:  $\gamma = 490.68 \text{ lb/ft}^3$
- Ivory:  $\gamma = 114 \text{ lb/ft}^3$  to  $120 \text{ lb/ft}^3$
- Lead:  $\gamma = 708.56 \text{ lb/ft}^3$
- Leather:  $\gamma = 54 \text{ lb/ft}^3$
- Magnesium:  $\gamma = 108.50 \text{ lb/ft}^3$
- Molybdenum:  $\gamma = 638.01 \text{ lb/ft}^3$
- Quartz:  $\gamma = 165 \text{ lb/ft}^3$
- Rubber (soft):  $\gamma = 69 \text{ lb/ft}^3$
- Rubber (hard):  $\gamma = 74 \text{ lb/ft}^3$
- Salt, rock:  $\gamma = 136 \text{ lb/ft}^3$
- Sugar:  $\gamma = 99 \text{ lb/ft}^3$
- Tar:  $\gamma = 66 \text{ lb/ft}^3$
- Wood, balsa:  $\gamma = 7 \text{ lb/ft}^3$  to  $9 \text{ lb/ft}^3$
- Wood, maple:  $\gamma = 39 \text{ lb/ft}^3$  to  $47 \text{ lb/ft}^3$

## 2.5 Dimensional analysis

An interesting parallel to the “unity fraction” unit conversion technique is something referred to in physics as *dimensional analysis*. Performing dimensional analysis on a physics formula means to set it up with units of measurement in place of variables, to see how units cancel and combine to form the appropriate unit(s) of measurement for the result.

For example, let’s take the familiar power formula used to calculate power in a simple DC electric circuit:

$$P = IV$$

Where,

$P$  = Power (watts)

$I$  = Current (amperes)

$V$  = Voltage (volts)

Each of the units of measurement in the above formula (watt, ampere, volt) are actually comprised of more fundamental physical units. One watt of power is one joule of energy transferred per second. One ampere of current is one coulomb of electric charge moving by per second. One volt of potential is one joule of energy per coulomb of electric charge. When we write the equation showing these units in their proper orientations, we see that the result (power in watts, or joules per second) actually does agree with the units for amperes and volts because the unit of electric charge (coulombs) cancels out. In dimensional analysis we customarily distinguish unit symbols from variables by using non-italicized letters and surrounding each one with square brackets:

$$P = IV$$

$$[\text{Watts}] = [\text{Amperes}] \times [\text{Volts}] \quad \text{or} \quad [\text{W}] = [\text{A}][\text{V}]$$

$$\left[ \frac{\text{Joules}}{\text{Seconds}} \right] = \left[ \frac{\text{Coulombs}}{\text{Seconds}} \right] \times \left[ \frac{\text{Joules}}{\text{Coulombs}} \right] \quad \text{or} \quad \left[ \frac{\text{J}}{\text{s}} \right] = \left[ \frac{\text{C}}{\text{s}} \right] \left[ \frac{\text{J}}{\text{C}} \right]$$

Dimensional analysis gives us a way to “check our work” when setting up new formulae for physics- and chemistry-type problems.

## 2.6 The International System of Units

The very purpose of physics is to quantitatively describe and explain the physical world in as few terms as possible. This principle extends to units of measurement as well, which is why we usually find different units used in science actually defined in terms of more fundamental units. The *watt*, for example, is one joule of energy transferred per second of time. The joule, in turn, is defined in terms of three base units, the kilogram, the meter, and the second:

$$[J] = \frac{[\text{kg}][\text{m}^2]}{[\text{s}^2]}$$

Within the metric system of measurements, an international standard exists for which units are considered fundamental and which are considered “derived” from the fundamental units. The modern standard is called *SI*, which stands for *Système International*. This standard recognizes seven fundamental, or *base* units, from which all others are derived<sup>4</sup>:

Physical quantity	SI unit	SI symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

An older standard existed for base units, in which the *centimeter*, *gram*, and *second* comprised the first three base units. This standard is referred to as the *cgs* system, in contrast to the SI system<sup>5</sup>. You will still encounter some derived cgs units used in instrumentation, including the *poise* and the *stokes* (both used to express fluid viscosity). Then of course we have the *British engineering system* which uses such wonderful<sup>6</sup> units as feet, pounds, and (thankfully) seconds. Despite the fact that the majority of the world uses the metric (SI) system for weights and measures, the British system is sometimes referred to as the *Customary* system.

---

<sup>4</sup>The only exception to this rule being units of measurement for angles, over which there has not yet been full agreement whether the unit of the *radian* (and its solid counterpart, the *steradian*) is a base unit or a derived unit.

<sup>5</sup>The older name for the SI system was “MKS,” representing meters, kilograms, and seconds.

<sup>6</sup>I’m noting my sarcasm here, just in case you are immune to my odd sense of humor.

## 2.7 Conservation Laws

The *Law of Mass Conservation* states that matter can neither be created nor destroyed. The *Law of Energy Conservation* states that energy can neither be created nor destroyed. However, both mass and energy may change forms, and even change into one another in the case of nuclear phenomena.

Conversion of mass into energy, or of energy into mass, is quantitatively described by Albert Einstein's famous equation:

$$E = mc^2$$

Where,

$E$  = Energy (joules)

$m$  = Mass (kilograms)

$c$  = Speed of light (approximately  $3 \times 10^8$  meters per second)

Conservation laws find practical context in many areas of science and life, but in the realm of process control we have the principles of *mass balance* and *energy balance* which are direct expressions of these Laws. "Mass balance" refers to the fact that the sum total of mass entering a process must equal the sum total of mass exiting the process, provided the process is in a steady-state condition (all variables remaining constant over time). To give a simple example of this, the mass flow rate of fluid entering a pipe *must* be equal to the mass flow rate of fluid exiting the pipe, provided the pipe is neither accumulating nor releasing mass within its internal volume. "Energy balance" is a parallel concept, stating that the sum total of energy entering a process must equal the sum total of energy exiting a process, provided a steady-state condition (no energy being stored or released from storage within the process).

## 2.8 Classical mechanics

Classical mechanics (often called *Newtonian* mechanics in honor of Isaac Newton) deal with forces and motions of objects in common circumstances. The vast majority of instrumentation applications deals with this realm of physics. Two other areas of physics, *relativistic* and *quantum*, will not be covered in this chapter because their domains lie outside the typical experience of industrial instrumentation<sup>7</sup>.

---

<sup>7</sup>Relativistic physics deals with phenomena arising as objects travel near the speed of light. Quantum physics deals with phenomena at the atomic level. Neither is germane to the vast majority of industrial instrument applications.

### 2.8.1 Newton's Laws of Motion

These laws were formulated by the great mathematician and physicist Isaac Newton (1642-1727). Much of Newton's thought was inspired by the work of an individual who died the same year Newton was born, Galileo Galilei (1564-1642).

1. An object at rest tends to stay at rest; an object in motion tends to stay in motion
2. The acceleration of an object is directly proportional to the net force acting upon it and inversely proportional to the object's mass
3. Forces between objects always exist in equal and opposite pairs

**Newton's first law** may be thought of as the *law of inertia*, because it describes the property of inertia that all objects having mass exhibit: resistance to change in velocity. This law is quite counter-intuitive for many people, who tend to believe that objects require continual force to keep moving. While this is true for objects experiencing friction, it is not for ideal (frictionless) motion. This is why satellites and other objects in space continue to travel with no mode of propulsion: they simply "coast" indefinitely on their own inertia because there is no friction in space to dissipate their kinetic energy and slow them down.

**Newton's second law** is the verbal equivalent of the force/mass/acceleration formula:  $F = ma$ . This law elaborates on the first, in that it mathematically relates force and motion in a very precise way. For a frictionless object, the *change in velocity* (i.e. its *acceleration*) is proportional to force. This is why a frictionless object may continue to move without any force applied: once moving, force would only be necessary for continued acceleration. If zero force is applied, the acceleration will likewise be zero, and the object will maintain its velocity indefinitely (again, assuming no friction at work).

**Newton's third law** describes how forces always exist in *pairs* between two objects. The rotating blades of a helicopter, for example, exert a downward force on the air (accelerating the air), but the air in turn exerts an upward force on the helicopter (suspending it in flight). A spider hanging on the end of a thread exerts a downward force (weight) on the thread, while the thread exerts an upward force of equal magnitude on the spider (tension). Force pairs are always equal in magnitude but opposite in direction.

### 2.8.2 Work, energy, and power

Two very fundamental and closely-related concepts in physics are *work* and *energy*. *Work* is simply what happens when any force acts through a parallel motion, such as when a weight is lifted against gravity or when a spring is compressed. *Energy* is a more abstract concept and therefore more difficult to define. One definition<sup>8</sup> of energy is “that which permits or results in motion,” where the word “motion” is used in a very broad sense including even the motion of individual atoms within a substance. Energy exists in many different forms, and may be transferred between objects and/or converted from one form to another, but cannot be created from nothing or be destroyed and turned into nothing (this is the *Law of Energy Conservation*). *Power* is the rate at which work is done, or alternatively the rate at which energy transfer occurs.

First, just a little bit of math. Work ( $W$ ) is mathematically defined as the dot-product of force ( $F$ ) and displacement ( $x$ ) vectors<sup>9</sup>, written as follows:

$$W = \vec{F} \cdot \vec{x}$$

Where,

$W$  = Work, in newton-meters (metric) or foot-pounds (British)

$\vec{F}$  = Force vector (force and direction exerted) doing the work, in newtons (metric) or pounds (British)

$\vec{x}$  = Displacement vector (distance and direction traveled) over which the work was done, in meters (metric) or feet (British)

---

<sup>8</sup>A common definition of energy is the “ability to do work” which is not always true. There are some forms of energy which may *not* be harnessed to do work, such as the thermal motion of molecules in an environment where all objects are at the same temperature. Energy that has the ability to do work is more specifically referred to as *exergy*. While energy is always conserved (i.e. never lost, never gained), exergy is a quantity that can never be gained but can be lost. The inevitable loss of exergy is closely related to the concept of *entropy*, where energy naturally diffuses into less useful (more homogeneous) forms over time. This important concept explains why no machine can never be perfectly (100.0%) efficient, among other things.

<sup>9</sup>A *vector* is a mathematical quantity possessing both a magnitude and a direction. Force ( $F$ ), displacement ( $x$ ), and velocity ( $v$ ) are all vector quantities. Some physical quantities such as temperature ( $T$ ), work ( $W$ ), and energy ( $E$ ) possess magnitude but no direction. We call these directionless quantities “scalar.” It would make no sense at all to speak of a temperature being “79 degrees Celsius due North” whereas it *would* make sense to speak of a force being “79 Newtons due North”. Physicists commonly use a little arrow symbol over the variable letter to represent that variable as a vector, when both magnitude and direction matter. Thus  $\vec{F}$  represents a force vector with both magnitude and direction specified, while plain  $F$  merely represents the magnitude of that force without a specified direction. A “dot-product” is one way in which vectors may be multiplied, and the result of a dot-product is always a scalar quantity.

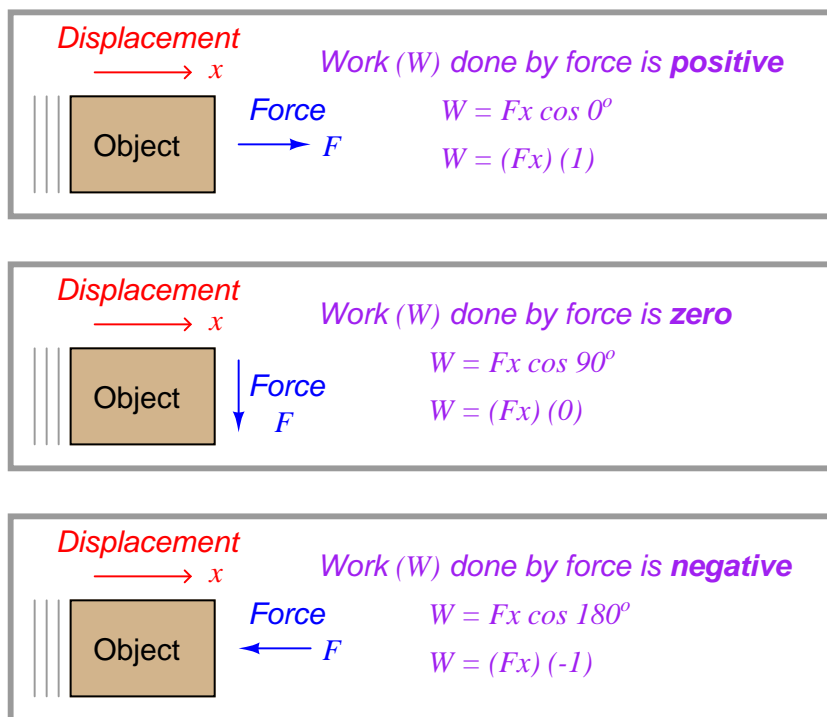

The fact that both force and displacement appear as *vectors* tells us their relative directions are significant to the calculation of work. If the force and displacement vectors point in exactly the same direction, work is simply the product of  $F$  and  $x$  magnitudes ( $W = Fx$ ). If the force and displacement vectors point in opposite directions, work is the *negative* product ( $W = -Fx$ ). Another way to express the calculation of work is as the product of the force and displacement magnitudes ( $F$  and  $x$ ) and the cosine of the angle separating the two force vectors ( $\cos \theta$ ):

$$W = Fx \cos \theta$$

When the two vectors  $\vec{F}$  and  $\vec{x}$  point the same direction, the angle  $\theta$  between them is zero and therefore  $W = Fx$  because  $\cos 0^\circ = 1$ . When the two vectors point in opposite directions, the angle between them is  $180^\circ$  and therefore  $W = -Fx$  because  $\cos 180^\circ = -1$ .

This means if a force acts in the same direction as a motion (i.e. force and displacement vectors pointing in the same direction), the work being done by that force will be a *positive* quantity. If a force acts in the opposite direction of a motion (i.e. force and displacement vectors pointing in opposite directions), the work done by that force will be a *negative* quantity. If a force acts perpendicularly to the direction of a motion (i.e. force and displacement vectors at right angles to each other), that force will do *zero* work.

Illustrations are helpful in explaining these concepts. Consider a crane hoisting a 2380 pound weight 15 feet up into the air by means of an attached cable:

**Crane does work on weight**  $W_{crane} = (2380 \text{ lb})(15 \text{ ft})(\cos 0^\circ) = +35700 \text{ ft-lbs}$   
**Work is done on the weight**  $W_{weight} = (2380 \text{ lb})(15 \text{ ft})(\cos 180^\circ) = -35700 \text{ ft-lbs}$

The amount of work done from the crane's perspective is  $W_{crane} = +35700 \text{ ft-lbs}$ , since the crane's force ( $F_{crane} = 2380 \text{ lbs}$ , up) points in the same upward direction as the cable's motion ( $x = 15 \text{ ft}$ , up) and therefore there is no angular difference between the crane force and motion vectors (i.e.  $\theta = 0$ ). The amount of work done from weight's perspective, however, is  $W_{weight} = -35700 \text{ ft-lbs}$  because the weight's force vector ( $F_{weight} = 2380 \text{ lbs}$ , down) points in the *opposite* direction as the cable's motion vector ( $x = 15 \text{ feet}$ , up), yielding an angular difference of  $\theta = 180^\circ$ . Another way of expressing these two work values is to state the crane's work in the active voice and the weight's work in the passive voice: *the crane did 35700 ft-lbs of work, while 35700 ft-lbs of work was done on the weight*. This language is truly appropriate, as the crane is indeed the *active* agent in this scenario, while the weight *passively opposes* the crane's efforts. In other words, the crane is the *motive source* of the work, while the weight is a *load*.

Now, how does *energy* fit into this illustration? Certainly we see that motion occurred, and therefore energy must have been involved. The energy lifting the 2380 pound weight 15 feet upward didn't come from nowhere – it must have been present somewhere in the universe prior to the weight's ascension if the Law of Energy Conservation is indeed true. If the crane is powered by an internal combustion engine, the energy came from the fuel stored in the crane's fuel tank. If the crane is electric, the energy to hoist the weight came from a battery or from an electrical generator somewhere sending power to the crane through an electric cable. The act of lifting the weight was actually an act of *energy transfer* from the crane's energy source, through the crane motor and cable, and finally to the weight. Along the way, some of the initial energy was also converted into heat through inefficiencies in the crane's motor and mechanism. However, if we were to calculate the sum of all the energy transferred to the lifted weight plus all energy "dissipated" in the form of heat, that total must be precisely equal to the initial energy of the fuel (or electricity) used by the crane in doing this lift. In other words, the sum total of all energy in the universe is the same after the lift as it was before the lift.

*Power* applies in this scenario to how *quickly* the weight rises. So far, all we know about the weight's lifting is that it took 35700 ft-lbs of energy to do that work. If we knew how long it took

the crane to do that work, we could calculate the crane's power output. For example, a crane with a power rating of 35700 ft-lbs per second could complete this 15-foot lift in only one second of time. Likewise, a crane with a power rating of only 3570 ft-lbs per second would require 10 seconds of time to execute the same lift.

An interesting thing happens if the crane moves sideways along the ground after lifting the weight 15 feet up into the air. No work is being done by the crane on the weight, or by the weight on the crane, because the displacement vector is now perpendicular ( $\theta = 90^\circ$ ) to both force vectors:

**No work done on or by the crane  $W_{crane} = (2380 \text{ lb})(15 \text{ ft})(\cos 90^\circ) = 0 \text{ ft-lbs}$**

**No work done on or by the weight  $W_{weight} = (2380 \text{ lb})(15 \text{ ft})(\cos -90^\circ) = 0 \text{ ft-lbs}$**

It should be noted that the crane's engine *will* do work as it overcomes rolling friction in the wheels to move the crane along, *but this is not work done on or by the hoisted weight*. When we calculate work – as with all other calculations in physics – we must be very careful to keep in mind where the calculation(s) apply in the scenario. Here, the forces and displacement with regard to the hoisted weight are perpendicular to each other, and therefore no work is being done there. The only work done anywhere in this system as the crane rolls 15 feet horizontally involves the horizontal force required to roll the crane, which is unspecified in this illustration.

Similarly, there is no transfer of energy to or from the hoisted weight while the crane rolls along. Whatever energy comes through the crane's engine only goes into overcoming rolling friction at the wheels and ground, not to do any work with the weight itself. Generally this will be a very small amount of energy compared to the energy required to hoist a heavy load.

A good question to ask after hoisting the weight is “Where did that 35700 ft-lbs of energy go after the lift was complete?” The Law of Energy Conservation tells us that energy cannot be destroyed, and so the 35700 ft-lbs of work must be accounted for somehow. In this case, the energy is now *stored* in the weight where it may be released at some later time. We may demonstrate this fact by slowly lowering the weight back down to the ground and watching the energy transfer:

**Work is done on the crane**  $W_{crane} = (2380 \text{ lb})(15 \text{ ft})(\cos 180^\circ) = -35700 \text{ ft-lbs}$

**Weight does work on crane**  $W_{weight} = (2380 \text{ lb})(15 \text{ ft})(\cos 0^\circ) = +35700 \text{ ft-lbs}$

Notice how the weight is now the actively-working object in the system, doing work on the crane. The crane is now the passive element, opposing the work being done by the weight. Both the crane and the weight are still pulling the same directions as before (crane pulling up, weight pulling down), but now the direction of displacement is going down which means the weight is “winning” and therefore doing the work, while the crane is “losing” and opposing the work.

If we examine what is happening inside the crane as the weight descends, we see that energy is being transferred from the descending weight to the crane. In most cranes, the descent of a load is controlled by a *brake* mechanism, regulating the speed of descent by applying friction to the cable’s motion. This brake friction generates a great deal of heat, which is a form of energy transfer: energy stored in the elevated weight is now being converted into heat which exits the crane in the form of hot air (air whose molecules are now vibrating at a faster speed than they were at their previous temperature). If the crane is electric, we have the option of *regenerative braking* where we recapture this energy instead of dissipating it in the form of heat. This works by switching the crane’s electric motor into an electric generator on demand, so the weight’s descent turns the motor/generator shaft to generate electricity to re-charge the crane’s battery or be injected back into the electric power grid to do useful work elsewhere.

Referring back to the illustration of the crane hoisting the weight, it is clear that the weight stored energy while it was being lifted up by the crane, and released this energy back to the crane while it was being lowered down to the ground. The energy held by the elevated weight may therefore be characterized as *potential energy*, since it had the *potential* to do work even if no work was being done by that energy at that moment.

A special version of the general work formula  $W = \vec{F} \cdot \vec{x}$  exists for calculating this *gravitational potential energy*. Rather than express force and displacement as vectors with arbitrary directions, we express the weight of the object as the product of its mass and the acceleration of gravity ( $F = mg$ ) and the vertical displacement of the object simply as its height above the ground ( $x = h$ ). The amount of potential energy stored in the lift is simply equal to the work done during the lift ( $W = E_P$ ):

$$E_p = mgh$$

Where,

$E_p$  = Gravitational potential energy in newton-meters (metric) or foot-pounds (British)

$m$  = Mass of object in kilograms (metric) or slugs (British)

$g$  = Acceleration of gravity in meters per second squared (metric) or feet per second squared (British)

$h$  = Height of lift in meters (metric) or feet (British)

There is no need for vectors or cosine functions in the  $E_p = mgh$  formula, because gravity and height are always guaranteed to act along the same axis. A positive height (i.e. *above* ground level) is assumed to yield a positive potential energy value for the elevated mass.

Many different forms of potential energy exist, although the standard “textbook” example is of a mass lifted to some height against the force of gravity. Compressed (or stretched) springs have potential energy, as do pressurized fluids, chemical bonds (e.g. fuel molecules prior to combustion), hot masses, electrically-charged capacitors, and magnetized inductors. Any form of energy with the potential to be released into a different form at some later time is, by definition, *potential* energy.

An important application of work, energy, and power is found in *rotational* motion. Consider the application of a truck towing some load by a rope. The truck exerts a linear (i.e. straight-line) pulling force on the load being towed, but it must do so by applying a *rotary* (i.e. turning) force through the axle shaft powering the drive wheels:

Clearly, the truck *does work* on the load by exerting a pulling force in the direction of motion. If we wish to quantify this work, we may consider the work done by the truck as it tows the load a distance of 40 feet:

$$W_{truck} = Fx \cos \theta$$

$$W_{truck} = (1200 \text{ lb})(40 \text{ ft}) \cos 0^\circ$$

$$W_{truck} = 48000 \text{ lb-ft}$$

It should also be clear that *work is being done on* the load, since the load's force on the tow rope points in the opposite direction of its motion:

$$W_{load} = Fx \cos \theta$$

$$W_{load} = (1200 \text{ lb})(40 \text{ ft}) \cos 180^\circ$$

$$W_{load} = -48000 \text{ lb-ft}$$

For the sake of this example, it matters not what happens to the energy delivered to the load. Perhaps it gets converted to heat through the mechanism of friction at the load (e.g. friction from road contact, friction from wind resistance), perhaps it gets converted into potential energy in the case of the road inclining to a greater altitude, or perhaps (most likely) it is some combination of all these.

In order to quantify this amount of work from the perspective of the truck's rotating wheel, we must cast the variables of pulling force and pulling distance into rotary terms. We will begin by first examining the distance traveled by the wheel. Any circular wheel has a radius, and the wheel must turn a certain number of revolutions in order to pull the load any distance. The obvious function of a wheel is to convert between linear and rotary motion, and the common measure between these two motions is the *circumference* of the wheel: each revolution of the wheel equates directly to one circumference's worth of linear travel. In our truck example, the wheel has a radius of 1.5 feet, which means it must have a circumference of 9.425 feet (i.e.  $2 \times \pi \times 1.5$  feet, since  $C = \pi D = 2\pi r$ ). Therefore, in order to travel 40 linear feet this wheel must rotate 4.244 times (i.e.  $40 \text{ feet} \div 9.425 \text{ feet/revolution} = 4.244 \text{ revolutions}$ ).

Next, we must relate pulling force to rotational force. The 1200 pounds of pulling force exerted by the wheel<sup>10</sup> originates from the twisting force exerted by the axle at the wheel's center. The technical term for this twisting force is *torque* (symbolized by the Greek letter "tau",  $\tau$ ), and it is a function of both the linear pulling force and the wheel's radius:

$$\tau = rF$$

Solving for torque ( $\tau$ ) in this application, we calculate 1800 pound-feet given the wheel's linear pulling force of 1200 pounds and a radius of 1.5 feet. Please note that the unit of "pound-feet" for torque is *not* the same as the unit of "foot-pounds" for work. Work is the product of force and displacement (distance of motion), while torque is the product of force and radius length. Work requires motion, while torque does not<sup>11</sup>.

The torque value of 1800 lb-ft and the turning of 4.244 revolutions should be sufficient to calculate work done by the wheel, since torque equates directly to pulling force and the number of revolutions equates directly to pulling distance. It should be obvious that the product of 1800 lb-ft and 4.244 revolutions does not, however, equal 48000 ft-lbs of work, and so our torque-revolutions-work formula must contain an additional multiplication factor  $k$ :

$$W = k\tau x$$

Substituting 48000 ft-lbs for work ( $W$ ), 1800 lb-ft for torque ( $\tau$ ), and 4.244 for the number of revolutions ( $x$ ), we find that  $k$  must be equal to 6.283, or  $2\pi$ . Knowing the value for  $k$ , we may re-write our rotational work formula more precisely:

$$W = 2\pi\tau x$$

This formula is correct no matter the wheel's size. A larger-radius wheel will certainly travel farther for each revolution, but that larger radius will proportionately reduce the pulling force for any given amount of torque, resulting in an unchanged work value.

---

<sup>10</sup>Note that this calculation will assume all the work of towing this load is being performed by a *single* wheel on the truck. Most likely this will not be the case, as most towing vehicles have multiple driving wheels (at least two). However, we will perform calculations for a single wheel in order to simplify the problem.

<sup>11</sup>Consider the example of applying torque to a stubbornly seized bolt using a wrench: the force applied to the wrench multiplied by the radius length from the bolt's center to the perpendicular line of force yields torque, but absolutely no work is done on the bolt until the bolt begins to move (turn).

Applying this work formula to another application, let us consider an electric *winch* where a load is lifted against the force of gravity. A “winch” is a mechanism comprised of a tubular drum and cable, the cable wrapping or unwrapping around the drum as the drum is turned by an electric motor. For comparison we will use the same weight and lifting distance of the crane example, merely replacing the crane with a winch located atop a tower. In this case we will make the winch drum 3 inches in diameter, and calculate both the torque required to rotate the drum as well as the number of rotations necessary to lift the weight 15 feet:

***Winch lifts weight 15 feet up***

From the crane example we already know the amount of work which must be done on the weight to hoist it 15 feet vertically:  $35700 \text{ ft}\cdot\text{lbs}$ . Our rotational work formula ( $W = 2\pi\tau x$ ) contains *two* unknowns at this point in time, since we know the value of  $W$  but not  $\tau$  or  $x$ . This means we cannot yet solve for either  $\tau$  or  $x$  using this formula. If we also knew the value of  $\tau$  we could solve for  $x$  and vice-versa, which means we must find some other way to solve for one of those unknowns.

A drum radius of 3 inches is equivalent to 0.25 feet, and since we know the relationship between radius, force, and torque we may solve for torque in that manner:

$$\tau = rF$$

$$\tau = (0.25 \text{ ft})(2380 \text{ lb})$$

$$\tau = 595 \text{ lb}\cdot\text{ft}$$

Now that we have a value for  $\tau$  we may substitute it into the rotational work formula to solve for the number of necessary drum rotations:

$$W = 2\pi\tau x$$

$$x = \frac{W}{2\pi\tau}$$

$$x = \frac{35700 \text{ ft}\cdot\text{lb}}{(2\pi)(595 \text{ lb}\cdot\text{ft})}$$

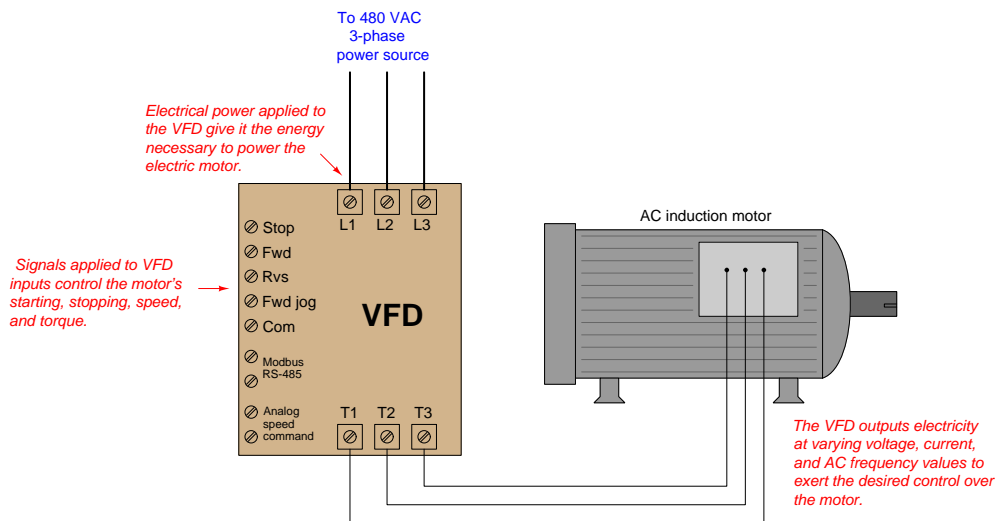

$$x = 9.549 \text{ revolutions}$$

As always, energy is conserved in this electric winch system just as it is in any other system. The 35700 foot-pounds of energy invested in the gravitational potential energy of the weight had to originate from somewhere, which in the case of an electric winch is the electrical power source feeding the winch motor. If that winch motor were allowed to turn in reverse and act as a generator, it would convert the descending weight's loss in potential energy into electrical power to be returned to the source, whether that source be a rechargeable battery or an electrical power “grid” with other electrical loads that may use that energy.

The same, of course, is true for the tow truck example. The energy expended in towing the load must come from somewhere, and in the case of a combustion-type truck engine that source is the fuel powering the engine. For electric vehicles, the energy source is a rechargeable battery, and the reversible nature of electric motors means the vehicle may use its drive motor as a generator to “brake” (slow down), returning the vehicle's kinetic energy into electrical energy to recharge the battery for later use. This is why all-electric and hybrid-electric vehicles are remarkably efficient in stop-and-go traffic conditions: they utilize their drive motors as *regenerative brakes* to recover the vehicle's kinetic energy rather than dissipating that same energy in the form of heat using friction-based brake mechanisms.

Many applications exist within the industrial world for rotational work and electric motors. Conveyor belts, pumps, fans, compressors, and a host of other mechanisms may be powered via electric motors, the speed and torque of those electric motors controlled using electronic circuits called *motor drives*. Alternating-current (AC) electric motors are controlled by electronic devices called *Variable Frequency Drives*, or *VFDs*, which achieve precise speed control by varying the frequency of the AC power feeding the motor, and achieve precise torque control by varying the voltage and current feeding the motor. VFDs are very important “final control” devices used in a wide variety of industrial control systems.

Sophisticated VFDs control regeneration as well (i.e. using the motor as a generator to “brake” a rotating machine), allowing energy to be applied to and then extracted from the same mechanism.

Potential energy is an important principle not just in the study of physics, but also for workplace safety. When large amounts of potential energy are released, the effects may be hazardous to personnel and/or destructive to equipment. An industrial maintenance procedure known as *lock-out, tag-out* requires that all potential energy sources on a system must either be exhausted or otherwise secured to that there will be negligible risk to maintenance personnel as they perform work on a system. The most common way to ensure this is to place a padlock on each energy-disconnect device (e.g. switch, valve, etc.) to secure its position so that potential energy cannot be released in a hazardous or destructive way. Each maintenance worker places a padlock on that disconnect device to prevent its actuation, and also places a tag on the device explaining when and why it was secured. Each and every person performing work on the system must use their own personal padlock, so that the system cannot be re-activated without the active consent of all persons working on that system.

An efficient strategy for safely locking out a large number of safety-disconnect devices on a system with multiple personal locks is to use a sheet-metal box containing a numbered padlock (with matching key) for each energy-flow device to be secured on the equipment, as well as a list identifying which lock goes on which energy-flow device. Each energy-disconnect device is placed in the safe position and then locked in that position with a dedicated padlock. After that, all the padlock keys are placed back inside the sheet-metal box. The lid of this box is then shut and secured with a multi-lock device, permitting multiple peoples' personal locks to be applied so the lid cannot be opened unless *all* personal locks are removed from it:

None of the energy-securing devices may be altered unless *all* personal locks have been removed from the lock box, thereby ensuring the safety of all persons working on the system.

Procedures created and maintained at the worksite will identify the energy-flow devices in need of securing prior to commencement of work on a piece of equipment. These procedures are literally life-saving documents, as they ensure no energy-securing device is overlooked by personnel doing work on the equipment or system.

A photograph of such a document – appropriately titled an “Energy Control Procedure” – shows the steps mandated to secure all potential energy sources prior to commencing work on a large industrial engine. This procedure also serves to document which locks were used to secure which energy flow devices during the procedure, as well as who performed the procedure:

Energy Control Procedure			
Revision Number & Date one 7/23/2009			
Ingersol Rand KVS 412 Minor maintenance			
Items to be completed before proceeding			
Initial all steps			
	1	Only qualified \authorized employees are allowed to complete this task.	
	2	Verify equipment has not changed before relying on this procedure	
	3	Redline and update any changes & notify effected employee if required	
	4	Notify all effected employees before starting	
	5	Notify Gas Control	
	6	If the crane is to be used complete crane inspection	
	7	Complete all required documentation	
	8	Identify required forms, Use updated forms	
	9	Hot Work Permit WGP- 0059 Procedure 65.0020.05	
	10	Crane pre use inspection. Form Attachment A Procedure 65.00.08.06	
	11	Drawing ##### Not available at this time	
Date & Time		7-28-11 10:00 a.m.	
Authorized Technician		Theresa Colas	
Scope of work		Spark plug wires expansion inlet	
Out of Service			
Step	Initials	Lock #	Task
1	JB	1	Tag out unit mode switch in off position
2	JB	2	Close starting air block valve. Lock and tag.
3	JB	3	Close fuel block valve. Lock and tag.
Return to Service			
Step	Initials	Lock # off	Task
1			Remove tag from unit mode switch. Place switch in local manual
2			Remove lock from starting air block valve open valve.
3			Remove tag from fuel block valve open valve
4			Reset unit panel alarms
5			Place unit panel selector switch in remote auto.
Affected employee log			
Lock	On	Off	Name
1	10:00		Theresa Colas
2	10:40		Theresa Colas
3		12:40	Theresa Colas

Note the particular lock-out steps required in this procedure: switching the control mode to the “off” position and tagging it, closing the fuel gas valve supplying fuel to the engine and locking/tagging it, and finally closing the valve supplying high-pressure air for engine starting and locking/tagging it. The closure of the starting air valve prevents the engine from being pneumatically turned while personnel are performing work on it. The closure of the fuel gas valve eliminates hazards resulting from the pressure of the fuel gas as well as its chemical energy (i.e. fire hazard) and/or biological threats (poisoning or asphyxiation). Note also how this procedure lists steps of notification to be taken prior to locking or tagging anything on the engine, as well as any other procedures possibly necessary (e.g. inspecting the maintenance crane if that will be needed for work on the engine).

The following is a set of incomplete lists of various energy-securing devices and energy sources which may be “locked out” for maintenance on a larger system:

**Electrical energy**

- Circuit breaker (locked in “off” position, also “racked out” if possible)
- Grounding switch (locked in “on” position to positively ground power conductors)
- Power cord (plastic cap locked onto plug, covering prongs)

**Mechanical energy**

- Block valve (locked in “shut” position) to prevent pressurized fluid motion
- Flange blind (installed in line) to prevent pressurized fluid motion
- Vent valve (locked in “open” position) to prevent fluid pressure buildup
- Mechanical clutch (disengaged, and locked in that position) to prevent prime mover from moving something
- Mechanical coupling (disassembled, and locked in that state) to prevent prime mover from moving something
- Mechanical brake (engaged, and locked in that position) to prevent motion
- Mechanical locking pin (inserted, and held in position by a padlock) to prevent motion
- Raised masses lowered to ground level, with lifting machines locked out

**Chemical energy**

- Block valve (locked in “shut” position) to prevent chemical fluid entry
- Vent valve (locked in “open” position) to prevent chemical fluid pressure buildup
- Ventilation fan (locked in “run” state) to prevent chemical vapor buildup

With all these preventive measures, the hope is that no form of potential energy great enough to pose danger may be accidentally released.

Let us return to the crane illustration to explore another concept called *kinetic energy*. As you might guess by the word “kinetic,” this form of energy exists when an object is in the process of *moving*. Let’s imagine the crane lifting the 2380 pound weight 15 feet up into the air, and then the cable snapping apart so that the weight free-falls back to the ground:

The Conservation of Energy still (and always!) holds true: all the potential energy stored in the elevated weight must be accounted for, even when it free-falls. What happens, of course, is that the weight accelerates toward the ground at the rate determined by Earth’s gravity: 32.2 feet per second per second ( $32.2\text{ ft/s}^2$ ). As the weight loses height, its potential energy decreases according to the gravitational potential energy formula ( $E_p = mgh$ ), but since we know energy cannot simply disappear we must conclude it is taking some other form. This “other form” is based on the weight’s *velocity* ( $v$ ), and is calculated by the kinetic energy formula:

$$E_k = \frac{1}{2}mv^2$$

Where,

$E_k$  = Kinetic energy in joules or newton-meters (metric), or foot-pounds (British)

$m$  = Mass of object in kilograms (metric) or slugs (British)

$v$  = Velocity of mass in meters per second (metric) or feet per second (British)

Thus, the Conservation of Energy explains why a falling object must fall faster as it loses height: kinetic energy must increase by the same amount that potential energy decreases, if energy is to be conserved. A very small amount of this falling weight’s potential energy will be dissipated in the form of heat (as air molecules are disturbed) rather than get converted into kinetic energy. However, the vast majority of the initial 35700 ft-lbs of potential energy gets converted into kinetic energy, until the weight’s energy is all kinetic and no potential the moment it first touches the ground.

When the weight finally slams into the ground, all that (nearly 35700 ft-lbs) of kinetic energy once again gets converted into other forms. Compression of the soil upon impact converts much of the energy into heat (molecular vibrations). Chunks of soil ejected from the impact zone possess their own kinetic energy, carrying that energy to other locations where they slam into other stationary objects. Sound waves rippling through the air also convey energy away from the point of impact. All in all, the 35700 ft-lbs of potential energy which turned into (nearly) 35700 ft-lbs of kinetic energy at ground level becomes dispersed.

The Law of Energy Conservation is extremely useful in projectile mechanics problems, where we typically assume a projectile loses no energy and gains no energy in its flight. The velocity of a projectile, therefore, depends on its height above the ground, because the sum of potential and kinetic energies must remain constant:

$$E_p + E_k = \text{constant}$$

As a projectile rises in altitude (i.e. its gravitational potential energy increases), its velocity must slow down (i.e. its kinetic energy decreases) in order that its total energy remain the same in accordance with the Law of Energy Conservation.

In free-fall problems, where the only source of energy for a projectile is its initial height, the initial potential energy must be equal to the final kinetic energy:

$$E_p \text{ (initial)} = E_k \text{ (final)}$$

$$mgh_i = \frac{1}{2}mv_f^2$$

We can see from this equation that mass cancels out of both sides, leaving us with this simpler form:

$$gh_i = \frac{1}{2}v_f^2$$

It also leads to the paradoxical conclusion that the mass of a free-falling object is irrelevant to its velocity. That is, both a heavy object and a light object in free fall hit the ground with the same velocity, and fall for the same amount of time, if released from the same height under the influence of the same gravity<sup>12</sup>.

---

<sup>12</sup>In practice, we usually see heavy objects fall faster than light objects due to the resistance of air. Energy losses due to air friction nullify our assumption of constant total energy during free-fall. Energy lost due to air friction never translates to velocity, and so the heavier object ends up hitting the ground faster (and sooner) because it had much more energy than the light object did to start.

Dimensional analysis confirms the common nature of energy whether in the form of potential, kinetic, or even mass (as described by Einstein's equation). First, we will set these three energy equations next to each other for comparison of their variables:

$$E_p = mgh \quad \text{Potential energy due to elevation}$$

$$E_k = \frac{1}{2}mv^2 \quad \text{Kinetic energy due to velocity}$$

$$E = mc^2 \quad \text{Mass-to-energy conversion}$$

Next, we will dimensionally analyze them using standard SI metric units (kilogram, meter, second). Following the SI convention, mass ( $m$ ) is always expressed in kilograms [kg], distance ( $h$ ) in meters [m], and time ( $t$ ) in seconds [s]. This means velocity ( $v$ , or  $c$  for the speed of light) in the SI system will be expressed in meters per second [m/s] and acceleration ( $a$ , or  $g$  for gravitational acceleration) in meters per second squared [m/s<sup>2</sup>]:

$$\frac{[\text{kg}][\text{m}^2]}{[\text{s}^2]} = [\text{kg}] \left[ \frac{\text{m}}{\text{s}^2} \right] [\text{m}] \quad \text{Potential energy due to elevation}$$

$$\frac{[\text{kg}][\text{m}^2]}{[\text{s}^2]} = [\text{kg}] \left[ \frac{\text{m}}{\text{s}} \right]^2 \quad \text{Kinetic energy due to velocity}$$

$$\frac{[\text{kg}][\text{m}^2]}{[\text{s}^2]} = [\text{kg}] \left[ \frac{\text{m}}{\text{s}} \right]^2 \quad \text{Mass-to-energy conversion}$$

In all three cases, the unit for energy is the same: kilogram-meter squared per second squared. This is the fundamental definition of a “joule” of energy (also equal to a “newton-meter” of energy), and it is the same result given by all three formulae.

*Power* is defined as the rate at which work is being done, or the rate at which energy is transferred. Mathematically expressed, power is the first time-derivative of work ( $W$ ):

$$P = \frac{dW}{dt}$$

The metric unit of measurement for power is the *watt*, defined as one joule of work performed per second of time. The British unit of measurement for power is the *horsepower*, defined as 550 foot-pounds of work performed per second of time.

Although the term “power” is often colloquially used as a synonym for force or strength, it is in fact a very different concept. A “powerful” machine is not necessarily a machine capable of doing a great amount of work, but rather (more precisely) a great amount of work *in a short amount of time*. Even a “weak” machine is capable of doing a great amount of work given sufficient time to complete the task. The “power” of any machine is the measure of *how rapidly* it may perform work.

### 2.8.3 Mechanical springs

Many instruments make use of springs to translate force into motion, or vice-versa. The basic “Ohm’s Law” equation for a mechanical spring relating applied force to spring motion (displacement) is called *Hooke’s Law*<sup>13</sup>:

$$F = -kx$$

Where,

$F$  = Force generated by the spring in newtons (metric) or pounds (British)

$k$  = Constant of elasticity, or “spring constant” in newtons per meter (metric) or pounds per foot (British)

$x$  = Displacement of spring in meters (metric) or feet (British)

Hooke’s Law is a linear function, just like Ohm’s Law is a linear function: doubling the displacement (either tension or compression) doubles the spring’s force. At least this is how springs behave when they are displaced a small percentage of their total length. If you stretch or compress a spring more substantially, the spring’s material will become strained beyond its elastic limit and either yield (permanently deform) or fail (break).

The amount of potential energy stored in a tensed spring may be predicted using calculus. We know that potential energy stored in a spring is the same as the amount of work done on the spring, and work is equal to the product of force and displacement (assuming parallel lines of action for both):

$$E_p = Fx$$

Thus, the amount of work done on a spring is the force applied to the spring ( $F = kx$ ) multiplied by the displacement ( $x$ ). The problem is, the force applied to a spring varies with displacement and therefore is not constant as we compress or stretch the spring. A mathematician would say that the spring’s force *is a function of*  $x$  because the force varies as  $x$  varies. Thus, in order to calculate the amount of potential energy stored in the spring ( $E_p = Fx$ ), we must calculate the amount of energy stored over infinitesimal amounts of displacement ( $F dx$ , or  $kx dx$ ) and then add those bits of energy up ( $\int$ ) to arrive at a total:

$$E_p = \int kx dx$$

---

<sup>13</sup>Hooke’s Law may be written as  $F = kx$  without the negative sign, in which case the force ( $F$ ) is the force *applied* on the spring from an external source. Here, the negative sign represents the spring’s reaction force to being displaced (the *restoring* force). A spring’s reaction force always opposes the direction of displacement: compress a spring, and it pushes back on you; stretch a spring, and it pulls back. A negative sign is the mathematically symbolic way of expressing the opposing direction of a vector.

We may evaluate this integral using the power rule ( $x$  is raised to the power of 1 in the integrand):

$$E_p = \frac{1}{2}kx^2 + E_0$$

Where,

$E_p$  = Energy stored in the spring in joules (metric) or foot-pounds (British)

$k$  = Constant of elasticity, or “spring constant” in newtons per meter (metric) or pounds per foot (British)

$x$  = Displacement of spring in meters (metric) or feet (British)

$E_0$  = The constant of integration, representing the amount of energy initially stored in the spring prior to our displacement of it

For example, if we take a very large spring with a constant  $k$  equal to 60 pounds per foot and displace it by 4 feet, we will store 480 foot-pounds of potential energy in that spring (i.e. we will do 480 foot-pounds of work on the spring).

Graphing the force-displacement function on a graph yields a straight line (as we would expect, because Hooke’s Law is a linear function). The area accumulated underneath this line from 0 feet to 4 feet represents the integration of that function over the interval of 0 to 4 feet, and thus the amount of potential energy stored in the spring:

Note how the geometric interpretation of the shaded area on the graph exactly equals the result predicted by the equation  $E_p = \frac{1}{2}kx^2$ : the area of a triangle is one-half times the base times the height. One-half times 4 feet times 240 pounds is 480 foot-pounds.

### 2.8.4 Rotational motion

Rotational motion may be quantified in terms directly analogous to linear motion, using different symbols and units.

The rotational equivalent of linear *force* ( $F$ ) is *torque* ( $\tau$ ). Linear force and rotational torque are both vector quantities, mathematically related to one another by the radial distance separating the force vector from the centerline of rotation. To illustrate with a string pulling on the circumference of a wheel:

This relationship may be expressed mathematically as a *vector cross-product*, where the vector directions are shown by the *right-hand rule* (the first vector  $\vec{r}$  is the direction of the index finger, the second vector  $\vec{F}$  is the direction of the middle finger, and the product vector  $\vec{\tau}$  is the direction of the thumb, with all three vectors perpendicular to each other):

$$\vec{\tau} = \vec{r} \times \vec{F}$$

Labeling force, radius, and torque as vectors is the formally correct way of noting the variables in a mechanical system such as this, and is the way college students studying physics typically learn the calculation of torque. In less academic settings, the force vector ( $\vec{F}$ ) is typically labeled as a force along the *line of action*, and the radius vector ( $\vec{r}$ ) is called the *moment arm*, with the line of action and moment arm always being perpendicular to each other.

The proper unit of measurement for torque is the product of the force unit and distance unit. In the metric system, this is customarily the *Newton-meter* (N-m). In the British system, this is customarily the *foot-pound* (ft-lb) or alternatively the *pound-foot* (lb-ft). Note that while these are the exact same *units* as those used to express work, they are not the same types of *quantities*. Torque is a vector cross-product, while work is a *dot-product* ( $W = \vec{F} \cdot \vec{x}$ ). The cross-product of two vectors

is always another vector<sup>14</sup>, while the dot-product of two vectors is always a scalar (direction-less) quantity. Thus, torque always has a direction, whereas work or energy does not.

An example calculation applied to a hand wrench turning a bolt appears here:

With the radius and force vectors at right angles to each other, torque is simply the product of both. In many non-academic settings, torque is calculated this way as a scalar quantity, with the direction of rotation determined by observation rather than by strict adherence to the right-hand rule of vector cross products. In this example, we see the magnitude of torque as the simple product of 58 pounds force and 0.61 feet of moment arm (35.38 lb-ft of torque), with the torque direction obviously counter-clockwise as viewed from the head of the bolt.

<sup>14</sup>Technically, it is a *pseudovector*, because it does not exhibit all the same properties of a true vector, but this is a mathematical abstraction far beyond the scope of this book!

If we apply the same force to the wrench handle at a different angle (not perpendicular to the handle), the resulting torque will be less. The radius vector (moment arm), however, will still remain perpendicular to the force vector (line of action) – it just decreases in length. To determine the placement of the radius vector, all one must do is draw a line straight from the axis of rotation perpendicular to the line of action, then use trigonometry to calculate its magnitude:

A very practical example of torque is in the action of meshing gears, transferring mechanical power from one gear to another. Each gear effectively acts as a wheel, the point of contact between gear teeth acting to transfer force perpendicular to the radius of each gear (wheel). Thus, torque applied to one gear becomes a linear force at the meshing teeth, which translates into another torque at the second gear:

The ratio of torques between two meshing gears is equal to the ratio of gear teeth:

$$\frac{\tau_1}{\tau_2} = \frac{n_1}{n_2}$$

Where,

$\tau_1$  = Torque of first gear

$\tau_2$  = Torque of second gear

$n_1$  = Number of teeth on first gear

$n_2$  = Number of teeth on second gear

For example, if a small gear having 28 teeth meshes with a larger gear having 75 teeth, the torque multiplication factor from the small gear to the large gear will be 75:28, or 2.679 to 1. A torque of 40 lb-ft applied to the small gear will result in a torque of 107.1 lb-ft or torque generated at the large gear. This ratio of gear teeth is called the *gear ratio*.

As gears multiply torque ( $\tau$ ), they divide rotational speed ( $\omega$ ). Thus, the 75:28 tooth gear set creates a multiplication of torque from the small gear to the large gear, and an identical *reduction ratio* of speed from the small gear to the large gear. Given this ratio, the small gear will have to be turned 2.679 revolutions in order to make the large gear turn just one revolution.

We may express gear speeds as another ratio of gear teeth, reciprocated in relation to torque:

$$\frac{\omega_1}{\omega_2} = \frac{n_2}{n_1}$$

Where,

$\omega_1$  = Rotational speed of first gear

$\omega_2$  = Rotational speed of second gear

$n_1$  = Number of teeth on first gear

$n_2$  = Number of teeth on second gear

In a set of meshed gears, the smaller gear will have the least torque and the greatest speed; the larger gear will have the greatest torque and the least speed.

This is precisely how gear sets are used in industry: to transform torque and speed in mechanical power systems. The complementary effects of a gear set on torque and speed is analogous to the complementary effects that a transformer has on AC voltage and current: a *step-up transformer* (having more turns of wire in the secondary coil than in the primary coil) will multiply voltage but reduce (divide) current, both by the same turns ratio.

Every quantity of force and motion which may be expressed in linear form has a rotational equivalent. As we have seen, torque ( $\tau$ ) is the rotational equivalent of force ( $F$ ). The following table contrasts equivalent quantities for linear and rotational motion (all units are metric, shown in *italic* font):

Linear quantity, symbol, and unit	Rotational quantity, symbol, and unit
Force ( $F$ ) <i>N</i>	Torque ( $\tau$ ) <i>N-m</i>
Linear displacement ( $x$ ) <i>m</i>	Angular displacement ( $\theta$ ) <i>radian</i>
Linear velocity ( $v$ ) <i>m/s</i>	Angular velocity ( $\omega$ ) <i>rad/s</i>
Linear acceleration ( $a$ ) <i>m/s<sup>2</sup></i>	Angular acceleration ( $\alpha$ ) <i>rad/s<sup>2</sup></i>
Mass ( $m$ ) <i>kg</i>	Moment of Inertia ( $I$ ) <i>kg-m<sup>2</sup></i>

Familiar equations for linear motion have rotational equivalents as well. For example, Newton's Second Law of motion states, "The acceleration of an object is directly proportional to the net force acting upon it and inversely proportional to the object's mass." We may modify this law for rotational motion by saying, "The angular acceleration of an object is directly proportional to the net torque acting upon it and inversely proportional to the object's moment of inertia." The mathematical expressions of both forms of Newton's Second Law are as follows:

$$F = ma \qquad \tau = I\alpha$$

The calculus-based relationships between displacement ( $x$ ), velocity ( $v$ ), and acceleration ( $a$ ) find parallels in the world of angular motion as well. Consider the following formula pairs, linear motion on the left and angular motion on the right:

$$v = \frac{dx}{dt} \quad (\text{Velocity as the time-derivative of displacement}) \quad \omega = \frac{d\theta}{dt}$$

$$a = \frac{dv}{dt} \quad (\text{Acceleration as the time-derivative of velocity}) \quad \alpha = \frac{d\omega}{dt}$$

$$a = \frac{d^2x}{dt^2} \quad (\text{Acceleration as the second time-derivative of displacement}) \quad \alpha = \frac{d^2\theta}{dt^2}$$

An object's “moment of inertia” represents its angular inertia (opposition to changes in rotational velocity), and is proportional to the object's mass and to the square of its radius. Two objects having the same mass will have different moments of inertia if there is a difference in the distribution of their mass relative to radius. Thus, a hollow tube will have a greater moment of inertia than a solid rod of equal mass, assuming an axis of rotation in the center of the tube/rod length:

This is why *flywheels*<sup>15</sup> are designed to be as wide as possible, to maximize their moment of inertia with a minimum of total mass.

The formula describing the amount of work done by a torque acting over an angular displacement is remarkably similar to the formula describing the amount of work done by a force acting over a linear displacement:

$$W = Fx \qquad W = \tau\theta$$

The formula describing the amount of kinetic energy possessed by a spinning object is also similar to the formula describing the amount of energy possessed by a linearly-traveling object:

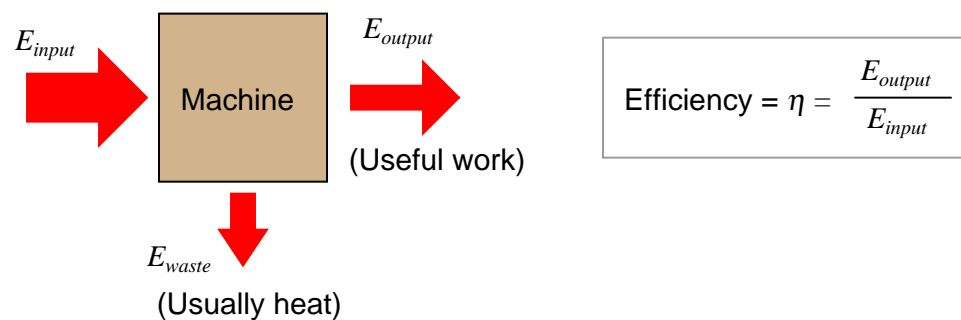

$$E_k = \frac{1}{2}mv^2 \qquad E_k = \frac{1}{2}I\omega^2$$

<sup>15</sup>A “flywheel” is a disk on a shaft, designed to maintain rotary motion in the absence of a motivating torque for the function of machines such as piston engines. The rotational kinetic energy stored by an engine's flywheel is necessary to give the pistons energy to compress the gas prior to the power stroke, during the times the other pistons are not producing power.

## 2.9 Simple machines

A *machine* in the broad sense of the word is any device designed to translate some form of energy into useful work. A “simple” machine is one where both the input energy and the output energy are mechanical in nature (i.e. both are forces acting along displacements). Examples of simple machines include levers, pulleys, ramps, wedges, gears, and chain/sprockets. More complex machines include such examples as electric motors, heat engines, pumps, compressors, and refrigerators.

The *efficiency* of any machine (symbolized by the Greek letter “eta”  $\eta$ ) is defined as the ratio of output energy to input energy:

Ideally, these two will be equal, with all of the input energy translated losslessly into output energy. However, no machine is perfectly efficient although some simple machines come very close to achieving 100% efficiency. It is physically impossible to achieve an energy efficiency greater than 100%, as that would violate the Law of Energy Conservation.

### 2.9.1 Levers

Perhaps the most basic type of machine is the *lever*: a rigid beam pivoting on an axis. This axis may be something as simple as a round cylinder, a pointed wedge, or even a sophisticated bearing. In any case, the general term for the pivot point on a lever is *fulcrum*:

If we look at the lever's motion at each end, we see that the distance the “output” end moves is a function of how far the “input” end moves as well as the ratio of lengths from each end to the fulcrum. Showing examples using three different classes of lever, each one with an  $\frac{8}{3}$  length ratio:

The ratio of output force to input force ( $\frac{F_{out}}{F_{in}}$ ) is called the *mechanical advantage*<sup>16</sup> of the machine. This ratio is always the reciprocal of the output versus input *motion*: if the output of the lever moves less than the input moves, the output force must be greater than the input force, and vice-versa. This makes perfect sense if you view a lever as a perfectly efficient machine where the output energy (work) must equal the input energy (work): since output energy is output force multiplied by output motion, and input energy is input force multiplied by input motion, in order for force to be multiplied, motion must be diminished.

Levers abound in everyday life. A shovel, for example, functions as either a first-class lever or a second-class lever, depending on its use. In either case, it is being used as a force multiplier, the trade-off being that the person must move the handle a farther distance than the rock moves, thus exchanging motion for force:

<sup>16</sup>Technically, mechanical advantage should be defined by the ratio of input *motion* to output *motion*, rather than being defined in terms of *force*. The reason for this is if friction happens to exist in the machine, it will cause a degradation of force but not of motion. Since “mechanical advantage” is supposed to represent the ideal ratio of the machine, it is always safest to define it in terms of motion where friction will not affect the calculation. For a frictionless machine, however, defining mechanical advantage in terms of force is perfectly legitimate, and in fact makes more intuitive sense, since a larger mechanical advantage always corresponds with force multiplication from input to output.

### 2.9.2 Pulleys

Another simple and useful machine is a *pulley* and rope. A “pulley” is nothing more than a wheel with a groove cut around its circumference to guide a rope or cable, a bearing and axle supporting the wheel and allowing it to freely turn. A single pulley hung from an overhead support has the ability to convert downward motion of a rope into upward motion to hoist a load:

A single-pulley system such as this exhibits no mechanical advantage, because  $F_{out} = F_{in}$ . If we get creative with multiple pulleys, however, we can achieve a mechanical advantage sufficient to hoist very heavy loads with modest input force:

Here, the weight is being supported by the tension within *two* ropes, not just one rope. Since the person’s force on the rope is what generates the rope’s tension,  $F_{in}$  is equal to rope tension, while  $F_{out}$  is equal to twice the rope’s tension. Thus, this simple machine has a mechanical advantage equal to 2. It also means the person’s motion while pulling the rope will be exactly *twice* the motion of the hoisted weight. Remember that we cannot cheat the Law of Energy Conservation: work

in cannot be less than work out. If the output force is twice as much as the input force due to mechanical advantage, the output motion can only be *half* as much as the input motion.

The mechanical advantage of a pulley system may be extended beyond two by adding even more pulleys. This pulley system has a mechanical advantage of 4, since the weight is being supported by the tension of *four* ropes, while the person pulling only feels the tension of a single rope:

Here is where one must be careful in analyzing pulley systems with regard to mechanical advantage. The mechanical advantage in each of these examples was based on the number of ropes supporting the weight. So far, this also happened to equal the number of pulleys in the system. Lest anyone be tempted to determine mechanical advantage by simply counting pulleys, here is an example that breaks the pattern:

Here there is only one pulley in the system, yet the weight is being supported by the tension in *two* ropes and the person pulling on the rope only feels the tension of one rope, which means the system has a mechanical advantage of 2.

This simple technology is commonly used on cranes to provide huge amounts of lifting force with modest amounts of cable tension. In this photograph you can see the multiple pulleys and lifting cable of a large industrial crane:

### 2.9.3 Inclined planes

A *wedge*, also referred to as an *inclined plane*, is another type of simple machine. A large enough wedge such as a ramp is useful for producing a mechanical advantage to lift a weight equipped with wheels. Instead of hoisting the weight vertically, the weight is rolled up the diagonal incline of the ramp:

In moving the heavy weight a short distance vertically, the person pushes with much less force over a longer distance. The mechanical advantage of this ramp, therefore, is equal to the ratio of the ramp's diagonal length (hypotenuse side) to its vertical height (opposite side). From the perspective of angle  $\theta$  shown in the illustration, this equates to the *cosecant* function ( $\csc \theta = \frac{\text{hypotenuse}}{\text{opposite}}$ ).

Another example of an inclined plane is a *screw conveyor* or *auger*, shown in the following photograph. The “fins” on the screw function as a long incline, wrapped around a central shaft:

Placed inside of a pipe and turned slowly, this simple machine moves semi-solid material linearly through the pipe.

In a similar fashion, this electric valve actuator uses the principle of an inclined plane to raise and lower a heavy gate to control the flow of wastewater through channels at a municipal wastewater treatment facility. The long threaded shaft pulls upward on the heavy gate (not shown), moved by the turning action of a nut engaged with the shaft's threads. The electric motor inside the blue-colored actuator turns the nut on command, raising or lowering the gate as needed:

### 2.9.4 Gears

A *gear set* is another type of simple machine, part of a whole class of simple machines converting one form of rotary motion into another forms of rotary motion. A set of *spur gears* are shown here:

Each gear rotates about a central axis (usually a rotating shaft), the teeth of each gear cut into shapes designed to smoothly “mesh” together as the gears rotate. Gears may be thought of as levers, with the radius of each gear equivalent to the distance between the fulcrum and the force point on a level. The gear with the largest radius turns the slowest, and with the most torque<sup>17</sup>.

The mechanical advantage of a gear set is simply the ratio of gear diameters. Another way to determine gear ratios is to count the number of teeth on each gear: since the teeth are all cut to the same size so as to smoothly mesh, the ratio of gear teeth will be proportional to the ratio of gear circumferences, which in turn must be proportional to the ratio of gear radii. If a gear set may be turned by hand, a simple counting of turns from input to output will also allow you to calculate the gear ratio. For example, if you turn one gear 15 revolutions to get the second gear to turn 4 revolutions, the mechanical advantage is  $\frac{15}{4}$ , or 3.75. As with levers, the gear that turns the farthest does so with less force (torque), and vice-versa. All simple machines work by trading motion for force, so that an increase in one necessarily results in a decrease of the other.

<sup>17</sup>“Torque” is to rotational motion as “force” is to linear motion. Mathematically, torque ( $\tau$ ) is defined as the cross-product of force acting on a radius ( $\vec{\tau} = \vec{r} \times \vec{F}$ ).

A variety of spur gear designs appears on this page. In this illustration<sup>18</sup>, we see an external spur gear set with straight-cut teeth, perhaps the simplest style of gear:

Next, we see variations on this design where the gear teeth are cut at angles instead of being parallel with the gears' shafts. This causes the meshing of the gear teeth to be smoother and quieter, but also causes a *thrust* force to develop along the axis of the gear shaft, since the teeth act as inclined planes. A “double” helical gear pattern (also known as a *herringbone* gear due to its resemblance to a fish skeleton) cancels any thrust force by angling the teeth in opposite angles. Herringbone gear sets are quiet and strong, but tend to be more expensive to manufacture than single-helical gears:

---

<sup>18</sup>I am indebted to NASA for this and the rest of the black-and-white gear illustrations found in this section. All these illustrations were taken from NASA technical reports on gearing.

The exposed gear sets commonly found in antique machinery provide excellent visual examples of gear designs. This next photograph shows sets of external spur gears. The upper photograph shows a pair of meshing spur gears with parallel teeth, while the lower photograph shows a set of four meshing spur gears with single-helical teeth, both sets of gears found on antique gasoline engines:

Another style of gear set is called *planetary*, because its shape resembles circular orbits of planets around a star. Planetary gear sets are exceptionally strong, and are capable of delivering multiple gear ratios depending on which gear (the “sun” gear, the “ring” gear, or the “planet” gears) is being held stationary, which gear is the input, and which gear is the output. If any two sets of gears are locked together such that they rotate at the same speed, the third gear in a planetary mechanism must also rotate at that same speed, for a 1:1 ratio. Typically, the planet gears are all anchored in their respective positions by a rotating frame called a *carrier*:

The particular planetary gear set shown in the above illustration uses two sets of helical gears (much like a herringbone design, only with two single-helical gears placed back-to-back instead of one gear with double-helical teeth) in order to eliminate thrust forces on the shafts.

Planetary gear sets are the standard type of gears used in automatic transmissions for automobiles. Different gear ratios (e.g. “Low”, “Drive”, “Overdrive”) are achieved in an automatic transmission by selecting which gears in a planetary gear set are input, output, and stationary. A series of clutches engage and disengage shafts to control which gears are input versus output, while a series of bands act as brakes to hold different gears stationary in the planetary gear set. These clutches and bands are all operated by hydraulic oil pressure inside the transmission, controlled either by a series of hydraulic relays and/or by an electronic computer telling the transmission when to shift.

The Synergy<sup>TM</sup> gear drive system designed by Toyota for use in its line of hybrid gasoline-electric cars is a unique application of planetary gears. In the first-generation Toyota Prius, an electric motor/generator (“MG1”) is coupled to the sun gear, the internal-combustion (gasoline) engine is coupled to the planet carrier, and the driveshaft is coupled to the ring gear (as well as a second electric motor/generator “MG2”). This planetary gear set allows power to be transferred smoothly and with great flexibility between the engine, the motor/generator, and the driveshaft. Motor/generator MG1 functions as a kind of variable brake (in “generator” mode, passing its power

to either the battery or to MG2) to slow down the sun gear to achieve an infinite number of effective gear ratios for the engine, and the gasoline engine may also be locked to keep the planet gear carrier from turning during all-electric operation.

With a simple set of parallel-shaft spur gears, the ratio of the gear set is simply the ratio of gear teeth (or of effective diameters). For example, if a spur gear set has 15 teeth on the driving gear ( $N_{driving} = 15$ ) and 45 teeth on the driven gear ( $N_{driven} = 45$ ), the gear ratio will be a 45:15 or 3:1 reduction in speed (multiplication in torque). Planetary gear sets are more complicated than this, as shown by the following table:

Condition	Slow	Fast	Ratio ( $x : 1$ )
Ring gear held stationary	Planet carrier	Sun	$\frac{N_r}{N_s} + 1$
Sun gear held stationary	Planet carrier	Ring	$\frac{N_s}{N_r} + 1$
Planet carrier held stationary	Ring	Sun	$-\frac{N_r}{N_s}$
Any two locked together	—	—	1

It is interesting to note that the only gear teeth (diameters) values factoring into these ratio calculations belong to the ring and sun gears. The negative sign for the stationary-carrier condition refers to the reversed rotation of the ring gear compared to the sun gear.

As always, one should strive to *understand* rather than memorize when learning anything new, and planetary gear set ratios are no exception to this rule. An excellent exercise is to mentally visualize each of the conditions listed in the table above, applied to a graphic image of a planetary gear<sup>19</sup> set. Run a series of “thought experiments” on the gear set, where you imagine one of the three pieces being held stationary while one of the free pieces is turned. Ask yourself whether the third piece turns faster or slower than the other free piece. Then, imagine the sun gear growing or shrinking in size, and ask yourself how this change in sun gear size affects the speed ratio:

<sup>19</sup>Here, each gear is shown simply as a toothless wheel for the sake of simplicity. Truth be told, your humble author has difficulty drawing realistic gear teeth!

A variety of gear set designs with perpendicular shafts exist to transfer mechanical power around corners. First, we see a *crossed helical spur gear*. Like parallel-shaft helical spur gears, crossed helical gears generate thrust forces due to the action of the gear teeth as inclined planes:

Next we see a *bevel gear* or *miter gear* set, where a *pinion* gear intersects with a *ring* gear to transfer mechanical power through perpendicular shafts. The left-hand illustration shows a *straight-toothed* bevel gear set, while the right-hand illustration shows a *spiral-toothed* bevel gear set.

These two styles of bevel gears are analogous to the straight- versus helical- toothed variants of the spur gear, with similar characteristics: spiral-toothed bevel gears provide smoother and quieter operation than straight-toothed bevel gears, but at the expense of generating large thrust forces on the pinion gear shaft, and radial forces on the ring gear shaft.

An interesting variation on the bevel gear concept is the *hypoid gear* system, where the two shaft axes do not intersect. In this gear set, the gear teeth actually rub against each other rather than merely touch, necessitating special lubricant to tolerate the dynamic pressures and stresses. Hypoid gear sets are exceptionally strong and quiet-running, and became popular for automotive axle drive systems because they allowed the driveshaft (attached to the pinion gear) to be lower than the axles (attached to the ring gear), providing more floor space in the vehicle. The non-intersecting shaft centerlines also make it possible to place support bearings on both ends of the pinion gear for extra strength, as seen in heavy-duty truck axle designs:

A photograph of a hypoid gear set inside the differential of an automobile is shown here, the differential housing cover removed for inspection:

An important type of gear set used for perpendicular-shaft applications with large speed-reduction ratios is the *worm gear*. A worm gear resembles a screw whose threads engage with matching helical-cut threads on another gear called a *worm wheel*:

***Worm gear mechanism***

An interesting and useful feature of a worm gear set is that power transfer occurs easily from the worm screw to the worm wheel, but not so easily from the worm wheel to the worm screw due to friction between the teeth of the two gears. This means when the worm screw is not being turned by an outside force, even small amounts of friction between the screw threads and wheel teeth will effectively “lock” the worm wheel in place such that it cannot turn when an outside force acts on it. A practical example of a worm gear exploiting this feature is a hand-crank winch, where we desire the winch drum to remain locked in position when we let go of the hand-crank.

Another interesting feature of worm gears is that the gear ratio is simply the number of teeth on the worm wheel, since the tooth pitch on the circumference of the worm wheel defines what the thread pitch *must* be on the worm screw. For example, a worm wheel having 40 teeth around its circumference will exhibit a 40:1 speed-reduction ratio regardless of worm screw size, since there is only one worm screw thread pitch that will engage with the teeth on this worm wheel.

A real worm gear assembly may be seen in this next photograph, as one component of an antique farm implement. Here, a hand-wheel turns the work screw, which then turns the worm wheel and either lifts or drops the height of the implement's blade:

The “one-way” action of a worm gear is advantageous in this application, so that the hand wheel does not spin on its own every time the implement’s blade encounters uneven ground. Wherever the hand wheel is set to adjust blade height, that blade height remains fixed until the hand wheel is turned to some new position.

It should be noted that modern worm gear sets, like nearly all types of gears, are more commonly found encased in a housings where they operate in a lubricated environment, sealed from contamination by dust and other matter both solid and liquid. Exposed gears are more commonly seen on antique machinery, where the mechanical stresses were low enough (i.e. low torque forces, large gears) to permit reliable operation of gears with the only lubrication typically being a coat of heavy grease smeared over the gear teeth.

As with other types of simple machines, gear sets may be combined into larger assemblies, with the over-all mechanical advantage (i.e. gear ratio) being the product of all individual gear ratios in the system. An example of a compound gear train is this helicopter transmission, designed to reduce the high-speed shaft rotation of the helicopter's turbine engine down to a speed more suitable for the main rotor:

Mechanical shaft power flows from the turbine shaft (usually several thousand RPM) to the rotor (a few hundred RPM) in this transmission via several types of gears. First, the turbine shaft's speed is reduced through multiple sets of bevel gear operating in parallel (from the "driving spur pinion" gear to the "face gears"). These multiple face gears then couple to a "combining" gear through a spur gear reduction. This combining gear then feeds power to a central "sun" gear in a planetary gear train. The "ring" gear of this planetary set is fixed to the case of the transmission so that it does not turn. Finally, four "planet" gears running in a common carrier assembly drive the helicopter's rotor.

The following photograph shows a modern “gearbox” used to decrease the rotational speed of an electric motor, to turn an auger feeding grain out of a storage bin at a beer brewery. Like all modern gear sets, the gears inside this gearbox operate in a continuously-lubricated environment, sealed to prevent contaminants such as dust and water from entering:

A very large gearbox is shown in this next photograph, used in the head of a Vestas wind turbine to “step up” the slow rotational speed of the turbine to the much higher rotational speed of the electric generator. Planetary gears are used in wind turbine gearboxes due to their ruggedness and relatively compact size:

The ratio of this wind turbine’s gear set happens to be 111.5:1, with the generator turning 111.5 times faster than the turbine blades (but with only  $\frac{1}{111.5}$  the torque of the turbine blades, of course)!

### 2.9.5 Belt drives

A *sheave* is very similar in form and function to a pulley, but designed to grip a flexible *belt* rather than a rope or a cable. Unlike a pulley which is designed to turn freely to re-direct the tension of a rope, a sheave works more like a gear to couple the belt's motion to a rotating shaft. The mechanical advantage of a pair of sheaves coupled by a common belt is simply the ratio of sheave radii, just like gears:

The following photograph shows a triple-belt drive from an electric motor to an agitator on the bottom of a sawdust storage bin:

As indicated by the respective sheave diameters, the electric motor turns much faster than the agitator, while the agitator spins with much greater torque than the motor.

Most modern belt drives are either *V-belt* or *toothed belt*, referring to the shapes of the belt and how they engage with the sheave. The triple-belt drive system for the sawdust agitator shown in the previous photograph used V-belts. A V-belt has a V-shaped cross-section, and sits in a V-shaped groove around the circumference of the sheave. Toothed belts almost resemble chains, in that their inner surface is characterized by regularly-spaced perpendicular ribs designed to engage with matching cavities machined into the circumference of the sheave. The advantage of a toothed belt is that it cannot slip on the sheave if overloaded, unlike a V-belt. A toothed belt is firmly “locked” into place on the sheave’s circumference so long as proper belt tension is maintained.

An older belt-and-sheave technology is the *flat belt*. Here, the sheave’s circumference is flat, and the belt itself is nothing more than a strip of flexible material with no special shape. The following photograph shows an antique flat belt drive in a workshop, where a central shaft ran along the ridge of the ceiling to power several machines in the shop, the shaft itself turned continuously by either a water turbine or a steam engine:

Flat belts are still used in modern times, but they tend to be much wider than V-belts or toothed belts of comparable rating in order to deliver adequate “grip” on the sheave. Also, sheave-to-sheave alignment is much more critical for a flat belt, which has no guides on the sheave to keep it centered<sup>20</sup>.

---

<sup>20</sup>An interesting feature of many flat-belt sheaves is a slight “crown” shape to the sheave, such that the diameter is slightly larger at the sheave’s center than it is at either side edge. The purpose of this crown is to help the belt center itself while in operation. As it turns out, a flat belt naturally tends to find the point at which it operates under maximum tension. If the belt happens to wander off-center, it will naturally find its way back to the center of the sheave as it rotates because that is where the tension reaches a maximum.

Like gear sets, industrial belt drive systems are typically shrouded for cleanliness and for personnel safety. Sheet-metal enclosures such as the one covering the top of this V-belt drive system on a “walking-beam” style of oil field pump. The sheet-metal enclosure protects the belts and sheaves from rain and snow. You will also note a large gearbox following the belt drive, further reducing rotational speed from the electric motor to the pump’s counter-weighted crank:

Belts of all styles are subject to wear and fatigue, and as such must be periodically replaced. Some belt drive systems employ *tensioner* mechanisms which maintain consistent belt tension by applying a constant force to the belt. Small tensioners are usually spring-loaded, while large belt tensioners (particularly conveyor belts) are loaded by the weight of a large mass. Minimum belt tension is extremely important for belt drives, as loose belts will begin to “slip” under load and quickly fail if the problem is not remedied.

When multiple belts are used to distribute loading between belts in high-power drive systems, it is important that all belts be replaced simultaneously, never partially. If a new belt is installed next to an old belt on the same sheave, the old belt will run “loose” and not bear its full share of the load, thus overloading the other (new) belt(s) in the drive system.

### 2.9.6 Chain drives

*Sprockets* are identical in function to sheaves, using *link chain* rather than belt to couple the two rotating pieces together. Bicycles are perhaps the best-known example of sprockets and chains from everyday life, being the most efficient simple machine for the purpose of coupling a person's leg power to a rotating wheel for propulsion. Like gear sets, the mechanical advantage ratio of a sprocket set may be determined by counting teeth on each sprocket and then dividing one tooth count by the other, or empirically by rotating one sprocket by hand and counting the number of turns (revolutions) each sprocket makes.

The following photograph shows a pair of sprockets linked together with a roller chain. The sprocket ratio here is 1:1, as both sprockets share the same number of teeth:

Bicycles use sprockets and a chain to transfer power from the crank to the rear wheel. Here, a multi-speed sprocket assembly allows the rider to select the best ratio (i.e. mechanical advantage) for riding at different speeds and in different conditions. Three sprockets on the crank and eight sprockets on the wheel give a theoretical<sup>21</sup> maximum of 24 different “speeds” or “gears” from which to select:

Chain drive systems require thorough lubrication and freedom from dirt and other abrasive particles in order to deliver full service life. Open-chain systems such as the two shown in the above photographs are challenging to maintain in good working order for these reasons.

<sup>21</sup>In practice, not all of these 24 “speeds” are recommended, because some of the front/rear sprocket selections would place the chain at an extreme angle as it engaged with both sprockets. In the interest of extending chain life, it should run as “straight” on each sprocket as possible.

## **2.10 Elementary thermodynamics**

Thermodynamics is the study of heat, temperature, and their related effects in physical systems. As a subject, thermodynamics is quite complex and expansive, usually taught as a course in itself at universities. The coverage in this book is limited to some of the more elementary and immediately practical facets of thermodynamics rather than a comprehensive overview.

### 2.10.1 Heat versus Temperature

Most people use the words *heat* and *temperature* interchangeably. This is unfortunate for every student of thermodynamics, because it means they must first deconstruct this false conception and replace it with one more scientifically accurate before any progress may be made. While “heat” and “temperature” are related concepts, they are not identical.

When people say something is “hot,” what they really mean is that the object has a high temperature. Temperature is a direct function of random molecular motion within an object or a fluid sample. This is usually easiest to visualize for a gas, where unattached molecules have great freedom to vibrate, collide, and otherwise move about. The molecules of a substance at high temperature are moving more vigorously (higher velocity) than the molecules of the same substance at low temperature.

Heat, by contrast, is an expression of thermal energy transfer. By placing a pot of water over a fire, we are *adding heat* to that pot (transferring thermal energy to the water), the effect of which is to *raise its temperature* (making the water molecules’ motions more vigorous). If that same pot is taken away from the fire and allowed to cool, its *loss of heat* (transferring energy out of the water to the surrounding air) will result in its *temperature lowering* (the individual water molecules slowing down).

Heat gain or loss often results in temperature change, but not always. In some cases heat may be gained or lost with negligible temperature change – here, the gain or loss of heat manifests as physical changes to the substance other than temperature. One example of this is the boiling of water at constant pressure: no matter how much heat is transferred to the water, its temperature will remain constant at the boiling point (100 degrees Celsius at sea level) until all the water has boiled to vapor. The addition of thermal energy to the boiling water does not raise its temperature (i.e. make the molecules move faster), but rather goes into the work of disrupting inter-molecular bonds so that the liquid turns into vapor. Another example is the heating of chemical reactants in an endothermic (heat-absorbing) reaction: much of the thermal energy added to the chemical solution goes into the work of separating chemical bonds, resulting in molecular changes but not (necessarily) increased temperature.

Heat transfer can *only* happen, though, where there is a difference of temperature between two objects. Thermal energy (heat) naturally flows from the “hotter” (higher-temperature) substance to the “colder” (lower-temperature) substance. To use the boiling water example, the only way to get heat transfer into the water is to subject the water to a hotter substance (e.g., a flame, or a hot electric heating element). If you understand temperature as being molecular motion within a substance, with a hotter object’s molecules vibrating more vigorously than a colder object’s molecules, this natural transfer of heat from hot to cold makes perfect sense: the molecular vibrations of the higher-temperature object literally transfer to the molecules of the lower-temperature object. As those respective molecules touch each other, with fast-vibrating molecules colliding against slow-vibrating molecules, the inter-molecular collisions transfer energy away from the fast-vibrating molecules (so they aren’t vibrating as fast anymore) and toward the slow-moving molecules (so they begin to vibrate faster than before). It’s like a vibrating tuning fork touched to a non-vibrating tuning fork: the vibrating fork loses some of its vibration by transferring energy to the (formerly) quiet tuning fork.

Much more attention will be directed to the concepts of heat and temperature in subsequent subsections.

### 2.10.2 Temperature

In an ideal, monatomic<sup>22</sup> gas (one atom per molecule), the mathematical relationship between average molecular velocity and temperature is as follows:

$$\frac{1}{2}m\overline{v^2} = \frac{3}{2}kT$$

Where,

$m$  = Mass of each molecule

$v$  = Velocity of a molecule in the sample

$\overline{v}$  = Average (“mean”) velocity of all molecules in the sample

$\overline{v^2}$  = Mean-squared molecular velocities in the sample

$k$  = Boltzmann’s constant ( $1.38 \times 10^{-23}$  J / K)

$T$  = Absolute temperature (Kelvin)

Non-ideal gases, liquids, and solids are more complex than this. Not only can the atoms of complex molecules move to and fro, but they may also twist and oscillate with respect to each other. No matter how complex the particular substance may be, however, the basic principle remains unchanged: temperature is an expression of how rapidly molecules move within a substance.

There is a temperature at which all molecular motion ceases. At that temperature, the substance cannot possibly become “colder,” because there is no more motion to halt. This temperature is called *absolute zero*, equal to  $-273.15$  degrees Celsius, or  $-459.67$  degrees Fahrenheit. Two temperature scales based on this absolute zero point, *Kelvin* and *Rankine*, express temperature relative to absolute zero. That is, zero Kelvin and zero degrees Rankine is equal to absolute zero temperature. Any temperature greater than absolute zero will be a positive value in either the Kelvin or the Rankine scales. A sample of freezing water at sea level, for example, is 0 degrees Celsius (32 degrees Fahrenheit) but could also be expressed as 273.15 Kelvin<sup>23</sup> (0 plus 273.15) or 491.67 degrees Rankine (32 plus 459.67).

---

<sup>22</sup>Helium at room temperature is a close approximation of an ideal, monatomic gas, and is often used as an example for illustrating the relationship between temperature and molecular velocity.

<sup>23</sup>Kelvin is typically expressed without the customary “degree” label, unlike the three other temperature units: (degrees) Celsius, (degrees) Fahrenheit, and (degrees) Rankine.

A table of melting and boiling points (at sea-level atmospheric pressure) for various substances appears in this table, labeled in these four different units of temperature measurement:

Melting or boiling substance	°C	°F	K	°R
Melting point of water (H <sub>2</sub> O)	0	32	273.15	491.67
Boiling point of water (H <sub>2</sub> O)	100	212	373.15	671.67
Melting point of ammonia (NH <sub>3</sub> )	−77.7	−107.9	195.45	351.77
Boiling point of ammonia (NH <sub>3</sub> )	−33.6	−28.5	239.55	431.17
Melting point of gold (Au)	1063	1945	1336	2405
Melting point of magnesium (Mg)	651	1203.8	924.2	1663.5
Boiling point of acetone (C <sub>3</sub> H <sub>6</sub> O)	56.5	133.7	329.65	593.37
Boiling point of propane (C <sub>3</sub> H <sub>8</sub> )	−42.1	−43.8	231.05	415.87
Boiling point of ethanol (C <sub>2</sub> H <sub>6</sub> O)	78.4	173.1	351.55	632.77

Note how degrees Celsius and Kelvin for each point on the table differ by a constant (offset) of 273.15, while each corresponding degree Fahrenheit and degree Rankine value differs by 459.67 (note that many of the figures in this table are slightly rounded, so the offset might not be *exactly* that much). You might think of Kelvin as nothing more than the Celsius scale zero-shifted by 273.15 degrees, and likewise degrees Rankine as nothing more than the Fahrenheit scale zero-shifted by 459.67 degrees.

Note also how *increments* in temperature measured in degrees Fahrenheit are the same as *increments* of temperature measured in degrees Rankine. The same is true for degrees Celsius and Kelvin. The difference between the melting point of ammonia (−77.7 degrees C) and the melting point of water (0 degrees C) is the same difference as that between the melting points of ammonia and water expressed in Kelvin: 195.45 and 273.15, respectively. Either way, the difference in temperature between these two substances' melting points is 77.7 degrees (C or K). This is useful to know when dealing with temperature changes over time, or temperature differences between points in a system – if an equation asks for a temperature difference ( $\Delta T$ ) in Kelvin, it is the same value as the temperature difference expressed in Celsius. Likewise, a  $\Delta T$  expressed in degrees Rankine is identical to a  $\Delta T$  expressed in degrees Fahrenheit. This is analogous to differences between two fluid pressures expressed in PSIG versus PSIA: the differential pressure value (PSID) will be the same.

Most people are familiar with the Fahrenheit and Celsius temperature scales used to express temperature in common applications, but the absolute scales of Rankine and Kelvin have special significance and purpose in scientific endeavors. The fact that Rankine and Kelvin are *absolute* scales in the same manner that *atmospheres* and *torr* are units of absolute pressure measurement makes them uniquely suited for expressing temperature (molecular motion) in relation to the absence of thermal energy. Certain scientific laws such as the *Ideal Gas Law* and the *Stefan-Boltzmann Law* relate other physical quantities to absolute temperature, and so require the use of these absolute units of measurement.

### 2.10.3 Heat

Heat, being the transfer of energy in thermal (molecular motion) form, may be measured in the same units as any other form of energy is measured: *joules* (metric) and *foot-pounds* (British). However, special units of measurement are often used for heat instead:

- calorie
- kilocalorie (or “dietary Calorie”)
- British Thermal Unit (BTU)

A *calorie* of heat is defined as the amount of thermal energy transfer required to change the temperature of one gram of water by one degree Celsius ( $\Delta T = 1\text{ }^{\circ}\text{C} = 1\text{ K}$ ). One calorie is equivalent to 4.186 joules.

A *British Thermal Unit*, or *BTU* is defined as the amount of thermal energy transfer required to change the temperature of one pound of water by one degree Fahrenheit ( $\Delta T = 1\text{ }^{\circ}\text{F} = 1\text{ }^{\circ}\text{R}$ ). One BTU is equivalent to 778.2 foot-pounds.

The unit of “dietary” calories is used to express the amount of thermal energy available in a sample of food by combustion<sup>24</sup>. Since the official unit of the “calorie” is so small compared to the typical amounts of energy contained in a meal, nutritionists use the unit of the kilocalorie (1000 calories, or 4186 joules) and call it “Calorie” (with a capital letter “C”).

Just as “Calories” are used to rate the energy content of food, the heat units of “calories” and “BTU” are very useful in describing the potency of various industrial fuels. The following table shows the *heat of combustion* for a few common fuels, in units of kilocalories per gram and BTU per pound:

Fuel	Combustion heat (kcal/g)	Combustion heat (BTU/lb)
Methane ( $\text{CH}_4$ )	13.3	23940
Methanol ( $\text{CH}_4\text{O}$ )	5.43	9767
Ethanol ( $\text{C}_2\text{H}_6\text{O}$ )	7.10	12783
Propane ( $\text{C}_3\text{H}_8$ )	12.1	21700
Carbon monoxide ( $\text{CO}$ )	2.415	4347

For example, if exactly one gram of methane gas were completely burnt, the resulting heat liberated in the fire would be sufficient to warm 13.3 kilograms of water from 20 degrees Celsius to 21 degrees Celsius (a temperature rise, or  $\Delta T$ , of one degree Celsius).

If a meal rated at 900 Calories (900 “dietary calories,” or 900 kilocalories) of energy were completely metabolized, the resulting heat would be sufficient to warm a pool of water 900 kilograms in mass (900 liters, or about 237 gallons) by one degree Celsius. This same amount of heat could raise half the amount of water twice the temperature rise: 450 liters of water warmed two degrees Celsius.

<sup>24</sup>Animals process food by performing a very slow version of combustion, whereby the carbon and hydrogen atoms in the food join with oxygen atoms inhaled to produce water and carbon dioxide gas (plus energy). Although it may seem strange to rate the energy content of food by measuring how much heat it gives off when *burnt*, burning is just a faster method of energy extraction than the relatively slow processes of biological metabolism.

### 2.10.4 Heat transfer

Heat spontaneously<sup>25</sup> flows from higher-temperature substances to lower-temperature substances. This is the phenomenon you experience standing next to a fire on a cold day. Your body is cold (low temperature), but the fire is much hotter (high temperature), and your proximity to the fire aids in heat transfer from the fire to you.

Three principal methods exist for heat to transfer from one substance to another:

- Radiation<sup>26</sup> (by light waves)
- Conduction (by direct contact)
- Convection (by intermediate contact with a moving fluid)

Practical examples of heat transfer often involve multiple modes rather than just one. For example, the transfer of heat to a person's body by sunlight obviously involves *radiation* from the Sun, but it also involves *conduction* through layers of clothing and *convection* by air passing from sun-warmed objects to the person.

Temperature-sensing instruments used to measure temperature in industrial applications likewise rely on multiple heat-transfer modes to sample thermal energy from a process fluid or object(s). Infrared thermometers detect temperature by sensing the intensity of infrared light *radiated* by hot objects. A thermocouple directly touching a hot object relies on *conduction* to sense the temperature of that object. An RTD inserted into a pipe carrying a hot fluid relies on *convection* to measure the average temperature of that fluid. A filled-bulb thermometer inserted into a thermowell, inserted into a fluid-filled process vessel relies on both *convection* (from the process fluid to the thermowell) and *conduction* (from the thermowell to the bulb) to sense process temperature.

---

<sup>25</sup>Heat may be forced to flow from cold to hot by the use of a machine called a *heat pump*, but this direction of heat flow does not happen naturally, which is what the word “spontaneous” implies. In truth, the rule of heat flowing from high-temperature to cold-temperature applies to heat pumps as well, just in a way that is not obvious from first inspection. Mechanical heat pumps cause heat to be drawn from a cool object by placing an even cooler object (the *evaporator*) in direct contact with it. That heat is then transferred to a hot object by placing an even hotter object (the *condenser*) in direct contact with it. Heat is moved against the natural (spontaneous) direction of flow from the evaporator to the condenser by means of mechanical compression and expansion of a refrigerant fluid.

<sup>26</sup>In this context, we are using the word “radiation” in a very general sense, to mean thermal energy radiated away from the hot source via photons. This is quite different from nuclear radiation, which is what some may assume this term means upon first glance.

### Radiation

If you have ever experienced the immediate sensation of heat from a large fire or explosion some distance away, you know how *radiation* works to transfer thermal energy. Radiation is also the method of heat transfer experienced in the Earth's receiving of heat from the Sun (and also the mechanism of heat loss from Earth to outer space). Radiation is the least efficient of the three heat transfer mechanisms. It may be quantified by the Stefan-Boltzmann Law, which states the rate of heat lost by an object ( $\frac{dQ}{dt}$ ) is proportional to the *fourth power* of its absolute temperature, and directly proportional to its radiating area:

$$\frac{dQ}{dt} = e\sigma AT^4$$

Where,

$\frac{dQ}{dt}$  = Radiant heat loss rate (watts)

$e$  = Emissivity factor (unitless)

$\sigma$  = Stefan-Boltzmann constant ( $5.67 \times 10^{-8} \text{ W / m}^2 \cdot \text{K}^4$ )

$A$  = Surface area (square meters)

$T$  = Absolute temperature (Kelvin)

Here is one of the scientific applications where temperature expressed in *absolute* units is truly necessary. Radiant energy is a direct function of molecular motion, and so we would logically expect objects to radiate energy at any temperature above absolute zero. The temperature value used in this formula *must* be in units of Kelvin<sup>27</sup> in order for the resulting  $\frac{dQ}{dt}$  value to be correct. If degrees Celsius were used for  $T$  instead of Kelvin, the formula would predict zero thermal radiation at the freezing point of water (0 °C) and *negative* radiation at any temperature below freezing, which is not true. Remember that the “zero” points of the Celsius and Fahrenheit scales were arbitrarily set by the inventors of those scales, but that the “zero” points of the Kelvin and Rankine scales reflect a fundamental limit of nature.

The emissivity factor varies with surface finish and color, ranging from one (ideal) to zero (no radiation possible). Dark-colored, rough surfaces offer the greatest emissivity factors, which is why heater elements and radiators are usually painted black. Shiny (reflective), smooth surfaces offer the least emissivity, which is why thermally insulating surfaces are often painted white or silver.

Like all heat-transfer modes, radiation is two-way. Objects may emit energy in the form of radiation, and they may also receive energy in the form of radiation. Everyone knows white-colored shirts are cooler than black-colored shirts worn on a hot, sunny day – this is an example of how emissivity affects heat absorption by radiant transfer. A black-colored shirt (high emissivity value) enhances the receiving of radiant energy by your body from the sun. What is not as obvious, though, is that a white-colored shirt will keep you warmer than a black-colored shirt on a cold, dark day because that same decreased emissivity inhibits body heat *loss* by radiation. Thus, high-emissivity objects both heat *and* cool more readily by radiation than low-emissivity objects.

---

<sup>27</sup>Or in degrees Rankine, provided a suitably units-corrected value for the Stefan-Boltzmann constant were used.

## Conduction

If you have ever accidentally touched a hot iron or stove heating element, you possess a very vivid recollection of heat transfer through *conduction*. In conduction, fast-moving molecules in the hot substance transfer some of their kinetic energy to slower-moving molecules in the cold substance. Since this transfer of energy requires collisions between molecules, it only applies when the hot and cold substances directly contact each other.

Perhaps the most common application of heat conduction in industrial processes is through the walls of a furnace or some other enclosure containing an extreme temperature. In such applications, the desire is usually to *minimize* heat loss through the walls, so those walls will be “insulated” with a substance having poor thermal conductivity.

Conductive heat transfer rate is proportional to the difference in temperature between the hot and cold points, the area of contact, the distance of heat travel from hot to cold, and the thermal conductivity of the substance:

$$\frac{dQ}{dt} = \frac{kA\Delta T}{l}$$

Where,

$\frac{dQ}{dt}$  = Conductive heat transfer rate

$k$  = Thermal conductivity

$A$  = Surface area

$\Delta T$  = Difference of temperature between “hot” and “cold” sides

$l$  = Length of heat flow path from “hot” to “cold” side

Note the meaning of “ $\Delta T$ ” in this context: it refers to the *difference* in temperature between two different locations in a system. Sometimes the exact same symbology (“ $\Delta T$ ”) refers to a *change in temperature over time* in the study of thermodynamics. Unfortunately, the only way to distinguish one meaning of  $\Delta T$  from the other is by context.

An illustration showing heat conduction through a wall gives context to the variables in the previous equation. As we see here,  $A$  refers to the surface area of the wall,  $\Delta T$  refers to the difference of temperature between either surface of the wall, and  $l$  refers to the thickness of the wall:

In the United States, a common measure of insulating ability used for the calculation of conductive heat loss in shelters is the *R-value*. The greater the R-value of a thermally insulating material, the less conductive it is to heat (lower  $k$  value). “R-value” mathematically relates to  $k$  and  $l$  by the following equation:

$$R = \frac{l}{k}$$

Rearranging this equation, we see that  $l = kR$ , and this allows us to substitute  $kR$  for  $l$  in the conduction heat equation, then cancel the  $k$  terms:

$$\begin{aligned} \frac{dQ}{dt} &= \frac{kA\Delta T}{kR} \\ \frac{dQ}{dt} &= \frac{A\Delta T}{R} \end{aligned}$$

$R$  is always expressed in the compound unit of square feet · hours · degrees Fahrenheit per BTU. This way, with a value for area expressed in square feet and a temperature difference expressed in degrees Fahrenheit, the resulting heat transfer rate ( $\frac{dQ}{dt}$ ) will naturally be in units of BTU per hour, which is the standard unit in the United States for expressing heat output for combustion-type heaters. Dimensional analysis shows how the units cancel to yield a heat transfer rate in BTUs per hour:

$$\frac{[\text{BTU}]}{[\text{h}]} = \frac{[\text{ft}^2][^\circ\text{F}]}{\frac{[\text{ft}^2][\text{h}][^\circ\text{F}]}{[\text{BTU}]}}$$

The utility of R-value ratings may be shown by a short example. Consider a contractor trailer, raised up off the ground on a mobile platform, with a total skin surface area of 2400 square feet (walls, floor, and roof) and a uniform R-value of 4 for all surfaces. If the trailer's internal temperature must be maintained at 70 degrees Fahrenheit while the outside temperature averages 40 degrees Fahrenheit, the required output of the trailer's heater will be:

$$\frac{dQ}{dt} = \frac{(2400 \text{ ft}^2)(30^\circ \text{ F})}{4 \text{ ft}^2 \cdot \text{h} \cdot ^\circ \text{ F}/\text{BTU}} = 18000 \text{ BTU per hour}$$

If the trailer's heater is powered by propane and rated at 80% efficiency (requiring 22500 BTU per hour of fuel heating value to produce 18000 BTU per hour of heat transfer into the trailer), the propane usage will be just over one pound per hour, since propane fuel has a heating value of 21700 BTU per pound.

### Convection

Most industrial heat-transfer processes occur through *convection*, where a moving fluid acts as an intermediary substance to transfer heat from a hot substance (heat *source*) to a cold substance (heat *sink*). Convection may be thought of as two-stage heat conduction on a molecular scale: fluid molecules come into direct contact with a hot object and absorb heat from that object through conduction, then those molecules later release that heat energy through conduction by direct contact with a cooler object. If the fluid is recycled in a piping loop, the two-stage conduction process repeats indefinitely, individual molecules heating up as they absorb heat from the heat source and then cooling down as they release heat to the heat sink.

Special process devices called *heat exchangers* perform this heat transfer function between two different fluids, the two fluids circulating past each other on different sides of tube walls. A simple example of a heat exchanger is the radiator connected to the engine of an automobile, being a water-to-air exchanger, the engine's hot water transferring heat to cooling air entering the grille of the car as it moves.

Another example of a liquid-to-air heat exchanger is the *condenser* on a heat pump, refrigerator, or air conditioner, a photograph appearing here:

Another common style of heat exchanger works to transfer heat between two liquids. A small example of this design used to transfer heat from a boat engine is shown here:

The purpose for this heat exchanger is to exchange heat between the liquid coolant of the boat engine and sea water, the latter being quite corrosive to most metals. An engine would soon be damaged if sea water were used directly as the coolant fluid, and so heat exchangers such as this provide a means to release excess heat to the sea without subjecting the engine block to undue corrosion. The heat exchanger, of course, *does* suffer from the corrosive effects of sea water, but at least it is less expensive and more convenient to replace than an entire engine when it reaches the end of its service life.

This marine engine heat exchanger is an example of a *shell-and-tube* design, where one fluid passes inside small tubes and a second fluid passes outside those same tubes, the tube bundle being contained in a shell. The interior of such an exchanger looks like this when cut away:

The tubes of this particular heat exchanger are made of copper, a metal with extremely high thermal conductivity ( $k$ ), to facilitate conductive heat transfer.

Liquid-to-liquid heat exchangers are quite common in industry, where a set of tubes carry one process liquid while a second process liquid circulates on the outside of those same tubes. The metal walls of the tubes act as heat transfer areas for conduction to occur. Metals such as copper with very high  $k$  values (very low  $R$  values) encourage heat transfer, while long lengths of tube ensure ample surface area for heat exchange.

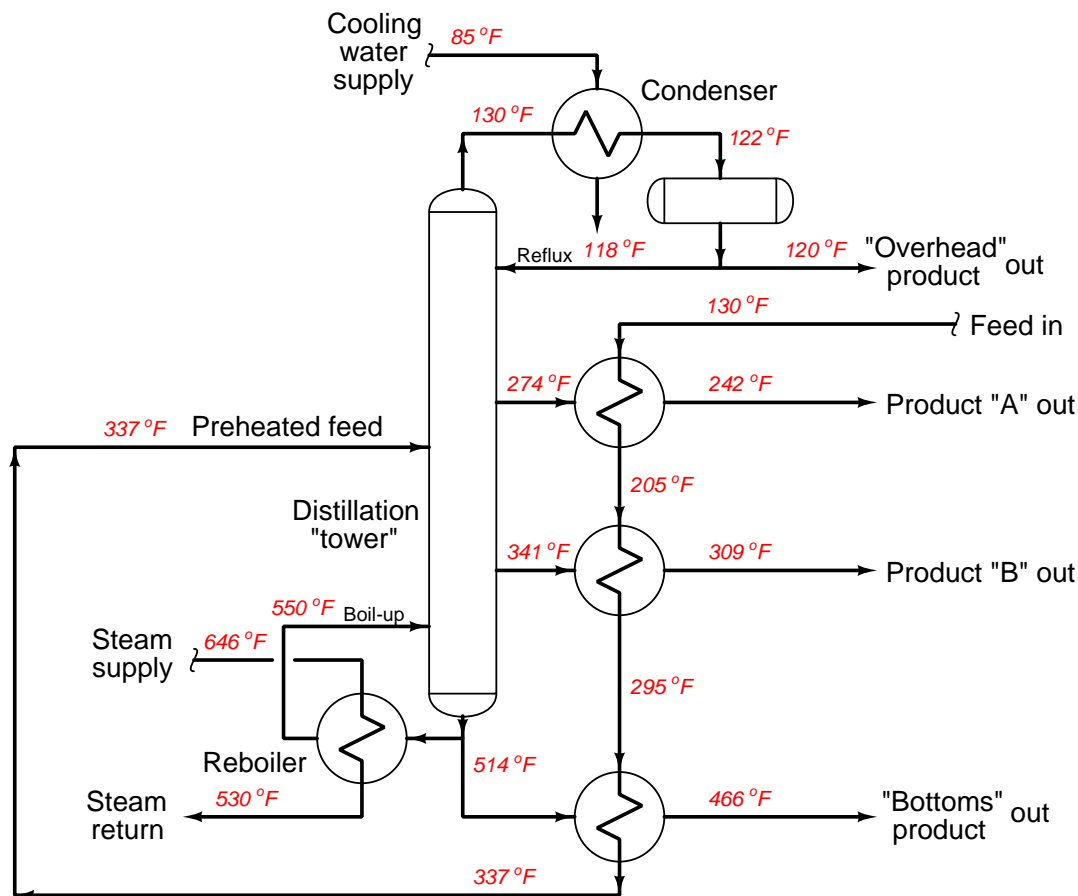

A common application of liquid-to-liquid heat exchangers is in exothermic (heat-releasing) chemical reaction processes where the reactants must be pre-heated before entering a reaction vessel (“reactor”). Since the chemical reaction is exothermic, the reaction itself may be used as the heat source for pre-heating the incoming feed. A simple P&ID shows how a heat exchanger accomplishes this transfer of heat:

Another industrial application of heat exchangers is in *distillation* processes, where mixed components are separated from each other by a continuous process of boiling and condensation. Alcohol purification is one example of distillation, where a mixture of alcohol and water are separated to yield a purer (higher-percentage) concentration of alcohol. Distillation (also called *fractionation*) is a very energy-intensive<sup>28</sup> process, requiring great inputs of heat to perform the task of separation. Any method of energy conservation typically yields significant cost savings in a distillation process, and so we often find heat exchangers used to transfer heat from outgoing (distilled, or fractionated) products to the incoming feed mixture, pre-heating the feed so that less heat need be added to the distillation process from an external source.

<sup>28</sup>Jim Cahill of Emerson wrote in April 2010 (“Reducing Distillation Column Energy Usage” Emerson Process Expert weblog) about a report estimating distillation column energy usage to account for approximately 6% of the total energy used in the United States. This same report tallied the number of columns in US industry to be approximately 40000 total, accounting for about 19% of all energy used in manufacturing processes!

The following P&ID shows a simple distillation process complete with heat exchangers for reboiling (adding heat to the bottom of the distillation column), condensing (extracting heat from the “overhead” product at the top of the column), and energy conservation (transferring heat from the hot products to the incoming feed):

Distillation “columns” (also called *fractionating towers* in the industry) are tall vessels containing sets of “trays” where rising vapors from the boiling process contact falling liquid from the condensing process. Temperatures increase toward the bottom of the column, while temperatures decrease toward the top. In this case, steam through a “reboiler” drives the boiling process at the bottom of the column (heat input), and cold water through a “condenser” drives the condensing process at the top of the column (heat extraction). Products coming off the column at intermediate points are hot enough to serve as pre-heating flows for the incoming feed. Note how the “economizing” heat exchangers expose the cold feed flow to the cooler Product A before exposing it to the warmer Product B, and then finally the warmest “Bottoms” product. This sequence of cooler-to-warmer maximizes the efficiency of the heat exchange process, with the incoming feed flowing past products of increasing temperature as it warms up to the necessary temperature for distillation entering the

column.

Some heat exchangers transfer heat from hot gases to cool(er) liquids. An example of this type of heat exchanger is the construction of a steam boiler, where hot combustion gases transfer heat to water flowing inside metal tubes:

Here, hot gases from the combustion burners travel past the metal “riser” tubes, transferring heat to the water within those tubes. This also serves to illustrate an important convection phenomenon: a *thermal siphon* (often written as *thermosiphon*). As water heats in the “riser” tubes, it becomes less dense, producing less hydrostatic pressure at the bottom of those tubes than the colder water in the “downcomer” tubes. This difference of pressure causes the colder water in the downcomer tubes to flow down to the mud drum, and hot water in the riser tubes to flow up to the steam drum. This natural *convection current* will continue as long as heat is applied to the riser tubes by the burners, and an unobstructed path exists for water to flow in a loop.

Natural convection also occurs in heated air, such as in the vicinity of a lit candle:

This thermally forced circulation of air helps *convect* heat from the candle to all other points within the room it is located, by carrying heated air molecules to colder objects.

### 2.10.5 Specific heat and enthalpy

Earlier, we saw how units of heat measurement were defined in terms of the amount of energy gain or loss required to alter the temperature of a water sample by one degree. In the case of the *calorie*, it was the amount of heat gain/loss required to heat/cool one gram of water one degree Celsius. In the case of the *BTU*, it was the amount of heat gain/loss required to heat/cool one pound of water one degree Fahrenheit.

As one might expect, one heat unit might be similarly defined as the amount of heat gain or loss to alter the temperature one-half of a degree for twice as much water, or two degrees for half as much water. We could express this as a proportionality:

$$Q \propto m\Delta T$$

Where,

$Q$  = Heat gain or loss

$m$  = Mass of sample

$\Delta T$  = Temperature change (rise or fall) over time

The next logical question to ask is, “How does the relationship between heat and temperature change work for substances other than water?” Does it take the same amount of heat to change the temperature of one gram of *iron* by one degree Celsius as it does to change the temperature of one gram of *water* by one degree Celsius? The answer to this question is a resounding *no!* Different substances require vastly different amounts of heat gain/loss to alter their temperature by the same degree, even when the masses of those substances happen to be identical.

We have a term for this ability to absorb or release heat, called *heat capacity* or *specific heat*, symbolized by the variable  $c$ . Thus, our heat/mass/temperature change relationship may be described as a true formula instead of a mere proportionality:

$$Q = mc\Delta T$$

Where,

$Q$  = Heat gain or loss (metric calories or British BTU)

$m$  = Mass of sample (metric grams or British pounds)

$c$  = Specific heat of substance

$\Delta T$  = Temperature change (metric degrees Celsius or British degrees Fahrenheit)

Pure water, being the standard by which all other substances are measured, has a specific heat value of 1. The smaller the value for  $c$ , the less heat gain or loss is required to alter the substance’s temperature by a set amount. That substance (with a low value of  $c$ ) has a low “heat capacity” because each degree of temperature rise or fall represents a relatively small amount of energy gained or lost. Substances with low  $c$  values are easy to heat and cool, while substances having high  $c$  values require much heat in order to alter their temperatures, assuming equal masses.

A table of specific heat values (at room temperature, 25 degrees Celsius<sup>29</sup>) for common substances appears here:

Substance	Specific heat value ( $c$ ) cal/g·°C or BTU/lb·°F
Aluminum (solid)	0.215
Iron (solid)	0.108
Copper (solid)	0.092
Lead (solid)	0.031
Ice (solid)	0.50
Water (liquid)	1.00
Methanol (liquid)	0.609
Ethanol (liquid)	0.587
Acetone (liquid)	0.521
Hydrogen (gas)	3.41
Helium (gas)	1.24
Nitrogen (gas)	0.249
Oxygen (gas)	0.219
Steam (gas)	0.476

If a liquid or a gas is chosen for use as a coolant (a substance to efficiently convect heat away from an object), greater values of  $c$  are better. Water is one of the best liquid coolants with its relatively high  $c$  value of one: it has more capacity to absorb heat than other liquids, for the same rise in temperature. The ideal coolant would have an infinite  $c$  value, being able to absorb an infinite amount of heat without itself rising in temperature at all.

As you can see from the table, the light gases (hydrogen and helium) have extraordinarily high  $c$  values. Consequently, they function as excellent media for convective heat transfer. This is why large electric power generators often use hydrogen gas as a coolant: hydrogen has an amazing ability to absorb heat from the wire windings of a generator without rising much in temperature. In other words, hydrogen absorbs a lot of heat while still remaining “cool” (i.e. remains at a low temperature). Helium, although not quite as good a coolant as hydrogen, has the distinct advantage of being chemically inert (non-reactive), in stark contrast to hydrogen’s extreme flammability. Some nuclear reactors use helium gas as a coolant rather than a liquid such as water or molten sodium metal.

Lead has an extraordinarily low  $c$  value, being a rather “easy” substance to heat up and cool down. Anyone who has ever cast their own lead bullets for a firearm knows how quickly a new lead bullet cools off after being released from the mold, especially if that same person has experience casting other metals such as aluminum.

---

<sup>29</sup>An important detail to note is that specific heat does *not* remain constant over wide temperature changes. This complicates calculations of heat required to change the temperature of a sample: instead of simply multiplying the temperature change by mass and specific heat ( $Q = mc\Delta T$  or  $Q = mc[T_2 - T_1]$ ), we must *integrate* specific heat over the range of temperature ( $Q = m \int_{T_1}^{T_2} c dT$ ), summing up infinitesimal products of specific heat and temperature change ( $c dT$ ) over the range starting from temperature  $T_1$  through temperature  $T_2$  then multiplying by the mass to calculate total heat required. So, the specific heat values given for substances at 25 °C only hold true for relatively small temperature changes deviating from 25 °C. To accurately calculate heat transfer over a large temperature change, one must incorporate values of  $c$  for that substance at different temperatures along the expected range.

Numerical examples are helpful to better understand specific heat. Consider a case where a copper pot filled with water receives heat from a small gas burner operating at an output of 5000 BTU per hour (350 calories per second):

A reasonable question to ask would be, “How much will the temperature of this water-filled pot rise after 40 seconds of heating?” With the burner’s heat output of 350 calories per second and a heating time of 40 seconds, we may assume<sup>30</sup> the amount of heat absorbed by the water-filled pot will be the simple product of heat rate times time:

$$Q = \left( \frac{dQ}{dt} \right) t = \left( \frac{350 \text{ cal}}{\text{s}} \right) 40 \text{ s} = 14000 \text{ calories}$$

This amount of heat not only goes into raising the temperature of the water, but it also raises the temperature of the copper pot. Each substance (water, copper) has its own specific heat and mass values ( $c$  and  $m$ ), but they will share the same temperature rise ( $\Delta T$ ), so we must sum their heats as follows:

$$Q_{total} = Q_{pot} + Q_{water}$$

$$Q_{total} = m_{pot}c_{pot}\Delta T + m_{water}c_{water}\Delta T$$

Since both the pot and the water start at the same temperature and end at the same temperature,  $\Delta T$  is a common variable to both terms and may therefore be factored out:

$$Q_{total} = (m_{pot}c_{pot} + m_{water}c_{water})\Delta T$$

<sup>30</sup>In reality, the amount of heat actually absorbed by the pot will be less than this, because there will be heat losses from the warm pot to the surrounding (cooler) air. However, for the sake of simplicity, we will assume *all* the burner’s heat output goes into the pot and the water it holds.

Solving this equation for temperature rise, we get:

$$\Delta T = \frac{Q_{total}}{m_{pot}c_{pot} + m_{water}c_{water}}$$

$$\Delta T = \frac{14000 \text{ cal}}{(1100 \text{ g})(0.092 \frac{\text{cal}}{\text{g}^\circ\text{C}}) + (3700 \text{ g})(1 \frac{\text{cal}}{\text{g}^\circ\text{C}})}$$

$$\Delta T = 3.68^\circ\text{C}$$

So, if the water and pot began at a temperature of 20 degrees Celsius, they will be at a temperature of 23.68 degrees Celsius after 40 seconds of heating over this small burner.

Another example involves the mixing of two substances at different temperatures. Suppose a heated mass of iron drops into a cool container<sup>31</sup> of water. Obviously, the iron will lose heat energy to the water, causing the iron to decrease in temperature while the water rises in temperature. Suppose the iron's mass is 100 grams, and its original temperature is 65 degrees Celsius. Suppose the water's mass is 500 grams, and its original temperature is 20 degrees Celsius:

<sup>31</sup>We will assume for the sake of this example that the container holding the water is of negligible mass, such as a Styrofoam cup. This way, we do not have to include the container's mass or its specific heat into the calculation.

What will the equilibrium temperature be after the iron falls into the water and both their temperatures equalize? We may solve this by setting two heat equations equal to each other<sup>32</sup>: the heat lost by the iron and the heat gained by the water, with the final equilibrium temperature being  $T$ :

$$Q_{iron} = Q_{water}$$

$$m_{iron}c_{iron}\Delta T_{iron} = m_{water}c_{water}\Delta T_{water}$$

$$m_{iron}c_{iron}(65^{\circ}\text{C} - T) = m_{water}c_{water}(T - 20^{\circ}\text{C})$$

Note how the  $\Delta T$  term is carefully set up for each side of the equation. In order to make the iron's heat loss a positive value and the water's heat gain a positive value, we must ensure the quantity within each set of parentheses is positive. For the iron, this means  $\Delta T$  will be 65 degrees minus the final temperature. For the water, this means  $\Delta T$  will be the final temperature minus its starting temperature of 20 degrees.

In order to solve for the final temperature ( $T$ ), we must distribute the terms, collecting all  $T$ -containing terms to one side of the equation, then factor and isolate  $T$ :

$$m_{iron}c_{iron}(65) - m_{iron}c_{iron}T = m_{water}c_{water}T - m_{water}c_{water}(20)$$

$$m_{iron}c_{iron}(65) + m_{water}c_{water}(20) = m_{iron}c_{iron}T + m_{water}c_{water}T$$

$$m_{iron}c_{iron}(65) + m_{water}c_{water}(20) = T(m_{iron}c_{iron} + m_{water}c_{water})$$

$$T = \frac{m_{iron}c_{iron}(65) + m_{water}c_{water}(20)}{m_{iron}c_{iron} + m_{water}c_{water}}$$

$$T = \frac{(100 \text{ g})(0.108 \text{ cal/g}^{\circ}\text{C})(65^{\circ}\text{C}) + (500 \text{ g})(1 \text{ cal/g}^{\circ}\text{C})(20^{\circ}\text{C})}{(100 \text{ g})(0.108 \text{ cal/g}^{\circ}\text{C}) + (500 \text{ g})(1 \text{ cal/g}^{\circ}\text{C})}$$

$$T = 20.95^{\circ}\text{C}$$

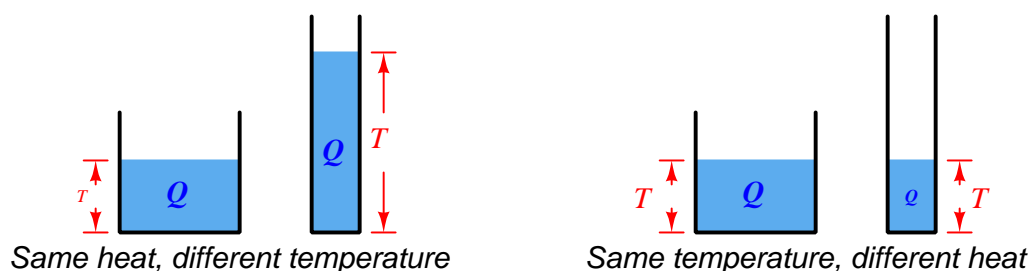

Thus, the iron's temperature falls from 65 degrees Celsius to 20.95 degrees Celsius, while the water's temperature rises from 20 degrees Celsius to 20.95 degrees Celsius. The water's tremendous specific heat value compared to the iron (nearly 10 times as much!), as well as its superior mass (5 times as much) results in a much larger temperature change for the iron than for the water.

---

<sup>32</sup>An alternative way to set up the problem would be to calculate  $\Delta T$  for each term as  $T_{final} - T_{start}$ , making the iron's heat loss a negative quantity and the water's heat gain a positive quantity, in which case we would have to set up the equation as a zero-sum balance, with  $Q_{iron} + Q_{water} = 0$ . I find this approach less intuitive than simply saying the iron's heat loss will be equal to the water's heat gain, and setting up the equation as two positive values equal to each other.

An analogy to help grasp the concept of specific heat is to imagine heat as a fluid<sup>33</sup> that may be “poured” into vessels of different size, those vessels being objects or substances to be heated. The amount of liquid held by any vessel represents the total amount of thermal energy, while the *height* of the liquid inside any vessel represents its temperature:

### Fluid analogy for heat and temperature

The factor determining the relationship between liquid volume (heat) and liquid height (temperature) is of course the cross-sectional area of the vessel. The wider the vessel, the more heat will be required to “fill” it up to any given temperature. In this analogy, the area of the vessel is analogous to the term  $mc$ : the product of mass and specific heat. Objects with larger mass require more heat to raise their temperature to any specific point, specific heats being equal. Likewise, objects with large specific heat values require more heat to raise their temperature to any specific point, masses being equal.

In the first numerical calculation example where we determined the temperature of a pot of water after 40 seconds of heating, the analogous model would be to determine the height of liquid in a vessel after pouring liquid into it for 40 seconds at a fixed rate. A model for the second numerical example would be to calculate the equilibrium height (of liquid) after connecting two vessels together at their bottoms with a tube. Although the liquid heights of those vessels may be different at first, the levels will equalize after time by way of liquid passing through the tube from the higher-level vessel to the lower-level vessel.

<sup>33</sup>This is not far from the hypotheses of eighteenth-century science, where heat was thought to be an invisible fluid called *caloric*.

Many industrial processes use fluids to convectively transfer thermal energy from one object (or fluid) to another. In such applications, it is important to know how much thermal energy will be carried by a specific quantity of that fluid over a specified temperature drop. One common way to express this quantity is called *enthalpy*. Enthalpy is the amount of heat lost by a unit mass (one gram metric, or one pound British) of a substance as it cools from a given temperature all the way down to the freezing point of water (0 degrees Celsius, or 32 degrees Fahrenheit). In other words, enthalpy is a measure<sup>34</sup> of a substance's thermal energy using the freezing temperature of water as a reference. A sample of water at a temperature of 125 degrees Fahrenheit, for example, has an enthalpy of 93 BTU per pound (or 93 calories per gram), because 93 BTU of thermal energy would be lost if one pound of that water happened to cool from its given temperature (125 °F) down to 32 °F:

$$Q = mc\Delta T$$

$$Q = (1 \text{ lb}) \left( 1 \frac{\text{BTU}}{\text{lb}^\circ\text{F}} \right) (125^\circ\text{F} - 32^\circ\text{F})$$

$$Q = 93 \text{ BTU}$$

Even if the substance in question does not cool down to the freezing temperature of water, enthalpy is a useful figure for comparing the thermal energy “content” of hot fluids (per unit mass). For example, if one were given the enthalpy values for a substance before and after heat transfer, it would be easy to calculate the amount of heat transfer that transpired simply by subtracting those enthalpy values<sup>35</sup>. If water at 125 °F has an enthalpy value of 93 BTU/lb and water at 170 °F has an enthalpy of value 138 BTU/lb, we may calculate the amount of heat needed to increase the temperature of a sample of water from 125 °F to 170 °F simply by subtracting 93 BTU/lb from 138 BTU/lb to arrive at 45 BTU/lb.

In this rather trivial example, it would have been just as easy for us to calculate the heat necessary to increase water's temperature from 125 °F to 170 °F by using the specific heat formula ( $Q = mc\Delta T$ )<sup>36</sup>, and so it might appear as though the concept of enthalpy sheds no new light on the subject of heat transfer. However, the ability to calculate heat transfer based on a simple subtraction of enthalpy values proves quite useful in more complex scenarios where substances change phase, as we will see next.

---

<sup>34</sup>A useful analogy for enthalpy is the *maximum available balance* of a bank account. Suppose you have a bank account with a minimum balance requirement of \$32 to maintain that account. Your maximum available balance at any time would be the total amount of money in that account minus \$32, or to phrase this differently your maximum available balance is the most money you may spend from this account while still keeping that account open. Enthalpy is much the same: the amount of thermal energy a sample may “spend” (i.e. lose) before its temperature reaches 32 degrees Fahrenheit.

<sup>35</sup>Appealing to the *maximum available balance* analogy, if we compared the maximum available balance in your bank account before and after a transaction, we could determine how much money was deposited or withdrawn from your account simply by subtracting those two values.

<sup>36</sup>Following the formula  $Q = mc\Delta T$ , we may calculate the heat as  $(1)(1)(170 - 125) = 45 \text{ BTU}$ . This is obviously the same result we obtained by subtracting enthalpy values for water at 170 °F and 125 °F.

### 2.10.6 Phase changes

Scientists often speak of four *phases* of matter: *solid*, *liquid*, *gas* (or *vapor*), and *plasma*. Of these four, the first three are common to everyday life. Plasma is a phase of matter where the atoms of a gas are excited (energized) to the point where they become electrically ionized, such as neon gas in an electric tube light, or the gas comprising stars in space.

Phase changes are very important in thermodynamics, principally because energy transfer (heat loss or heat gain) must occur for a substance to change states, often with negligible change in temperature. To cite an example, consider the case of water (a liquid) turning into steam (a vapor) at atmospheric pressure. At sea level, this phase change will occur at a temperature of 100 degrees Celsius, or 212 degrees Fahrenheit. The amount of energy required to increase the temperature of water from ambient up to its boiling point is a simple function of the sample's mass and its original temperature. For instance, a sample of water 70 grams in mass starting at 24 degrees Celsius will require 5320 calories of heat to reach the boiling point:

$$Q = mc\Delta T$$

$$Q = (70 \text{ g}) \left( 1 \frac{\text{cal}}{\text{g}^\circ\text{C}} \right) (100^\circ\text{C} - 24^\circ\text{C})$$

$$Q = 5320 \text{ cal}$$

However, actually boiling the 70 grams of water into 70 grams of steam (both at 100 degrees Celsius) requires a comparatively enormous input of heat: *37734 calories* – over seven times as much heat to turn the water to steam as what is required to warm the water to its boiling point! Furthermore, this additional input of 37734 calories does not increase the temperature of the water at all: the resulting steam is still at a temperature of (only) 100 degrees Celsius. If further heat is added to the 70 gram steam sample, its temperature will rise, albeit at a rate proportional to the value of steam's specific heat (0.476 calories per gram degree Celsius, or BTU per pound degree Fahrenheit).

What we see here is a fundamentally different phenomenon than we saw with specific heat. Here, we are looking at the thermal energy required to transition a substance from one phase to another, not to change its temperature. We call this quantity *latent heat* rather than *specific heat*, because no temperature change occurs<sup>37</sup>. Conversely, if we allow the steam to condense back into liquid water, it must release the same 37734 calories of heat energy we invested in it turning the water into steam before it may cool at all below the boiling point (100 degrees Celsius).

Latent heat has the effect of greatly increasing a substance's enthalpy. Recall that “enthalpy” is the amount of heat lost by one pound (mass) of a substance if it happened to cool from its given temperature all the way down to the freezing temperature of water (0 °C, or 32 °F). Hot water has an enthalpy of 1 BTU/lb for every degree of temperature above freezing. Steam, however, possesses far greater enthalpy because of the latent heat released in the phase change from vapor to liquid before it releases heat as water cooling down to 32 °F.

---

<sup>37</sup>The word “latent” refers to something with potential that is not yet realized. Here, heat exchange takes place without there being any realized change in temperature. By contrast, heat resulting in a temperature change ( $Q = mc\Delta T$ ) is called *sensible heat*.

As with specific heat, there is a formula relating mass, latent heat, and heat exchange:

$$Q = mL$$

Where,

$Q$  = Heat of transition required to completely change the phase of a sample (metric calories or British BTU)

$m$  = Mass of sample (metric grams or British pounds)

$L$  = Latent heat of substance

Each substance has its own set of latent heat values, one<sup>38</sup> for each phase-to-phase transition. Water, for example, exhibits a latent heat of vaporization (boiling/condensing) of 539.1 calories per gram, or 970.3 BTU per pound, at atmospheric pressure (boiling point = 100 °C = 212 °F). Water also exhibits a latent heat of fusion (melting/freezing) of 79.7 calories per gram, or 143.5 BTU per pound. Both figures are enormous compared to water's specific heat value of 1 calorie per gram-degree Celsius (or 1 BTU per pound-degree Fahrenheit<sup>39</sup>): it takes only one calorie of heat to warm one gram of water one degree Celsius, but it takes *539.1 calories* of heat to boil that same gram of water into one gram of steam, and *79.7 calories* of heat to melt one gram of ice into one gram of water. The lesson here is simple: phase changes involve huge amounts of heat.

A table showing various latent heats of vaporization (all at room temperature, 70 degrees Fahrenheit) for common industrial fluids appears here, contrasted against their specific heat values (as liquids). In each case you will note how much larger  $L$  is than  $c$ :

Fluid (@ 70 °F)	$L_{\text{vaporization}}$ , BTU/lb	$L_{\text{vaporization}}$ , cal/g	$c_{\text{liquid}}$
Water	970.3	539.1	1
Ammonia	508.6	282.6	1.1
Carbon dioxide	63.7	35.4	0.66
Butane	157.5	87.5	0.56
Propane	149.5	83.06	0.6

One of the most important, and also non-intuitive, consequences of latent heat is the relative stability of temperature during the phase-change process. Referencing the table of latent heats of vaporization, we see how much more heat is needed to boil a liquid into a vapor than is needed to warm that same liquid by one degree of temperature. During the process of boiling, all heat input to the liquid goes into the task of phase change (latent heat) and none of it goes into increased temperature. In fact, until all the liquid has been vaporized, the liquid's temperature *cannot* rise above its boiling point! The requirement of heat input to vaporize a liquid forces temperature to stabilize (not rise further) until *all* the liquid has evaporated from the sample.

<sup>38</sup>Latent heat of vaporization also varies with pressure, as different amounts of heat are required to vaporize a liquid depending on the pressure that liquid is subject to. Generally, increased pressure (increased boiling temperature) results in less latent heat of vaporization.

<sup>39</sup>The reason specific heat values are identical between metric and British units, while latent heat values are not, is because latent heat does not involve temperature change, and therefore there is one less unit conversion taking place between metric and British when translating latent heats. Specific heat in both metric and British units is *defined* in such a way that the three different units for heat, mass, and temperature all cancel each other out. With latent heat, we are only dealing with mass and heat, and so we have a proportional conversion of  $\frac{5}{9}$  or  $\frac{9}{5}$  left over, just the same as if we were converting between degrees Celsius and Fahrenheit alone.

If we take a sample of ice and add heat to it over time until it melts, warms, boils, and then becomes steam, we will notice a temperature profile that looks something like this:

The flat areas of the graph during the melting and boiling periods represents times where the sample's temperature does not change at all, but where all heat input goes into the work of changing the sample's phase. Only where we see the curve rising does the temperature change. So long as there is a *mixture* of different phases, the temperature remains “locked” at one value. Only when there is a single phase of material is the temperature “allowed” to rise or fall.

The sloped areas of the graph reveal the specific heat of the substance in each particular phase. Note how the liquid (water) portion of the graph has a relatively shallow slope, due to the specific heat value ( $c$ ) of water being equal to 1. Both the ice and the steam portions of the graph have steeper slopes because both of those phases possess smaller values of specific heat ( $c = 0.5$  and  $c = 0.476$ , respectively). The smaller the value of  $c$ , the more a sample's temperature will rise for any given input of thermal energy. For any given rate of heat transfer, smaller  $c$  values result in more rapid temperature changes.

We may employ our liquid-filled vessel analogy to the task of explaining latent heat. Any point of phase change is analogous to a point along the vessel's height equipped with a large expansion chamber, so that the vessel "acts" as if its area were much larger at one point, requiring *much* more fluid volume (heat) to change height (temperature) past that one point:

Liquid poured into this vessel will fill it at a rate proportional to the volume added and inversely proportional to the vessel's cross-sectional area at the current liquid height. As soon as the liquid level reaches the expansion chamber, a great deal more liquid must be added to cause level to increase, since this chamber must completely fill before the liquid level may rise above it. Once that happens, the liquid level rises at a different rate with addition introduced volume, because now the phase is different (with a different specific heat value).

Remember that the filling of a vessel with liquid is merely an analogy for heat and temperature, intended to provide an easily visualized process mimicking another process not so easily visualized. The important concept to realize with latent heat and phase change is that it constitutes a discontinuity in the temperature/heat function for any given substance.

A vivid demonstration of this phenomenon is to take a paper<sup>40</sup> cup filled with water and place it in the middle of a roaring fire<sup>41</sup>. "Common sense" might tell you the paper will burn through with the fire's heat, so that the water runs out of the cup through the burn-hole. This does not happen, however. Instead, the water in the cup will rise in temperature until it boils, and there it will maintain that temperature no matter how hot the fire burns. The boiling point of water happens to be substantially below the burning point of paper, and so the boiling water keeps the paper cup too cool to burn. As a result, the paper cup remains intact so long as water remains in the cup. The *rim* of the cup above the water line will burn up because the steam does not have the same temperature-stabilizing effect as the water, leaving a rimless cup that grows shorter as the water boils away.

<sup>40</sup>Styrofoam and plastic cups work as well, but paper exhibits the furthest separation between the boiling point of water and the burning point of the cup material, and it is usually thin enough to ensure good heat transfer from the outside (impinging flame) to the inside (water).

<sup>41</sup>This is a lot of fun to do while camping!

The point at which a pure substance changes phase not only relates to temperature, but to pressure as well. We may speak casually about the boiling point of water being 100 degrees Celsius (212 degrees Fahrenheit), but that is only if we assume the water and steam are at atmospheric pressure (at sea level). If we reduce the ambient air pressure<sup>42</sup>, water will boil at a lesser temperature. Anyone familiar with cooking at high altitudes knows you must generally cook for longer periods of time at altitude, because the decreased boiling temperature of water is not as effective for cooking. Conversely, anyone familiar with *pressure cooking* (where the cooking takes place inside a vessel pressurized by steam) knows how comparatively little cooking time is required because the pressure raises water's boiling temperature. In either of these scenarios, where pressure influences<sup>43</sup> boiling temperature, the latent heat of water acts to hold the boiling water's temperature stable until all the water has boiled away. The only difference is the temperature at which the water begins to boil (or when the steam begins to condense).

Many industrial processes use boiling liquids to convectively transfer heat from one object (or fluid) to another. In such applications, it is important to know how much heat will be carried by a specific quantity of the vapor as it condenses into liquid over a specified temperature drop. The quantity of *enthalpy* (heat content) used for rating the heat-carrying capacity of liquids applies to condensing vapors as well. Enthalpy is the amount of heat lost by a unit mass (one gram metric, or one pound British) of the fluid as it cools from a given temperature all the way down to the freezing point of water (0 degrees Celsius, or 32 degrees Fahrenheit)<sup>44</sup>. When the fluid's initial state is vapor, and it condenses into liquid as it cools down to the reference temperature (32 °F), the heat content (enthalpy) is not just a function of specific heat, but also of latent heat.

Water at its atmospheric boiling point has an enthalpy of approximately 180 BTU per pound. Steam at atmospheric pressure and 212 °F, however, has an enthalpy of about 1150 BTU per pound: more than six times as much heat as water at the same temperature. 970 of that 1150 BTU/lb is due to the phase change from steam to water, while the rest is due to water's specific heat as it cools from 212 °F to 32 °F.

Many technical reference books contain a set of data known as a *steam table* showing various properties of steam at different temperatures and pressures. Enthalpy is one of the most important parameters given in a steam table, showing how much available energy resides in steam under different pressure and temperature conditions. For this reason, enthalpy is sometimes referred to as *total heat* ( $h_g$ ). Steam tables also show saturation temperature (the condensing temperature for steam at that pressure) and steam density.

---

<sup>42</sup>This may be done in a vacuum jar, or by traveling to a region of high altitude where the ambient air pressure is less than at sea level.

<sup>43</sup>The mechanism of this influence may be understood by considering what it means to boil a liquid into a vapor. Molecules in a liquid reside close enough to each other that they cohere, whereas molecules in a vapor or gas are relatively far apart and act as independent objects. The process of boiling requires that cohesion between liquid molecules to be broken, so the molecules may drift apart. Increased pressure encourages cohesion in liquid form by helping to hold the molecules together, while decreased pressure encourages the separation of molecules into a vapor/gas.

<sup>44</sup>As mentioned previously, a useful analogy for enthalpy is the *maximum available balance* for a bank account with a \$32 minimum balance requirement: that is, how much money may be spent from that account without closing it out.

If the vapor in question is at a temperature greater than its boiling point at that pressure, the vapor is said to be *superheated*. The enthalpy of superheated vapor comes from three different heat-loss mechanisms:

- Cooling the vapor down to its condensing temperature (specific heat of vapor)
- Phase-changing from vapor to liquid (latent heat of phase change)
- Cooling the liquid down to the reference temperature (specific heat of liquid)

Using steam as the example once more, a sample of superheated steam at 500 °F and atmospheric pressure (boiling point = 212 °F) has an enthalpy of approximately 1287 BTU per pound. We may calculate the heat lost by one pound of this superheated steam as it cools from 500 °F to 32 °F in each of the three steps previously described. Here, we will assume a specific heat for steam of 0.476, a specific heat for water of 1, and a latent heat of vaporization for water of 970:

Heat loss mechanism	Formula	Quantity
Cooling vapor	$Q = mc\Delta T$	$(1)(0.476)(500 - 212) = 137 \text{ BTU}$
Phase change	$Q = mL$	$(1)(970) = 970 \text{ BTU}$
Cooling liquid	$Q = mc\Delta T$	$(1)(1)(212 - 32) = 180 \text{ BTU}$
TOTAL		1287 BTU

Enthalpy values are very useful<sup>45</sup> in steam engineering to predict the amount of thermal energy delivered to a load given the steam's initial temperature, its final (cooled) temperature, and the mass flow rate. Although the definition of enthalpy – where we calculate heat value by supposing the vapor cools all the way down to the *freezing point* of water – might seem a bit strange and impractical (how common is it for steam to lose so much heat to a process that it reaches freezing temperature?), it is not difficult to shift the enthalpy value to reflect a more practical final temperature. Since we know the specific heat of liquid water is very nearly one, all we have to do is offset the enthalpy value by the amount that the final temperature differs from freezing in order to calculate how much heat the steam will lose (per pound) to its load<sup>46</sup>.

Furthermore, the *rate* at which heat is delivered to a substance by steam (or conversely, the rate at which heat is required to boil water into steam) may be easily calculated if we take this heat value in units of BTU per pound and multiply it by the mass flow rate in pounds per minute: as the unit of “pound” cancels in the multiplication, we arrive at a result for heat transfer rate in units of BTU per minute.

<sup>45</sup>At first it may seem as though the enthalpy of steam is so easy to calculate it almost renders steam tables useless. If the specific heats of water and steam were constant, and the latent heat of vaporization for water likewise constant, this would be the case. However, both these values ( $c$  and  $L$ ) are not constant, but rather change with pressure and with temperature. Thus, steam tables end up being quite valuable to engineers, allowing them to quickly reference heat content of steam across a broad range of pressures and temperatures without having to account for changing  $c$  and  $L$  values (performing integral calculus in the form of  $Q = m \int_{T_1}^{T_2} c dT$  for specific heat) in their heat calculations.

<sup>46</sup>This is not unlike calculating the voltage dropped across an electrical load by measuring the voltage at each of the load's two terminals with respect to *ground*, then subtracting those two measured voltage values. In this analogy, electrical “ground” is the equivalent of water at freezing temperature: a common reference point for energy level.

For example, suppose we were to employ the same 500 °F superheated steam used in the previous example to heat a flow of oil through a heat exchanger, with the steam condensing to water and then cooling down to 170 degrees Fahrenheit as it delivers heat to the flowing oil. Here, the steam's enthalpy value of 1287 BTU per pound may simply be offset by 138 (170 degrees minus 32 degrees) to calculate how much heat (per pound) this steam will deliver to the oil:  $1287 - 138 = 1149$  BTU per pound:

*Heat exchanger application**Thermal diagram*

Here we see how 500 °F steam has an enthalpy (total heat) of 1287 BTU/lb, but since the steam does not in fact cool all the way down to 32 °F in the act of heating oil in the heat exchanger, we must subtract the enthalpy of the 170 °F water (138 BTU/lb) to determine<sup>47</sup> the amount of heat actually delivered to the oil by the steam (1149 BTU/lb). Calculating heat transfer rate is a simple matter of multiplying this heat per pound of steam by the steam's mass flow rate: for example, if the mass flow rate of this steam happened to be 2 pounds per minute, the heat transfer rate would be 2298 BTU per minute.

If we happen to be dealing with a situation where steam gives up some heat energy to a process fluid but not enough to cool to the point of condensation, all we need to do to calculate the amount of heat liberated by the superheated steam as it cools is subtract the enthalpy values between its hot and cool(er) states.

For example, suppose we have a heat-exchange process where superheated steam enters at 105 PSIG and 600 °F, exiting at 75 PSIG and 360 °F. The enthalpy of the steam under those two sets of conditions as given by a superheated steam table are 1328 BTU/lb and 1208 BTU/lb, respectively. Thus, the heat lost by the steam as it goes through this heat exchanger is the difference in enthalpy values:  $1328 \text{ BTU/lb} - 1208 \text{ BTU/lb} = 120 \text{ BTU/lb}$ . Once again, calculating heat transfer rate is a simple matter of multiplication: if the mass flow rate of this steam happened to be 80 pounds per hour, the heat transfer rate would be  $120 \text{ BTU/lb} \times 80 \text{ lb/hr} = 9600 \text{ BTU/hr}$ .

<sup>47</sup>Applying the *maximum available balance* analogy to this scenario, it would be as if your bank account began with a maximum available balance of \$1287 and then finished with a maximum available balance of \$138 after an expenditure: the amount of money you spent is the different between the initial and final maximum available balances ( $\$1287 - \$138 = \$1149$ ).

By encompassing both specific heat and latent heat into one quantity, enthalpy figures given in steam tables greatly simplify heat transfer calculations, as compared to evaluating specific heat and latent heat formulae ( $Q = mc\Delta T$  and  $Q = mL$ , respectively) for water. Calculations based on steam tables are also more accurate than those derived from the specific and/or latent heat formulae, because steam tables take into account the changing values of  $c$  and  $L$  over wide temperature and pressure ranges. This is the power of empirical data: steam tables were developed by taking actual calorimetric measurements of steam under those temperature and pressure conditions, and as such are a *record* of water's true behavior rather than a *prediction* of water's theoretical behavior.

### 2.10.7 Phase diagrams and critical points

A comprehensive way of describing the relationship between pressure, temperature, and substance phase is with something called a *phase diagram*. With pressure shown on one axis, and temperature on the other, a phase diagram describes the various phases of a substance in possible equilibrium at certain pressure/temperature combinations.

This phase diagram (for water) illustrates some of the features common to all phase diagrams: curved lines define the boundaries between solid, liquid, and vapor phases; the point of intersection of these three curves is where the substance may exist in all three phases simultaneously (called the *triple point*<sup>48</sup>) and points where a curve simply ends within the span of the graph indicate critical points, where the certain phases cease to exist.

The curved line from the triple point up and to the right defines the boundary between liquid water and water vapor. Each point on that line represents a set of unique pressure and temperature conditions for boiling (changing phase from liquid to vapor) or for condensation (changing phase from vapor to liquid). As you can see, increased pressure results in an increased boiling point (i.e. at higher pressures, water must be heated to greater temperatures before boiling may take place).

<sup>48</sup>When  $\text{H}_2\text{O}$  is at its triple point, vapor (steam), liquid (water), and solid (ice) of water will co-exist in the same space. One way to visualize the triple point is to consider it the pressure at which the boiling and freezing temperatures of a substance become the same.

In fact, the whole concept of a singular boiling *point* for water becomes quaint in the light of a phase diagram: boiling is seen to occur over a wide range of temperatures<sup>49</sup>, the exact temperature varying with pressure.

Something interesting happens when the temperature is raised above a certain value called the *critical temperature*. At this value (approximately 374 degrees Celsius for water), no amount of pressure will maintain it in a liquid state. Water, once heated beyond 374 degrees Celsius, is no longer a liquid and may only exist in a stable condition as a vapor. The *critical pressure* of any substance is the pressure value at the liquid/vapor boundary at the point of critical temperature.

A vivid example of critical temperature is this photograph of an ultra-high pressure storage vessel for oxygen gas, at a rocket engine testing facility:

The critical temperature for oxygen is 154.58 Kelvin, which is equal to  $-118.57$  degrees Celsius or  $-181.43$  degrees Fahrenheit. Since this pressure vessel is completely uninsulated, we know the temperature of the oxygen inside of it will be the same (or nearly the same) as ambient temperature, which is obviously much warmer than  $-118.57$  °C. Since the oxygen's temperature is well above the critical temperature for the element oxygen, we may safely conclude that the oxygen inside this vessel must exist as a gas. Even at the extremely high pressure this vessel is capable of holding (15000 PSIG), the oxygen cannot liquefy.

The slightly curved line from the triple point up and to the left defines the boundary between solid ice and liquid water. As you can see, the near-vertical pitch of this curve suggests the freezing temperature of water is quite stable over a wide pressure range.

---

<sup>49</sup>Anywhere between the triple-point temperature and the critical temperature, to be exact.

Carbon dioxide exhibits a different set of curves than water on its phase diagram, with its own unique critical temperature and pressure values:

Note how the triple-point pressure of carbon dioxide is well above ambient conditions on Earth. This means carbon dioxide is not stable in its liquid state unless put under substantial pressure (at least 60.4 PSIG). This is why solid carbon dioxide is referred to as *dry ice*: it does not liquefy with the application of heat, rather it *sublimates* directly into its vapor phase.

Another interesting difference between the carbon dioxide and water phase diagrams is the slope of the solid/liquid boundary line. With water, this boundary drifts to the left (lower temperature) as pressure increases. With carbon dioxide, this boundary drifts to the right (higher temperature) as pressure increases. Whether the fusion temperature increases or decreases with increasing pressure marks whether that substance contracts or expands as it transitions from liquid to solid. Carbon dioxide, like most pure substances, contracts to a smaller volume when it goes from liquid to solid, and its fusion curve drifts to the right as pressure increases. Water is unusual in this regard, expanding to a larger volume when freezing, and its fusion curve drifts to the left as pressure increases.

### 2.10.8 Saturated steam table

A saturated steam table shows temperatures and pressures for water at the liquid/vapor transition (i.e. points lying along the liquid/vapor interface shown in a phase change diagram), as well as enthalpy values for the water and steam under those conditions. The sensible heat of water is the amount of thermal energy per pound necessary to raise water's temperature from the freezing point to the boiling point. The latent heat of vapor is the amount of energy per pound necessary to convert water (liquid) into steam (vapor). The total heat is the enthalpy of steam (thermal energy per pound) between the listed condition in the table and the freezing temperature of water.

By definition a saturated steam table does *not* describe steam at temperatures greater than the boiling point. For such purposes, a *superheated steam table* is necessary.

Data for this saturated steam table was taken from *Thermal Properties of Saturated and Superheated Steam* by Lionel Marks and Harvey Davis, published in 1920 by Longmans, Green, and Company.

Saturated Steam Table

Temperature (Deg F)	Pressure (PSIA)	Sensible heat of liquid (BTU/lb)	Latent heat of vapor (BTU/lb)	Total heat (BTU/lb)
32	0.0886	0.00	1073.4	1073.4
40	0.1217	8.05	1068.9	1076.9

### 2.10.9 Thermodynamic degrees of freedom

If we look at the areas bounded by phase transition curves in a phase diagram (solid area, liquid area, and vapor area), we see that both pressure and temperature may change independent of one another. A vessel filled with liquid water, for instance, may be at 30 degrees Celsius and 2 atmospheres, or at 50 degrees Celsius and 2 atmospheres, or at 50 degrees Celsius and 1 atmosphere, all equally stable. A more technical way to state this is to say the liquid water has *two degrees of freedom*. Here, the word “degree” has a completely different meaning than it does when used to denote a unit of temperature or angle. In this context, “degree” may be thought of loosely as “dimension.” A cube has three physical dimensions, a square has two and a line has one. A point within a cube has three degrees of freedom (motion), while a point within a square only has two, and a point along a line only has one. Here, we use the word “degree” to denote the number of independent ways a system may change. For areas bounded by phase transition curves in a phase diagram, *pressure* and *temperature* are the two “free” variables, because within those bounded areas we may freely alter pressure without altering temperature, and vice-versa.

Such is not the case at any point lying along one of the phase transition curves. Any point on a curve is geometrically defined by a pair of coordinates, which means that for a two-phase mixture in equilibrium there will be exactly one temperature value valid for each unique pressure value. At any point along a phase transition curve, pressure and temperature are not independent variable, but rather are *related*. This means that for any single substance, there is only one degree of freedom along any point of a phase transition curve.

To illustrate this concept, suppose we equip a closed vessel containing water with both a thermometer and a pressure gauge. The thermometer measures the temperature of this water, while the pressure gauge measures the pressure of the water. A burner beneath the vessel adds heat to alter the water’s temperature, and a pump adds water to the vessel to alter the pressure inside:

So long as the water is all liquid (one phase), we may adjust its pressure and temperature independently. In this state, the system has two thermodynamic degrees of freedom.

However, if the water becomes hot enough to boil, creating a system of two phases in direct contact with each other (equilibrium), we will find that pressure and temperature become linked: one cannot alter one without altering the other. For a steam boiler, operation at a given steam

pressure thus *defines* the temperature of the water, and vice-versa. In a single-component, two-phase system, there is only one degree of thermodynamic freedom.

Our freedom to alter pressure and temperature becomes even more restricted if we ever reach the *triple point*<sup>50</sup> of the substance. For water, this occurs (only) at a pressure of  $-14.61$  PSIG (0.006 atmospheres) and a temperature of 0.01 degrees Celsius: the coordinates where all three phase transition curves intersect on the phase diagram. In this state, where solid (ice), liquid (water), and vapor (steam) coexist, there are zero degrees of thermodynamic freedom. Both the temperature and pressure are *locked* at these values until one or more of the phases disappears.

The relationship between degrees of freedom and phases is expressed neatly by *Gibbs' Phase Rule* – the sum of phases and degrees of freedom equals the number of substances (“components”) plus two:

$$N_{\text{freedom}} + N_{\text{phase}} = N_{\text{substance}} + 2$$

We may simplify Gibbs' rule for systems of just one substance (1 “component”) by saying the number of degrees of freedom plus phases in direct contact with each other is always equal to three. So, a vessel filled with nothing but liquid water (one component, one phase) will have two thermodynamic degrees of freedom: we may change pressure or temperature independently of one another. A vessel containing nothing but boiling water (two phases – water and steam, but still only one component) has just one thermodynamic degree of freedom: we may change pressure and temperature, but just not independently of one another. A vessel containing water at its triple point (three phases, one component) has no thermodynamic freedom at all: both temperature and pressure are fixed<sup>51</sup> so long as all three phases coexist in equilibrium.

### 2.10.10 Applications of phase changes

Applications of phase changes abound in industrial and commercial processes. Some of these applications exploit phase changes for certain production goals, such as the storage and transport of energy. Others merely serve to illustrate certain phenomena such as latent heat and degrees of thermodynamic freedom. This subsection will highlight several different processes for your learning benefit.

---

<sup>50</sup>The triple point for any substance is the pressure at which the boiling and freezing temperatures become one and the same.

<sup>51</sup>The non-freedom of both pressure and temperature for a pure substance at its triple point means we may exploit different substances' triple points as *calibration standards* for both pressure and temperature. Using suitable laboratory equipment and samples of sufficient purity, anyone in the world may force a substance to its triple point and calibrate pressure and/or temperature instruments against that sample.

### Propane storage tanks

A common example of a saturated liquid/vapor (two-phase) system is the internal environment of a propane storage tank, such as the kind commonly used to store propane fuel for portable stoves and gas cooking grills. If multiple propane storage tanks holding different volumes of liquid propane are set side by side, pressure gauges attached to each tank will all register the exact same pressure:

This is counter-intuitive, as most people tend to think the fullest tank should register the highest pressure (having the least space for the vapor to occupy). However, since the interior of each tank is a liquid/vapor system in equilibrium, the pressure is defined by the point on the liquid/vapor transition curve on the phase diagram for pure propane matching the tanks' *temperature*. Thus, the pressure gauge on each tank actually functions as a *thermometer*<sup>52</sup>, since pressure is a direct function of temperature for a saturated liquid/vapor system and therefore cannot change without a corresponding change in temperature. This is a thermodynamic system with just *one* degree of freedom.

Storage tanks containing liquid/vapor mixtures in equilibrium present unique safety hazards. If ever a rupture were to occur in such a vessel, the resulting decrease in pressure causes the liquid to spontaneously boil, halting any further decrease in pressure. Thus, a punctured propane tank does not lose pressure in the same manner than a punctured compressed air tank loses pressure. This gives the escaping vapor more “power” to worsen the rupture, as its pressure does not fall off over time the way it would in a simple compressed-gas application. As a result, relatively small punctures can and often do grow into catastrophic ruptures, where all liquid previously held inside the tank escapes and flashes into vapor, generating a vapor cloud of surprisingly large volume<sup>53</sup>.

Compounding the problem of catastrophic tank rupture is the fact that propane happens to be highly flammable. The thermodynamic properties of a boiling liquid combined with the chemical

<sup>52</sup>To be more precise, a propane tank acts like a *Class II filled-bulb* thermometer, with liquid and vapor coexisting in equilibrium.

<sup>53</sup>Steam boilers exhibit this same explosive tendency. The expansion ratio of water to steam is on the order of a thousand to one (1000:1), making steam boiler ruptures very violent even at relatively low operating pressures.

property of flammability in air makes propane tank explosions particularly violent. Fire fighters often refer to this as a *BLEVE*: a *Boiling Liquid Expanding Vapor Explosion*.

### Class II Filled-bulb thermometers

This same pressure-temperature interdependence finds application in a type of temperature measurement instrument called a *Class II filled-bulb*, where a metal bulb, tube, and pressure-sensing element are all filled with a saturated liquid/vapor mixture:

Heat applied to the bulb literally “boils” the liquid inside until its pressure reaches the equilibrium point with temperature. As the bulb’s temperature increases, so does the pressure throughout the sealed system, indicating at the operator display where a bellows (or some other pressure-sensing element) moves a pointer across a calibrated scale.

The only difference between the two filled-bulb thermometers shown in the illustration is which end of the instrument is warmer. The Class IIA system on the left (where liquid fills the pressure-indicating element) is warmer at the bulb than at the indicating end. The Class IIB system on the right (where vapor fills the indicating bellows) has a cooler bulb than the indicating bellows. The long length and small internal diameter of the connecting tube prevents any substantial heat transfer from one end of the system to the other, allowing the sensing bulb to easily be at a different temperature than the indicating bellows. Both types of Class II thermometers work the same<sup>54</sup>, the indicated pressure being a strict function of the bulb’s temperature where the liquid and vapor coexist in equilibrium.

<sup>54</sup>Class IIA systems do suffer from *elevation error* where the indicator may read a higher or lower temperature than it should due to hydrostatic pressure exerted by the column of liquid inside the tube connecting the indicator to the sensing bulb. Class IIB systems do not suffer from this problem, as the gas inside the tube exerts no pressure over an elevation.

### Nuclear reactor pressurizers

Nuclear reactors using pressurized water as the moderating and heat-transfer medium must maintain the water coolant in liquid form despite the immense heat output of the reactor core, to avoid the formation of steam bubbles within the reactor core which could lead to destructive “hot spots” inside the reactor. The following diagram shows a simplified<sup>55</sup> pressurized water reactor (PWR) cooling system:

In order to maintain a liquid-only cooling environment for the reactor core, the water is held at a pressure too high for boiling to occur inside the reactor vessel. Typical operating conditions for a pressurized water reactor are 575 °F and 2100 PSIG. A steam table shows the boiling point of water at 2100 PSIG to be over 640 °F, which means the water inside the reactor cannot boil if the reactor only operates at 575 °F. Referencing the phase diagram for water, the operating point of the reactor core is maintained *above* the liquid/vapor phase transition line by an externally supplied pressure.

This excess pressure comes from a device in the primary coolant loop called a *pressurizer*. Inside the pressurizer is an array of immersion-style electric heater elements. The pressurizer is essentially an electric boiler, purposely boiling the water inside at a temperature greater<sup>56</sup> than that reached

<sup>55</sup>Circulation pumps and a multitude of accessory devices are omitted from this diagram for the sake of simplicity.

<sup>56</sup>This is another example of an important thermodynamic concept: the distinction between *heat* and *temperature*. While the temperature of the pressurizer heating elements exceeds that of the reactor core, the total heat output of course does not. Typical comparative values for pressurizer power versus reactor core power are 1800 kW versus

by the reactor core itself. For the example figure of 2100 PSIG, the pressurizer elements would have to operate at a temperature of approximately 644 °F to maintain a boiling condition inside the pressurizer.

By maintaining the water temperature inside the pressurizer greater than at the reactor core, the water flowing through the reactor core literally *cannot* boil. The water/vapor equilibrium inside the pressurizer is a system with one degree of freedom (pressure and temperature linked), while the water-only environment inside the reactor core has two degrees of freedom (temperature may vary to any amount below the pressurizer's temperature without water pressure changing at all). Thus, the pressurizer functions like the temperature-sensing bulb of a *gigantic* Class IIA filled-bulb thermometer, with a liquid/vapor equilibrium inside the pressurizer vessel and liquid only inside the reactor vessel and all other portions of the primary coolant loop. Reactor pressure is then controlled by the temperature inside the pressurizer, which is in turn controlled by the amount of power applied to the heating element array<sup>57</sup>.

### Steam boilers

Boilers in general (the nuclear reactor system previously described being just one example of a large “power” boiler) are outstanding examples of phase change applied to practical use. The purpose of a boiler is to convert water into steam, sometimes for heating purposes, sometimes as a means of producing mechanical power (through a steam engine), sometimes for chemical processes requiring pressurized steam as a reactant, sometimes for utility purposes (maintenance-related cleaning, process vessel purging, sanitary disinfection, fire suppression, etc.) or all of the above. Steam is a tremendously useful substance in many industries, so you will find boilers in use at almost every industrial facility.

---

3800 MW, respectively: a ratio exceeding three orders of magnitude. The pressurizer heating elements don't have to dissipate much power (compared to the reactor core) because the pressurizer is not being cooled by a forced convection of water like the reactor core is.

<sup>57</sup>In this application, the heaters are the *final control element* for the reactor pressure control system.

A simplified diagram of a *water tube* boiler appears here:

Water enters the boiler through a heat exchanger in the stack called an *economizer*. This allows cold water to be pre-heated by the warm exhaust gases before they exit the stack. After pre-heating in the economizer, the water enters the boiler itself, where water circulates by natural convection (“thermosiphon”) through a set of tubes exposed to high-temperature fire. Steam collects in the “steam drum,” where it is drawn off through a pipe at the top. Since this steam is in direct contact with the boiling water, it will be at the same temperature as the water, and the steam/water environment inside the steam drum represents a two-phase system with only one degree of freedom. With just a single degree of freedom, steam temperature and pressure are direct functions of each other – coordinates at a single point along the liquid/vapor phase transition line of water’s phase diagram. One cannot change one variable without changing the other.

Consulting a steam table<sup>58</sup>, you will find that the temperature required to boil water at a pressure of 120 PSIG is approximately 350 degrees Fahrenheit. Thus, the temperature of the steam drum will be fixed at 350 °F while generating steam pressure at 120 PSIG. The only way to increase pressure in that boiler is to increase its temperature, and vice-versa.

When steam is at the same temperature as the boiling water it came from, it is referred to as *saturated* steam. Steam in this form is very useful for heating and cleaning, but not as much for operating mechanical engines or for process chemistry. If saturated steam loses any temperature at all (by losing its latent heat), it immediately condenses back into water. Liquid water can cause major mechanical problems inside steam engines (although “wet” steam works wonderfully well as a cleaning agent!), and so steam must be made completely “dry” for some process applications.

<sup>58</sup>Since the relationship between saturated steam pressure and temperature does not follow a simple mathematical formula, it is more practical to consult published tables of pressure/temperature data for steam. A great many engineering manuals contain steam tables, and in fact entire books exist devoted to nothing but steam tables.

The way this is done is by a process known as *superheating*. If steam exiting the steam drum of a boiler is fed through another heat exchanger inside the firebox so it may receive more heat, its temperature will rise beyond the saturation point. This steam is now said to be *superheated*:

Superheated steam is absolutely dry, containing no liquid water at all. It is therefore safe to use as a fluid medium for engines (piston and turbine alike) and as a process reactant where liquid water is not tolerable. The difference in temperature between superheated steam and saturated steam at any given pressure is the amount of *superheat*. For example, if saturated steam at 350 degrees Fahrenheit and 120 PSI drawn from the top of the steam drum in a boiler is heated to a higher temperature of 380 degrees Fahrenheit (at the same pressure of 120 PSI), it is said to have 30 degrees (Fahrenheit) of superheat.

**Fruit crop freeze protection**

An interesting application of phase changes and latent heat occurs in agriculture. Fruit growers, needing to protect their budding crop from the damaging effects of a late frost, will spray water over the fruit trees to maintain the sensitive buds above freezing temperature. As cold air freezes the water, the water's latent heat of fusion prevents the temperature at the ice/water interface from dropping below 32 degrees Fahrenheit. So long as liquid water continues to spray over the trees, the buds' temperature *cannot* fall below freezing. Indeed, the buds cannot even freeze in this condition, because once they cool down to the freezing point, there will be no more temperature difference between the freezing water and the buds. With no difference of temperature, no heat will transfer out of the buds. With no heat loss, water inside the buds cannot change phase from liquid to solid (ice) even if held at the freezing point for long periods of time, thus preventing freeze damage<sup>59</sup>. Only if the buds are exposed to cold air (below the freezing point), or the water turns completely to ice and no longer holds stable at the freezing point, can the buds themselves ever freeze solid.

---

<sup>59</sup>An experiment illustrative of this point is to maintain an ice-water mixture in an open container, then to insert a sealed balloon containing liquid water into this mixture. The water inside the balloon will eventually equalize in temperature with the surrounding ice-water mix, but it will not itself freeze. Once the balloon's water reaches 0 degrees Celsius, it stops losing heat to the surrounding ice-water mix, and therefore cannot make the phase change to solid form.

### Evaporative cooling towers

A very common use of a liquid-to-vapor phase change is for cooling purposes: taking hot water and mechanically forcing that hot water to evaporate in order to remove large quantities of heat energy from the water, thus cooling it to a lower temperature. Devices called *evaporative cooling towers* accomplish this task by causing ambient air to flow past droplets of water. As the rising air contacts the falling water droplets, some of the water is forced to evaporate, the heat required of this evaporation being provided by sensible heat within the remaining liquid water. As a result, the still-liquid water must cool in temperature as it gives up heat energy to the newly-formed water vapor.

Smaller evaporative cooling towers use fans to force air upward through the tower, employing inert "fill" material to provide large amounts of surface area for the liquid water and the air to contact each other. Some large evaporative cooling towers are self-drafting, the heat of the water providing enough convective force to the air that no fans are needed.

The following photograph shows a pair of induced-draft evaporative cooling towers used at a beer brewery:

This next photograph shows a forced-draft evaporative cooling tower used at a coal-fired electric power plant. Note the large air fans located around the circumference of the cooling tower, blowing cool air into the tower from outside. This fan placement eliminates problems arising from having the fan blades and motor located within the moist air stream:

## 2.11 Fluid mechanics

A *fluid* is any substance having the ability to *flow*: to freely change shape and move under the influence of a motivating force. Fluid motion may be analyzed on a microscopic level, treating each fluid molecule as an individual projectile body. This approach is extraordinarily tedious on a practical level, but still useful as a model of fluid behavior.

Some fluid properties are accurately predicted by this model, especially predictions dealing with potential and kinetic energies. However, the ability of a fluid's molecules to independently move give it unique properties that solids do not possess. One of these properties is the ability to effortlessly transfer *pressure*, defined as force applied over area.

### 2.11.1 Pressure

The common phases of matter are *solid*, *liquid*, and *gas*. Liquids and gases are fundamentally distinct from solids in their intrinsic inability to maintain a fixed shape. In other words, liquids and gases tend to fill whatever solid containers they are held in. Similarly, both liquids and gases both have the ability to flow, which is why they are collectively called *fluids*.

Due to their lack of definite shape, fluids tend to disperse any force applied to them. This stands in marked contrast to solids, which tend to transfer force only in the applied direction. Take for example the force transferred by a nail, from a hammer to a piece of wood:

The impact of the hammer's blow is directed straight through the solid nail into the wood below – nothing surprising here.

Now consider what a *fluid* would do when subjected to the same hammer blow:

Given the freedom of a fluid's molecules to move about, the impact of the hammer blow becomes directed *everywhere* against the inside surface of the container (the cylinder). This is true for all fluids: liquids and gases alike. The only difference between the behavior of a liquid versus a gas in the same scenario is that the gas will compress (i.e. the piston will move down as the hammer struck it), whereas the liquid will not compress (i.e. the piston will remain in its resting position). Gases yield under pressure, liquids do not.

It is very useful to quantify force applied to a fluid in terms of force per unit area, since the force applied to a fluid becomes evenly dispersed in all directions to the surface containing it. This is the definition of *pressure*<sup>60</sup> ( $P$ ): the amount of force ( $F$ ) distributed across a given area ( $A$ ).

$$P = \frac{F}{A}$$

In the metric system, the standard unit of pressure is the *pascal* (Pa), defined as one Newton (N) of force per square meter ( $\text{m}^2$ ) of area. In the British system of measurement, the standard unit of pressure is the *PSI*: pounds (lb) of force per square inch ( $\text{in}^2$ ) of area. Pressure is often expressed in units of kilopascals (kPa) when metric units are used because one pascal is a rather small<sup>61</sup> pressure for most engineering applications.

<sup>60</sup>The concept of pressure is also applicable to solid materials: applying either a compressive or tensile force to a solid object of given cross-sectional area generates a *pressure* within that object, also referred to as *stress*.

<sup>61</sup>To give some perspective on this, 1 pascal of pressure is equal to (only) 0.000145 pounds per square inch!

The even distribution of force throughout a fluid has some very practical applications. One application of this principle is the *hydraulic lift*, which functions somewhat like a fluid lever:

Force applied to the small piston creates a pressure throughout the fluid. That pressure exerts a greater force on the large piston than what is exerted on the small piston, by a factor equal to the ratio of piston areas. Since area for a circular piston is proportional to the square of the radius ( $A = \pi r^2$ ), even modest ratios of piston diameter yield large ratios of area and therefore of force. If the large piston has five times the area of the small piston (i.e. the large piston's diameter is 2.236 times greater than the small piston's diameter), force will be multiplied five-fold. Just as with the lever, however, there must be a trade-off so as to not violate the Conservation of Energy. The trade-off for increased force is decreased distance, whether in the lever system or in the hydraulic lift system. If the large piston generates a force five times greater than what is applied to the small piston, it must move only one-fifth as far as the small piston's motion. In this way, energy in equals energy out (remember that *work*, which is equivalent to energy, is calculated by multiplying force by parallel distance traveled).

For those familiar with electricity, what you see here in either the lever system or the hydraulic lift is analogous to a *transformer*: we can step AC voltage up, but only by reducing AC current. Being a passive device, a transformer cannot boost power. Therefore, power out can never be greater than power in, and given a perfectly efficient transformer, power out will always be precisely equal to power in:

$$\text{Power} = (\text{Voltage in})(\text{Current in}) = (\text{Voltage out})(\text{Current out})$$

$$\text{Work} = (\text{Force in})(\text{Distance in}) = (\text{Force out})(\text{Distance out})$$

Fluid may be used to transfer power just as electricity is used to transfer power. Such systems are called *hydraulic* if the fluid is a liquid (usually oil), and *pneumatic* if the fluid is a gas (usually air). In either case, a machine (pump or compressor) is used to generate a continuous fluid pressure, pipes are used to transfer the pressurized fluid to the point of use, and then the fluid is allowed to exert a force against a piston or a set of pistons to do mechanical work:

### Hydraulic power system

### Pneumatic power system

To learn more about fluid power systems, refer to section [10.2](#) beginning on page [692](#).

An interesting use of fluid we see in the field of instrumentation is as a *signaling medium*, to transfer information between places rather than to transfer power between places. This is analogous to using electricity to transmit voice signals in telephone systems, or digital data between computers along copper wire. Here, fluid pressure represents some other quantity, and the principle of force being distributed equally throughout the fluid is exploited to transmit that representation to some distant location, through piping or tubing:

This illustration shows a simple temperature-measuring system called a *filled bulb*, where an enclosed bulb filled with fluid is exposed to a temperature that we wish to measure. A rise in temperature makes the fluid expand and thereby increases pressure sensed at the gauge. The purpose of the fluid here is two-fold: first to sense temperature, and second to relay this temperature measurement a long distance away to the gauge. The principle of even pressure distribution allows the fluid to act as a signal medium to convey the information (bulb temperature) to a distant location.

### 2.11.2 Pascal's Principle and hydrostatic pressure

We learned earlier that fluids tend to evenly distribute any applied force. This fundamental principle is the basis of fluid power and fluid signaling systems, where pressure is assumed to be transferred equally to all points in a confined fluid. In the example of a hydraulic lift given earlier, we assume that the pressure throughout the fluid pathway is equal:

If additional force is applied to the small piston (say, 160 lbs instead of 150 lbs), the fluid pressure throughout the system will increase, not just the fluid pressure in the vicinity of the piston. The effect of this additional force will be immediately<sup>62</sup> “felt” at all points of the system. The phenomenon of pressure changes being evenly distributed throughout an enclosed fluid is called *Pascal's principle*.

Pascal's principle is really nothing more than the direct consequence of fluids' ability to *flow*. The only way an additional applied pressure would *not* be transmitted to all points within a confined fluid volume is if the fluid molecules were somehow not free to move. Since they are mobile, any compression applied to one region of that fluid will propagate to all other regions within that fluid volume. As fluid molecules are subjected to greater pressure, they naturally try to migrate to regions of lower pressure where they “bump up” against other fluid molecules, distributing that increased pressure in doing so.

<sup>62</sup>There is actually a speed of propagation to this increase in pressure, and it is the *speed of sound* within that particular fluid. This makes sense, since sound waves are nothing more than rapidly-changing regions of pressure within a material.

Pascal's principle tells us any *change* in applied pressure to a confined fluid will be distributed evenly throughout, but it does not say *pressure* will be the same throughout all points. If forces other than those applied to pistons exert pressure on the fluid, we may indeed experience gradients of pressure throughout a confined fluid volume.

In cases where we are dealing with tall columns of dense fluid, there is another force we must consider: the weight of the fluid itself. Suppose we took a cubic foot of water which weighs approximately 62.4 pounds, and poured it into a very tall vertical tube with a cross-sectional area of 1 square inch:

Naturally, we would expect the pressure measured at the bottom of this tall tube to be 62.4 pounds per square inch<sup>63</sup>, since the entire column of water (weighing 62.4 pounds) has its weight supported by one square inch of area.

<sup>63</sup>Interestingly, the amount of pressure generated by the weight of a fluid depends only on the *height* of that fluid column, not its cross-sectional area. Suppose we had a column of water the same height (144 feet) but in a tube having an area twice as large: 2 square inches instead of 1 square inch. Twice the area means twice the volume of water held in the tube, and therefore twice the weight (124.8 lbs). However, since this greater weight is distributed over a proportionately greater area at the bottom of the tube, the pressure there remains the same as before: 124.8 pounds ÷ 2 square inches = 62.4 pounds per square inch.

If we placed another pressure gauge mid-way up the tube, though, how much pressure would it register? At first you might be inclined to say 62.4 PSI as well, because you learned earlier in this lesson that fluids naturally distribute force throughout their bulk. However, in this case the pressure is *not* the same mid-way up the column as it is at the bottom:

The reason for this apparent discrepancy is that the source of pressure in this fluid system comes from the weight of the water column itself. Half-way up the column, the water only experiences half the total weight (31.2 pounds), and so the pressure is half of what it is at the very bottom. We did not consider this effect before, because we assumed the force exerted by the piston in the hydraulic lift was so large it “swamped” the weight of the fluid itself. Here, with our very tall column of water (144 feet tall!), the effect of gravity upon the water’s mass is quite substantial. Indeed, without a piston to exert an external force on the water, weight is the *only* source of force we have to consider when calculating pressure.

This fact does not invalidate Pascal’s principle. Any *change* in pressure applied to the fluid column will still be distributed equally throughout. For example, if we were to place a piston at the top of this fluid column and apply a force to the fluid, pressure at all points in that fluid column would increase by the same amount<sup>64</sup>. This is not the same as saying all pressures will be equal throughout the column, however.

<sup>64</sup>Suppose a 1 square inch piston were set on the top of this tall fluid column, and a downward force of 20 lbs were applied to it. This would apply an *additional* 20 PSI pressure to the fluid molecules at all points within the column. The pressure at the bottom would be 82.4 PSI, and the pressure at the middle would be 51.2 PSI.

An interesting fact about pressure generated by a column of fluid is that the width or shape of the containing vessel is irrelevant: the *height* of the fluid column is the only dimension we need to consider. Examine the following tube shapes, all connected at the bottom:

Since the force of fluid weight is generated only along the axis of gravitational attraction (straight down), that is the only axis of measurement important in determining “hydrostatic” fluid pressure.

The fixed relationship between the vertical height of a water column and pressure is such that sometimes water column height is used as a unit of measurement for pressure. That is, instead of saying “30 PSI,” we could just as correctly quantify that same pressure as 830.4 inches of water (“W.C. or ”H<sub>2</sub>O”), the conversion factor being approximately 2.768 inches of vertical water column per PSI.

As one might guess, the *density* of the fluid in a vertical column has a significant impact on the hydrostatic pressure that column generates. A liquid twice as dense as water, for example, will produce twice the pressure for a given column height. For example, a column of this liquid (twice as dense as water) 14 inches high will produce a pressure at the bottom equal to 28 inches of water (28 ”W.C.), or just over 1 PSI. An extreme example is liquid mercury, which is over 13.5 times as dense as water. Due to its exceptional density and ready availability, the height of a mercury column is also used as a standard unit of pressure measurement. For instance, 25 PSI could be expressed as 50.9 inches of mercury (”Hg), the conversion factor being approximately 2.036 inches of vertical mercury column per PSI.

The mathematical relationship between vertical liquid height and hydrostatic pressure is quite simple, and may be expressed by either of the following formulae:

$$P = \rho gh$$

$$P = \gamma h$$

Where,

$P$  = Hydrostatic pressure in units of weight per square area unit: pascals (N/m<sup>2</sup>) or lb/ft<sup>2</sup>

$\rho$  = Mass density of liquid in kilograms per cubic meter (metric) or slugs per cubic foot (British)

$g$  = Acceleration of gravity (9.81 meters per second squared or 32.2 feet per second squared)

$\gamma$  = Weight density of liquid in newtons per cubic meter (metric) or pounds per cubic foot (British)

$h$  = Vertical height of liquid column

Dimensional analysis – where we account for all units of measurement in a formula – validates the mathematical relationship between pressure, density, and height. Taking the second formula as an example:

$$P = \gamma h$$

$$\left[ \frac{\text{lb}}{\text{ft}^2} \right] = \left[ \frac{\text{lb}}{\text{ft}^3} \right] \left[ \frac{\text{ft}}{1} \right]$$

As you can see, the unit of “feet” in the height term cancels out one of the “feet” units in the denominator of the density term, leaving an answer for pressure in units of pounds per *square* foot. If one wished to set up the problem so the answer presented in a more common pressure unit such as pounds per square *inch*, both the liquid density and height would have to be expressed in appropriate units (pounds per cubic *inch* and *inches*, respectively).

Applying this to a realistic problem, consider the case of a tank filled with 8 feet (vertical) of castor oil, having a weight density of 60.5 pounds per cubic foot:

This is how we would set up the formula to calculate for hydrostatic pressure at the bottom of the tank:

$$P = \gamma h$$

$$P = \left( \frac{60.5 \text{ lb}}{\text{ft}^3} \right) (8 \text{ ft})$$

$$P = \frac{484 \text{ lb}}{\text{ft}^2}$$

If we wished to convert this result into a more common unit such as PSI (pounds per square inch), we could do so using an appropriate fraction of conversion units:

$$P = \left( \frac{484 \text{ lb}}{\text{ft}^2} \right) \left( \frac{1 \text{ ft}^2}{144 \text{ in}^2} \right)$$

$$P = \frac{3.36 \text{ lb}}{\text{in}^2} = 3.36 \text{ PSI}$$

### 2.11.3 Fluid density expressions

The *density* of any substance is defined as the ratio of its mass or weight to the volume occupied by that mass or weight. Common expressions of density include pounds per cubic foot (British units) and kilograms per cubic meter (metric units). When the substance in question is a liquid, a common form of expression for density is a ratio of the liquid's density to the density of pure water at standard temperature<sup>65</sup>. This ratio is known as *specific gravity*. For example, the specific gravity of glycerin may be determined by dividing the density of glycerin by the density of water:

$$\begin{aligned}\text{Specific gravity of any liquid} &= \frac{D_{\text{liquid}}}{D_{\text{water}}} \\ \text{Specific gravity of glycerin} &= \frac{D_{\text{glycerin}}}{D_{\text{water}}} = \frac{78.6 \text{ lb/ft}^3}{62.4 \text{ lb/ft}^3} = 1.26\end{aligned}$$

The density of gases may also be expressed in ratio form, except the standard of comparison is ambient air instead of water. Chlorine gas, for example, has a specific gravity of 2.47 (each volumetric unit of chlorine having 2.47 times the mass of the same volume of air under identical temperature and pressure conditions). Specific gravity values for gases are sometimes called *relative gas densities* to avoid confusion with “specific gravity” values for liquids.

As with all ratios, specific gravity is a unitless quantity. In our example with glycerine, we see how the identical units of pounds per cubic foot cancel out of both numerator and denominator, to leave a quotient with no unit at all.

An alternative to expressing fluid density as a ratio of mass (or weight) to volume, or to compare it against the density of a standard fluid such as pure water or air, is to express it as the ratio of volume to mass. This is most commonly applied to vapors such as steam, and it is called *specific volume*. The relationship between specific volume and density is one of mathematical reciprocation: the reciprocal of density (e.g. pounds per cubic foot) is specific volume (e.g. cubic feet per pound). For example, consulting a table of saturated steam properties, we see that saturated steam at a pressure of 60 PSIA has a specific volume of 7.175 cubic feet per pound. Translating this into units of pounds per cubic feet, we reciprocate the value 7.175 to arrive at 0.1394 pounds per cubic foot.

Industry-specific units of measurement also exist for expressing the relative density of a fluid. These units of measurement all begin with the word “degree” much the same as for units of temperature measurement, for example:

- Degrees API (*used in the petroleum industries*)
- Degrees Baumé (*used in a variety of industries including paper manufacture and alcohol production*)
- Degrees Twaddell (*used in the textile industry for tanning solutions and the like*)

---

<sup>65</sup>Usually, this standard temperature is 4 degrees Celsius, the point of maximum density for water. However, sometimes the specific gravity of a liquid will be expressed in relation to the density of water at some other temperature. In some cases specific gravity is expressed for a liquid at one temperature compared to water at another temperature, usually in the form of a superscript such as 20/4 (liquid at 20 degrees Celsius compared to water at 4 degrees Celsius).

The mathematical relationships between each of these “degree” units of density versus specific gravity<sup>66</sup> is as follows:

$$\text{Degrees API} = \frac{141.5}{\text{Specific gravity}} - 131.5$$

$$\text{Degrees Twaddell} = 200 \times (\text{Specific gravity} - 1)$$

Two different formulae exist for the calculation of degrees Baumé, depending on whether the liquid in question is heavier or lighter than water. For lighter-than-water liquids:

$$\text{Degrees Baumé (light)} = \frac{140}{\text{Specific gravity}} - 130$$

Note that pure water would measure 10° Baumé on the light scale. As liquid density decreases, the light Baumé value increases. For heavier-than-water liquids:

$$\text{Degrees Baumé (heavy)} = 145 - \frac{145}{\text{Specific gravity}}$$

Note that pure water would measure 0° Baumé on the heavy scale. As liquid density increases, the heavy Baumé value increases.

Just to make things confusing, there are different standards for the heavy Baumé scale. Instead of the constant value 145 shown in the above equation (used throughout the United States of America), an older Dutch standard used the same formula with a constant value of 144. The *Gerlach* heavy Baumé scale uses a constant value of 146.78:

$$\text{Degrees Baumé (heavy, old Dutch)} = 144 - \frac{144}{\text{Specific gravity}}$$

$$\text{Degrees Baumé (heavy, Gerlach scale)} = 146.78 - \frac{146.78}{\text{Specific gravity}}$$

There exists a seemingly endless array of “degree” scales used to express liquid density, scattered throughout the pages of history. For the measurement of sugar concentrations in the food industries, the unit of degrees *Balling* was invented. This scale was later revised to become the unit of degrees *Brix*, which is directly proportional to the percent concentration of sugar in the liquid. Another density scale used for expressing sugar concentration is degrees *Plato*. The density of tanning liquor may be measured in degrees *Bark*. Milk density may be measured in degrees *Sorhlet*. Vegetable oil density (and in older times, the density of oil extracted from sperm whales) may be measured in degrees *Oleo*.

---

<sup>66</sup>For each of these calculations, specific gravity is defined as the ratio of the liquid’s density at 60 degrees Fahrenheit to the density of pure water, also at 60 degrees Fahrenheit.

### 2.11.4 Manometers

Expressing fluid pressure in terms of a vertical liquid column makes perfect sense when we use a very simple kind of motion-balance pressure instrument called a *manometer*. A manometer is nothing more than a piece of clear (glass or plastic) tubing filled with a liquid of known density, situated next to a scale for measuring distance. The most basic form of manometer is the *U-tube* manometer, shown here:

The basis for all manometers is the mathematical relationship between a liquid's density ( $\rho$  in mass units or  $\gamma$  in weight units) and vertical height. The diameter of the manometer tubes is irrelevant:

$$P = \rho gh$$

$$P = \gamma h$$

Pressure is read on the scale as the difference in height ( $h$ ) between the two liquid columns. One nice feature of a manometer is it really cannot become “uncalibrated” so long as the fluid is pure and the assembly is maintained in an upright position. If the fluid used is water, the manometer may be filled and emptied at will, and even rolled up for storage if the tubes are made of flexible plastic.

We may create even more sensitive manometers by purposely inclining one or more of the tubes, so that the liquid must travel a farther distance along the tube length to achieve the same vertical shift in height. This has the effect of “amplifying” the liquid’s motion to make it easier to resolve small pressures:

*Inclined manometer*

This way, a greater motion of liquid ( $x$ ) is required to generate the same hydrostatic pressure (vertical liquid displacement,  $h$ ) than in an upright manometer, making the inclined manometer more sensitive. As the similar triangle in the illustration shows,  $x$  and  $h$  are related trigonometrically by the sine function:

$$\sin \theta = \frac{h}{x}$$

The difference in fluid column positions measured diagonally along the scale ( $x$ ) must always be greater than the vertical height difference between the two columns ( $h$ ) by a factor of  $\frac{1}{\sin \theta}$ , which will always be greater than one for angles less than  $90^\circ$ . The smaller the angle  $\theta$ , the greater the ratio between  $x$  and  $h$ , leading to more sensitivity.

If even more sensitivity is desired, we may construct something called a *micromanometer*, consisting of a gas bubble trapped in a clear horizontal tube between two large vertical manometer chambers:

*A simple micromanometer*

Pressure applied to the top of either vertical chamber will cause the vertical liquid columns to shift just the same as any U-tube manometer. However, the bubble trapped in the clear horizontal tube will move much farther than the vertical displacement of either liquid column, owing to the huge difference in cross-sectional area between the vertical chambers and the horizontal tube. This amplification of motion is analogous to the amplification of motion in a hydraulic piston system (where the smaller piston moves farther than the larger piston), and makes the micromanometer exceptionally sensitive to small pressures.

The movement of the gas bubble within the clear horizontal viewing tube ( $x$ ) relates to applied pressure by the following formula:

$$x = \frac{\gamma h A_{large}}{2 A_{small}}$$

Using water as the working liquid in a standard U-tube manometer, 1 PSI of applied gas pressure results in approximately 27.7 inches of vertical liquid column displacement (i.e. 27.7 inches of height *difference* between the two water columns). This relatively large range of motion limits the usefulness of water manometers to modest pressures only. If we wished to use a water manometer to measure the pressure of compressed air in an industrial pneumatic supply system at approximately 100 PSI, the manometer would have to be in excess of 230 feet tall! Clearly, a water manometer would not be the proper instrument to use for such an application.

However, water is not the only viable liquid for use in manometers. We could take the exact same clear U-tube and fill it partially full of liquid *mercury* instead, which is substantially denser than water. In a mercury manometer, 1 PSI of applied gas pressure results in very slightly more than 2 inches of liquid column displacement. A mercury manometer applied to the task of measuring air pressure in an industrial pneumatic system would only have to be 17 feet tall – still quite large and cumbersome<sup>67</sup> for a measuring instrument, but not impossible to construct or to use.

<sup>67</sup>A colleague of mine told me once of working in an industrial facility with a very old steam boiler, where boiler

A common form of manometer seen in industrial instrument calibration shops is the *well* type, consisting of a single vertical tube and a relatively large reservoir (called the “well”) acting as the second column:

Due to the well’s much larger cross-sectional area, liquid motion inside of it is negligible compared to the motion of liquid inside the clear viewing tube. For all practical purposes<sup>68</sup>, the liquid level inside the “well” is constant, and so the liquid inside the tube moves the full distance equivalent to the applied pressure. Thus, the well manometer provides an easier means of reading pressure: no longer does one have to measure the difference of height between *two* liquid columns, only the height of a single column.

---

steam pressure was actually indicated by tall mercury manometers reaching from floor to ceiling. Operations personnel had to climb a ladder to accurately read pressure indicated by these manometers!

<sup>68</sup>To give some perspective on just how little the liquid level changes in the well, consider a well-type manometer with a 1/4 inch (inside) diameter viewing tube and a 4-inch diameter circular well. The ratio of diameters for these two liquid columns is 16:1, which means their ratio of areas is 256:1. Thus, for every inch of liquid motion in the viewing tube, the liquid inside the well moves *only*  $\frac{1}{256}$  of an inch. Unless the viewing tube is quite tall, the amount of error incurred by interpreting the tube’s liquid height directly as pressure will be minimal – quite likely less than what the human eye is able to discern on a ruler scale anyway. If the utmost accuracy is desired in a well manometer, however, we may compensate for the trifling motion of liquid in the well by building a custom ruler for the vertical tube – one with a  $\frac{255}{256}$  reduced scale (so that  $\frac{255}{256}$  of an inch of liquid motion in the tube reads as exactly 1 inch of liquid column) in the case of the 1/4 inch tube and 4 inch well dimensions.

### 2.11.5 Systems of pressure measurement

Pressure measurement is often a relative thing. When we say there is 35 PSI of air pressure in an inflated car tire, what we mean is that the pressure inside the tire is 35 pounds per square inch *greater than* the surrounding, ambient air pressure. It is a fact that we live and breathe in a pressurized environment. Just as a vertical column of liquid generates a hydrostatic pressure, so does a vertical column of gas. If the column of gas is very tall, the pressure generated by it will be substantial. Such is the case with Earth’s atmosphere, the pressure at sea level caused by the weight of the atmosphere being approximately 14.7 PSI.

You and I do not perceive this constant air pressure around us because the pressure inside our bodies is equal to the pressure outside our bodies. Thus our eardrums, which serve as differential pressure-sensing diaphragms, detect no *difference* of pressure between the inside and outside of our bodies. The only time the Earth’s air pressure becomes perceptible to us is if we rapidly ascend or descend, where the pressure inside our bodies does not have time to equalize with the pressure outside, and we feel the force of that differential pressure on our eardrums.

If we wish to speak of a fluid pressure in terms of how it compares to a perfect vacuum (absolute zero pressure), we specify it in terms of *absolute* units. For example, when I said earlier that the atmospheric pressure at sea level was 14.7 PSI, what I really meant is it is 14.7 PSIA (pounds per square inch *absolute*), meaning 14.7 pounds per square inch *greater than a perfect vacuum*. When I said earlier that the air pressure inside an inflated car tire was 35 PSI, what I really meant is it was 35 PSIG (pounds per square inch *gauge*), meaning 35 pounds per square inch *greater than ambient air pressure*. The qualifier “gauge” implies the pressure indicated by a pressure-measuring gauge, which in most cases works by comparing the sample fluid’s pressure to that of the surrounding atmosphere. When units of pressure measurement are specified without a “G” or “A” suffix, “gauge” pressure is usually<sup>69</sup> assumed.

---

<sup>69</sup>With few exceptions!

Gauge and absolute pressure values for some common fluid pressures are shown in this table:

Gauge pressure	Fluid example	Absolute pressure
90 PSIG	Bicycle tire air pressure	104.7 PSIA
35 PSIG	Automobile tire air pressure	49.7 PSIA
0 PSIG	Atmospheric pressure at sea level	14.7 PSIA
−9.8 PSIG (9.8 PSI vacuum)	Engine manifold vacuum under idle conditions	4.9 PSIA
−14.7 PSIG (14.7 PSI vacuum)	Perfect vacuum (no fluid molecules present)	0 PSIA

Note that the only difference between each of the corresponding *gauge* and *absolute* pressures is an offset of 14.7 PSI, with absolute pressure being the larger (more positive) value.

This offset of 14.7 PSI between *absolute* and *gauge* pressures can be confusing if we must convert between different pressure units. Suppose we wished to express the tire pressure of 35 PSIG in units of inches of water column ("W.C.). If we stay in the gauge-pressure scale, all we have to do is multiply by 27.68:

$$\frac{35 \text{ PSI}}{1} \times \frac{27.68 \text{ "W.C.}}{1 \text{ PSI}} = 968.8 \text{ "W.C.}$$

Note how the fractions have been arranged to facilitate cancellation of units. The "PSI" unit in the numerator of the first fraction cancels with the "PSI" unit in the denominator of the second fraction, leaving inches of water column ("W.C.) as the only unit standing. Multiplying the first fraction (35 PSI over 1) by the second fraction (27.68 "W.C. over 1 PSI) is "legal" to do since the second fraction has a *physical* value of unity (1): being that 27.68 inches of water column is the same physical pressure as 1 PSI, the second fraction is really the number "1" in disguise. As we know, multiplying any quantity by unity does not change its value, so the result of 968.8 "W.C. we get has the exact same physical meaning as the original figure of 35 PSI. This technique of unit conversion is sometimes known as *unity fractions*, and it is discussed in more general terms in another section of this book (refer to section 2.4 beginning on page 60).

If, however, we wished to express the car's tire pressure in terms of inches of water column *absolute* (in reference to a perfect vacuum), we would have to include the 14.7 PSI offset in our calculation, and do the conversion in two steps:

$$35 \text{ PSIG} + 14.7 \text{ PSI} = 49.7 \text{ PSIA}$$

$$\frac{49.7 \text{ PSIA}}{1} \times \frac{27.68 \text{ "W.C.A}}{1 \text{ PSIA}} = 1375.7 \text{ "W.C.A}$$

The ratio between inches of water column and pounds per square inch is still the same (27.68:1) in the absolute scale as it is in the gauge scale. The only difference is that we included the 14.7 PSI offset in the very beginning to express the tire's pressure on the absolute scale rather than on the gauge scale. From then on, all conversions were performed in absolute units.

This two-step conversion process is not unlike converting between different units of temperature (degrees Celsius versus degrees Fahrenheit), and for the exact same reason. To convert from °F to

$^{\circ}\text{C}$ , we must first *subtract* an offset of 32 degrees, then *multiply* by  $\frac{5}{9}$ . The reason an offset is involved in this temperature conversion is because the two temperature scales do not share the same “zero” point:  $0^{\circ}\text{C}$  is *not* the same temperature as  $0^{\circ}\text{F}$ . Likewise, 0 PSIG is *not* the same pressure as 0 PSIA, and so an offset is always necessary to convert between gauge and absolute pressure units.

As seen with the unit of pounds per square inch (PSI), the distinction between gauge and absolute pressure is typically shown by a lettered suffix “G” or “A” following the unit, respectively. Following this convention, we may encounter other units of pressure measurement qualified as either gauge or absolute by these letters: kPaA (kilopascals absolute), inches HgG (inches of mercury gauge), inches W.C.A (inches of water column absolute), etc.

There are some pressure units that are *always* in absolute terms, and as such require no letter “A” to specify. One is the unit of *atmospheres*, 1 atmosphere being 14.7 PSIA. There is no such thing as “atmospheres gauge” pressure. For example, if we were given a pressure as being 4.5 atmospheres and we wanted to convert that into pounds per square inch gauge (PSIG), the conversion would be a two-step process:

$$\frac{4.5 \text{ atm}}{1} \times \frac{14.7 \text{ PSIA}}{1 \text{ atm}} = 66.15 \text{ PSIA}$$

$$66.15 \text{ PSIA} - 14.7 \text{ PSI} = 51.45 \text{ PSIG}$$

Another unit of pressure measurement that is always absolute is the *torr*, equal to 1 millimeter of mercury column absolute (mmHgA). 0 torr is absolute zero, equal to 0 atmospheres, 0 PSIA, or  $-14.7$  PSIG. Atmospheric pressure at sea level is 760 torr, equal to 1 atmosphere, 14.7 PSIA, or 0 PSIG.

If we wished to convert the car tire’s pressure of 35 PSIG into torr, we would once again have to offset the initial value to get everything into absolute terms.

$$35 \text{ PSIG} + 14.7 \text{ PSI} = 49.7 \text{ PSIA}$$

$$\frac{49.7 \text{ PSIA}}{1} \times \frac{760 \text{ torr}}{14.7 \text{ PSIA}} = 2569.5 \text{ torr}$$

One last unit of pressure measurement deserves special comment, for it may be used to express either gauge or absolute pressure, yet it is *not* customary to append a “G” or an “A” to the unit. This unit is the *bar*, exactly equal to 100 kPa, and approximately equal<sup>70</sup> to 14.5 PSI. Some technical references append a lower-case letter “g” or “a” to the word “bar” to show either gauge pressure (*barg*) or absolute pressure (*bara*), but this notation seems no longer favored. Modern usage typically omits the “g” or “a” suffix in favor of context: the word “gauge” or “absolute” may be included in the expression to clarify the meaning of “bar.” Sadly, many references fail to explicitly declare either “gauge” or “absolute” when using units of *bar*, leaving the reader to interpret the intended context. Despite this ambiguity, the *bar* is frequently used in European literature as a unit of pressure measurement.

<sup>70</sup>The origin of this unit for pressure is the atmospheric pressure at sea level: 1 atmosphere, or 14.7 PSIA. The word “bar” is short for *barometric*, in reference to Earth’s ambient atmospheric pressure.

### 2.11.6 Negative pressure

If a chamber is completely evacuated of any and all fluid molecules such that it contains nothing but empty space, we say that it contains a perfect *vacuum*. With no fluid molecules inside the chamber whatsoever, there will be no pressure exerted on the chamber walls by any fluid. This is the defining condition of zero absolute pressure (e.g. 0 PSIA, 0 torr, 0 atmospheres, etc.). Referencing atmospheric air pressure<sup>71</sup> outside of this vessel, we could say that the “gauge” pressure of a perfect vacuum is  $-14.7$  PSIG.

A commonly-taught principle is that a perfect vacuum is the lowest pressure possible in any physical system. However, this is not strictly true. It is, in fact, possible to generate pressures *below* 0 PSIA – pressures that are actually *less* than that of a perfect vacuum. The key to understanding this is to consider non-gaseous systems, where the pressure in question exists within a solid or a liquid substance.

Let us begin our exploration of this concept by considering the case of weight applied to a solid metal bar:

Recall that pressure is defined as force exerted over area. This metal bar certainly has a cross-sectional area, and if a compressive force is applied to the bar then the molecules of metal inside the bar will experience a pressure attempting to force them closer together. Supposing the bar in question measured 1.25 inches wide and thick, its cross-sectional area would be  $(1.25 \text{ in})^2$ , or  $1.5625 \text{ in}^2$ . Applying a force of 80 pounds along the bar's length would set up an internal pressure within the bar of 51.2 pounds per square inch, or 51.2 PSI:

<sup>71</sup>At sea level, where the absolute pressure is 14.7 PSIA. Atmospheric pressure will be different at different elevations above (or below) sea level.

Now suppose we reverse the direction of the applied force to the bar, applying *tension* to the bar rather than *compression*. If the force is still 80 pounds and the cross-sectional area is still 1.5625 square inches, then the internal pressure inside the bar must be  $-51.2$  PSI:

The negative pressure value describes the tensile force experienced by the molecules of metal inside the bar: a degree of force per unit area attempting to pull those molecules apart from each other rather than push them closer together as was the case with a compressive force.

If you believe that the lowest possible pressure is a perfect vacuum (0 PSIA, or  $-14.7$  PSIG), then this figure of  $-51.2$  PSI seems impossible. However, it is indeed possible because we are dealing with a solid rather than with a gas. Gas molecules exert pressure on a surface by striking that surface and exerting a force by the momentum of their impact. Since gas molecules can only strike (i.e. *push*) against a surface, and cannot *pull* against a surface, one cannot generate a negative absolute pressure using a gas. In solids, however, the molecules comprising the sample exhibit *cohesion*, allowing us to set up a tension within that material impossible in a gaseous sample where there is no cohesion between the molecules. Thus, negative pressures are possible within samples of solid material even though they are impossible within gases.

Negative pressures are also possible within *liquid* samples, provided there are no bubbles of gas or vapor anywhere within the sample. Like solids, the molecules within a liquid also exhibit cohesion (i.e. they tend to “stick” together rather than drift apart from each other). If a piston-and-cylinder arrangement is completely filled with liquid, and a tension applied to the movable piston, the molecules within that liquid will experience tension as well. Thus, it is possible to generate negative pressures (below 0 PSIA) within liquids that are impossible with gases.

Even vertical columns of liquid may generate negative pressure. The famous British scientists Hooke and Boyle demonstrated a negative pressure of  $-0.2$  MPa ( $-29$  PSI) using a column of liquid mercury. Trees naturally generate huge negative pressures in order to draw water to their full height, up from the ground. Two scientists, H.H. Dixon and J. Joly, presented a scientific paper entitled *On the Ascent of Sap* in 1895 proposing liquid tension as the mechanism by which trees could draw water up tremendous heights.

If even the smallest bubble of gas exists within a liquid sample, however, negative pressures become impossible. Since gases can only exert positive pressures, and Pascal’s Principle tells us that pressure will be equally distributed throughout a fluid sample, the low-limit of 0 PSIA for gases establishes a low pressure limit for the entire liquid/gas sample. In other words, the presence of any gas within an otherwise liquid sample prevents the entire sample from experiencing tension.

One limitation to the generation of negative pressures within liquids is that disturbances and/or impurities within the liquid may cause that liquid to spontaneously boil (changing phase from liquid to vapor), at which point a sustained negative pressure becomes impossible.

### 2.11.7 Buoyancy

When a solid body is immersed in a fluid, it *displaces* an equal volume of that fluid. This displacement of fluid generates an upward force on the object called the *buoyant force*. The magnitude of this force is equal to the weight of the fluid displaced by the solid body, and it is always directed exactly opposite the line of gravitational attraction. This is known as *Archimedes' Principle*.

Buoyant force is what makes ships float. A ship sinks into the water just enough so the weight of the water displaced is equal to the total weight of the ship and all it holds (cargo, crew, food, fuel, etc.):

If we could somehow measure the weight of that water displaced, we would find it exactly equals the dry weight of the ship:

Expressed mathematically, Archimedes' Principle states that the buoyant force is the product of the liquid volume and liquid density:

$$F_{\text{buoyant}} = \gamma V$$

Where,

$F_b$  = Buoyant force exerted on object, opposite in direction from gravity

$\gamma$  = Weight density of liquid

$V$  = Volume of liquid displaced by the submerged object

We may use dimensional analysis to confirm correct cancellation of British units in the Archimedes' Principle formula:

$$F_{\text{buoyant}} = \gamma V$$

$$[\text{lb}] = \frac{[\text{lb}]}{[\text{ft}^3]} [\text{ft}^3]$$

Notice how the units of measurement for weight density (pounds per cubic foot) combine with the unit of measurement for volume (cubic feet) to cancel the unit of cubic feet and leave us with force measured in pounds.

Archimedes' Principle also explains why hot-air balloons and helium aircraft float. By filling a large enclosure with a gas that is less dense than the surrounding air, that enclosure experiences an upward (buoyant) force equal to the difference between the weight of the air displaced and the weight of the gas enclosed. If this buoyant force equals the weight of the craft and all it holds (cargo, crew, food, fuel, etc.), it will exhibit an apparent weight of zero, which means it will float. If the buoyant force exceeds the weight of the craft, the resultant force will cause an upward acceleration according to Newton's Second Law of motion ( $F = ma$ ).

Submarines also make use of Archimedes' Principle, adjusting their buoyancy by adjusting the amount of water held by *ballast tanks* on the hull. Positive buoyancy is achieved by "blowing" water out of the ballast tanks with high-pressure compressed air, so the submarine weighs less (but still occupies the same hull volume and therefore displaces the same amount of water). Negative buoyancy is achieved by "flooding" the ballast tanks so the submarine weighs more. Neutral buoyancy is when the buoyant force exactly equals the weight of the submarine and the remaining water stored in the ballast tanks, so the submarine is able to "hover" in the water with no vertical acceleration or deceleration.

An interesting application of Archimedes' Principle is the quantitative determination of an object's density by submersion in a liquid. For instance, copper is 8.96 times as dense as water, with a mass of 8.96 grams per cubic centimeter ( $8.96 \text{ g/cm}^3$ ) as opposed to water at 1.00 gram per cubic centimeter ( $1.00 \text{ g/cm}^3$ ). If we had a sample of pure, solid copper exactly 1 cubic centimeter in volume, it would have a mass of 8.96 grams. Completely submerged in pure water, this same sample of solid copper would appear to have a mass of only 7.96 grams, because it would experience a buoyant force equivalent to the mass of water it displaces (1 cubic centimeter = 1 gram of water). Thus, we see that the difference between the dry mass (mass measured in air) and the wet mass (mass measured when completely submerged in water) is the mass of the water displaced. Dividing the sample's dry mass by this mass difference (dry – wet mass) yields the ratio between the sample's mass and the mass of an equivalent volume of water, which is the very definition of specific gravity. The same calculation yields a quantity for specific gravity if *weights* instead of *masses* are used, since weight is nothing more than mass multiplied by the acceleration of gravity ( $F_{\text{weight}} = mg$ ), and the constant  $g$  cancels out of both numerator and denominator:

$$\text{Specific Gravity} = \frac{m_{\text{dry}}}{m_{\text{dry}} - m_{\text{wet}}} = \frac{m_{\text{dry}}g}{m_{\text{dry}}g - m_{\text{wet}}g} = \frac{\text{Dry weight}}{\text{Dry weight} - \text{Wet weight}}$$

Another application of Archimedes' Principle is the use of a *hydrometer* for measuring liquid density. If a narrow cylinder of precisely known volume and weight (most of the weight concentrated at one end) is immersed in liquid, that cylinder will sink to a level dependent on the liquid's density. In other words, it will sink to a level sufficient to displace its own weight in fluid. Calibrated marks made along the cylinder's length may then serve to register liquid density in any unit desired.

A simple style of hydrometer used to measure the density of lead-acid battery electrolyte is shown in this illustration:

To use this hydrometer, you must squeeze the rubber bulb at the top and dip the open end of the tube into the liquid to be sampled. Relaxing the rubber bulb will draw a sample of liquid up into the tube where it immerses the float. When enough liquid has been drawn into the tube to suspend the float so that it neither rests on the bottom of the tapered glass tube or "tops out" near the bulb, the liquid's density may be read at the air/liquid interface.

A denser electrolyte liquid results in the float rising to a higher level inside the hydrometer tube:

Like all floating objects, the hydrometer float naturally seeks a condition of neutral buoyancy where the weight of the displaced liquid exactly equals the dry weight of the float. If the liquid happens to be very dense, the float will not have to sink very far in order to achieve neutral buoyancy; the less dense the liquid, the deeper the float must sink in order to achieve neutral buoyancy.

This means the float's graduated density scale will read less density toward the top and greater density toward the bottom.

The following photograph shows a set of antique hydrometers used to measure the density of beer. The middle hydrometer bears a label showing its calibration to be in degrees Baumé (heavy):

Liquid density measurement is useful in the alcoholic beverage industry to infer alcohol content. Since alcohol is less dense than water, a sample containing a greater concentration of alcohol (a greater *proof* rating) will be less dense than a “weaker” sample, all other factors being equal.

A less sophisticated version of hydrometer uses multiple balls of differing density. A common application for such a hydrometer is measuring the concentration of “antifreeze” coolant for automobile engines, comprised of a mixture of ethylene glycol and water. Ethylene glycol is a denser compound than water, and so a “stronger” mixture of antifreeze will have a greater bulk density than a “weaker” density of antifreeze. This style of hydrometer yields a crude measurement of ethylene glycol concentration based on the number of balls that float:

A greater number of floating balls represents a “stronger” concentration of glycol in the coolant. “Weak” glycol concentrations represent a greater percentage of water in the coolant, with a correspondingly higher freezing temperature.

Similar hydrometers are used to measure the concentration of sulfuric acid in lead-acid battery electrolyte, comprised of acid and water. The more fully charged a lead-acid battery is, the higher the concentration of sulfuric acid in the electrolyte fluid. The more discharged a lead-acid battery becomes, the less sulfuric acid (and the more water) is present in the electrolyte. Since sulfuric acid is a denser compound than water, measuring electrolyte density with a hydrometer yields a crude measurement of battery charge state.

### 2.11.8 Gas Laws

The *Ideal Gas Law* relates pressure, volume, molecular quantity, and temperature of an ideal gas together in one concise mathematical expression:

$$PV = nRT$$

Where,

$P$  = Absolute pressure (atmospheres)

$V$  = Volume (liters)

$n$  = Gas quantity (moles)

$R$  = Universal<sup>72</sup> gas constant (0.0821 L · atm / mol · K)

$T$  = Absolute temperature (K)

For example, the Ideal Gas Law predicts five moles of helium gas (20 grams worth) at a pressure of 1.4 atmospheres and a temperature of 310 Kelvin will occupy 90.9 liters of volume.

An alternative form of the Ideal Gas Law uses the number of actual gas molecules ( $N$ ) instead of the number of moles of molecules ( $n$ ):

$$PV = NkT$$

Where,

$P$  = Absolute pressure (Pascals)

$V$  = Volume (cubic meters)

$N$  = Gas quantity (molecules)

$k$  = Boltzmann's constant ( $1.38 \times 10^{-23}$  J / K)

$T$  = Absolute temperature (K)

Interestingly, the Ideal Gas Law holds true for *any* gas. The theory behind this assumption is that gases are mostly empty space: there is far more volume of empty space *separating* individual gas molecules in a sample than there is space *occupied* by the gas molecules themselves. This means variations in the sizes of individual gas molecules within any sample is negligible, and therefore the type of gas molecules contained within the sample is irrelevant. Thus, we may apply either form of the Ideal Gas Law to situations regardless of the type of gas involved. This is also why the Ideal Gas Law does *not* apply to liquids or to phase changes (e.g. liquids boiling into gas): only in the gaseous phase will you find individual molecules separated by relatively large distances.

To modify the previous example, where 5 moles of helium gas occupied 90.9 liters at 1.4 atmospheres and 310 Kelvin, it is also true that 5 moles of *nitrogen* gas will occupy the same volume (90.9 liters) at 1.4 atmospheres and 310 Kelvin. The only difference will be the *mass* of each gas sample. 5 moles of helium gas ( $^4\text{He}$ ) will have a mass of 20 grams, whereas 5 moles of nitrogen gas ( $^{14}\text{N}_2$ ) will have a mass of 140 grams.

Although no gas in real life is ideal, the Ideal Gas Law is a close approximation for conditions of modest gas density, and no phase changes (gas turning into liquid or vice-versa). You will find this

---

<sup>72</sup>It should be noted that many different values exist for  $R$ , depending on the units of measurement. For liters of volume, atmospheres of pressure, moles of substance, and Kelvin for temperature,  $R = 0.0821$ . If one prefers to work with different units of measurement for volume, pressure, molecular quantity, and/or temperature, different values of  $R$  are available.

Law appearing again and again in calculations of gas volume and gas flow rates, where engineers and technicians must know the relationship between gas volume, pressure, and temperature.

Since the molecular quantity of an enclosed gas is constant, and the universal gas constant *must* be constant, the Ideal Gas Law may be written as a proportionality instead of an equation:

$$PV \propto T$$

Several “gas laws” are derived from this proportionality. They are as follows:

$$PV = \text{Constant} \quad \textbf{Boyle's Law} \text{ (assuming constant temperature } T\text{)}$$

$$V \propto T \quad \textbf{Charles's Law} \text{ (assuming constant pressure } P\text{)}$$

$$P \propto T \quad \textbf{Gay-Lussac's Law} \text{ (assuming constant volume } V\text{)}$$

You will see these laws referenced in explanations where the specified quantity is constant (or very nearly constant).

For non-ideal conditions, the “Real” Gas Law formula incorporates a corrected term for the *compressibility* of the gas:

$$PV = ZnRT$$

Where,

$P$  = Absolute pressure (atmospheres)

$V$  = Volume (liters)

$Z$  = Gas compressibility factor (unitless)

$n$  = Gas quantity (moles)

$R$  = Universal gas constant (0.0821 L · atm / mol · K)

$T$  = Absolute temperature (K)

The compressibility factor for an ideal gas is unity ( $Z = 1$ ), making the Ideal Gas Law a limiting case of the Real Gas Law. Real gases have compressibility factors less than unity ( $< 1$ ). What this means is real gases tend to compress more than the Ideal Gas Law would predict (i.e. occupies less volume for a given amount of pressure than predicted, and/or exerts less pressure for a given volume than predicted).

### 2.11.9 Fluid viscosity

*Viscosity* is a measure of a fluid's resistance to shear. It may be visualized as a sort of internal friction, where individual fluid molecules experience either cohesion or collision while flowing past one another. The more “viscous” a fluid is, the “thicker” it is when stirred. Clean water is an example of a low-viscosity liquid, while liquid honey at room temperature is an example of a high-viscosity liquid.

There are two different ways to quantify the viscosity of a fluid: *absolute viscosity* and *kinematic viscosity*. Absolute viscosity (symbolized by the Greek symbol “eta”  $\eta$ , or sometimes by the Greek symbol “mu”  $\mu$ ), also known as *dynamic viscosity*, is a direct relation between stress placed on a fluid and its rate of deformation (or shear). The textbook definition of absolute viscosity is based on a model of two flat plates moving past each other with a film of fluid separating them. The relationship between the shear stress applied to this fluid film (force divided by area) and the velocity/film thickness ratio is viscosity:

$$\eta = \frac{FL}{Av}$$

Where,

$\eta$  = Absolute viscosity (pascal-seconds), also symbolized as  $\mu$

$F$  = Force (newtons)

$L$  = Film thickness (meters) – typically *much* less than 1 meter for any realistic demonstration!

$A$  = Plate area (square meters)

$v$  = Relative velocity (meters per second)

Another common unit of measurement for absolute viscosity is the *poise*, with 1 poise being equal to 0.1 pascal-seconds. Both units are too large for common use, and so absolute viscosity is often expressed in *centipoise*. Water has an absolute viscosity of very nearly 1.000 centipoise.

Kinematic viscosity (symbolized by the Greek letter “nu”  $\nu$ ) includes an assessment of the fluid’s density in addition to all the above factors. It is calculated as the quotient of absolute viscosity and mass density:

$$\nu = \frac{\eta}{\rho}$$

Where,

$\nu$  = Kinematic viscosity (stokes)

$\eta$  = Absolute viscosity (poise)

$\rho$  = Mass density (grams per cubic centimeter)

As with the unit of poise, the unit of stokes is too large for convenient use, so kinematic viscosities are often expressed in units of *centistokes*. Water has a kinematic viscosity of very nearly 1.000 centistokes.

The mechanism of viscosity in liquids is inter-molecular *cohesion*. Since this cohesive force is overcome with increasing temperature, most liquids tend to become “thinner” (less viscous) as they heat up. The mechanism of viscosity in gases, however, is inter-molecular *collisions*. Since these collisions increase in frequency and intensity with increasing temperature, gases tend to become “thicker” (more viscous) as they heat up.

As a ratio of stress to strain (applied force to yielding velocity), viscosity is often constant for a given fluid at a given temperature. Interesting exceptions exist, though. Fluids whose viscosities change with applied stress, and/or over time with all other factors constant, are referred to as *non-Newtonian fluids*. A simple example of a non-Newtonian fluid is cornstarch mixed with water, which “solidifies” under increasing stress and then returns to a liquid state when the stress is removed.

### 2.11.10 Reynolds number

*Viscous flow* is a condition where friction forces dominate the behavior of a moving fluid, typically in cases where viscosity (internal fluid friction) is great. *Inviscid flow*, by contrast, is a condition where friction within a moving fluid is negligible and the fluid moves freely. The *Reynolds number* of a fluid is a dimensionless quantity expressing the ratio between a moving fluid's momentum and its viscosity, and is a helpful gauge in predicting how a fluid stream will move.

A couple of formulae for calculating Reynolds number of a flow are shown here:

$$\text{Re} = \frac{D\bar{v}\rho}{\mu}$$

Where,

Re = Reynolds number (unitless)

$D$  = Diameter of pipe, (meters)

$\bar{v}$  = Average velocity of fluid (meters per second)

$\rho$  = Mass density of fluid (kilograms per cubic meter)

$\mu$  = Absolute viscosity of fluid (pascal-seconds)

$$\text{Re} = \frac{(3160)G_fQ}{D\mu}$$

Where,

Re = Reynolds number (unitless)

$G_f$  = Specific gravity of liquid (unitless)

$Q$  = Flow rate (gallons per minute)

$D$  = Diameter of pipe (inches)

$\mu$  = Absolute viscosity of fluid (centipoise)

3160 = Conversion factor for British units

The first formula, with all metric units, is the textbook “definition” for Reynolds number. If you take the time to dimensionally analyze this formula, you will find that all units do indeed cancel to leave the Reynolds number unitless:

$$\text{Re} = \frac{D\bar{v}\rho}{\mu}$$

$$\text{Re} = \frac{[\text{m}] \left[ \frac{\text{m}}{\text{s}} \right] \left[ \frac{\text{kg}}{\text{m}^3} \right]}{[\text{Pa} \cdot \text{s}]}$$

Recalling that the definition of a “pascal” is one Newton of force per square meter:

$$\text{Re} = \frac{\left[ \frac{\text{kg}}{\text{m} \cdot \text{s}} \right]}{\left[ \frac{\text{N} \cdot \text{s}}{\text{m}^2} \right]}$$

$$\text{Re} = \left[ \frac{\text{kg}}{\text{m} \cdot \text{s}} \right] \cdot \left[ \frac{\text{m}^2}{\text{N} \cdot \text{s}} \right]$$

$$\text{Re} = \left[ \frac{\text{kg} \cdot \text{m}}{\text{N} \cdot \text{s}^2} \right]$$

Recalling that the definition of a “newton” is one kilogram times meters per second squared (from Newton’s Second Law equation  $F = ma$ ):

$$\text{Re} = \left[ \frac{\text{kg} \cdot \text{m} \cdot \text{s}^2}{\text{kg} \cdot \text{m} \cdot \text{s}^2} \right]$$

$$\text{Re} = \text{unitless}$$

The second formula given for calculating Reynolds number includes a conversion constant of 3160, which bears the unwieldy unit of “inches-centipoise-minutes per gallon” in order that the units of all variables (flow in gallons per minute, pipe diameter in inches, and viscosity in centipoise) may cancel. Note that specific gravity ( $G_f$ ) is unitless and therefore does not appear in this dimensional analysis:

$$\text{Re} = \frac{(3160)G_f Q}{D\mu}$$

$$\text{Re} = \frac{\left[ \frac{\text{in} \cdot \text{cp} \cdot \text{min}}{\text{gal}} \right] \left[ \frac{\text{gal}}{\text{min}} \right]}{[\text{in} \cdot \text{cp}]}$$

$$\text{Re} = \text{unitless}$$

You will often find this formula, and the conversion constant of 3160, shown without units at all. Its sole purpose is to make the calculation of Reynolds number easy when working with British units customary in the United States.

The Reynolds number of a fluid stream may be used to qualitatively predict whether the flow regime will be *laminar* or *turbulent*. Low Reynolds number values predict laminar (viscous) flow, where fluid molecules move in straight “stream-line” paths, and fluid velocity near the center of the pipe is substantially greater than near the pipe walls:

High Reynolds number values predict turbulent (inviscid) flow, where individual molecule motion is chaotic on a microscopic scale, and fluid velocities across the face of the flow profile are similar:

It should be emphasized that this turbulence is microscopic in nature, and occurs even when the fluid flows through a piping system free of obstructions, rough surfaces, and/or sudden directional changes. At high Reynolds number values, turbulence simply *happens*.

Other forms of turbulence, such as *eddies* and *swirl* are possible at high Reynolds numbers, but are caused by disturbances in the flow stream such as pipe elbows, tees, control valves, thermowells, and other irregular surfaces. The “micro-turbulence” naturally occurring at high Reynolds numbers will actually randomize such macroscopic (large-scale) motions if the fluid subsequently passes through a long enough length of straight pipe.

Turbulent flow is actually the desired condition for many industrial processes. When different fluids must be mixed together, for example, laminar flow is a bad thing: only turbulent flow will guarantee thorough mixing. The same is true for convective heat exchange: in order for two fluids to effectively exchange heat energy within a heat exchanger, the flow must be turbulent so that molecules from all portions of the flow stream will come into contact with the exchanger walls. Many types of flowmeters require a condition called *fully-developed turbulent flow*, where the flow profile is relatively flat and the only turbulence is that existing on a microscopic scale. Large-scale disturbances in the flow profile such as eddies and swirl tend to negatively affect the measurement performance of many flowmeter designs. This is why such flowmeters usually require long lengths of “straight-run” piping both upstream and downstream: to give micro-turbulence the opportunity to randomize any large-scale motions and homogenize the velocity profile.

A generally accepted rule-of-thumb is that Reynolds number values less than 2000 will probably be laminar, while values in excess of 10000 will probably be turbulent. There is no definite threshold value for all fluids and piping configurations, though. To illustrate, I will share with you some examples of Reynolds number thresholds for laminar versus turbulent flows given by various technical sources:

Chapter 2.8: Laminar Flowmeters of the *Instrument Engineers' Handbook, Process Measurement and Analysis, Third Edition* (pg. 105 – authors: R. Siev, J.B. Arant, B.G. Lipták) define  $Re < 2000$  as “laminar” flow,  $Re > 10000$  as “fully developed turbulent” flow, and any Reynolds number values between 2000 and 10000 as “transitional” flow.

Chapter 2: Fluid Properties – Part II of the *ISA Industrial Measurement Series – Flow* (pg. 11) define “laminar” flow as  $Re < 2000$ , “turbulent” flow as  $Re > 4000$ , and any Reynolds values in between 2000 and 4000 as “transitional” flow.

The Laminar Flow in a Pipe section in the *Standard Handbook of Engineering Calculations* (pg. 1-202) defines “laminar” flow as  $Re < 2100$ , and “turbulent” flow as  $Re > 3000$ . In a later section of that *same book* (Piping and Fluid Flow – page 3-384), “laminar” flow is defined as  $Re < 1200$  and “turbulent” flow as  $Re > 2500$ .

Douglas Giancoli, in his physics textbook *Physics* (third edition, pg. 11), defines “laminar” flow as  $Re < 2000$  and “turbulent” flow as  $Re > 2000$ .

Finally, a source on the Internet (<http://flow.netfirms.com/reynolds/theory.htm>) attempts to define the threshold separating laminar from turbulent flow to an unprecedented degree of precision:  $Re < 2320$  is supposedly the defining point of “laminar” flow, while  $Re > 2320$  is supposedly marks the onset of “turbulent” flow.

Clearly, Reynolds number alone is insufficient for consistent prediction of laminar or turbulent flow, otherwise we would find far greater consistency in the reported Reynolds number values for each regime. Pipe roughness, swirl, and other factors influence flow regime, making Reynolds number an approximate indicator only. It should be noted that laminar flow may be sustained at Reynolds numbers significantly in excess of 10000 under very special circumstances. For example, in certain coiled capillary tubes, laminar flow may be sustained all the way up to  $Re = 15000$ , due to a phenomenon known as the *Dean effect*!

### 2.11.11 Law of Continuity

Any fluid moving through a pipe obeys the Law of Continuity, which states that the product of average velocity ( $\bar{v}$ ), pipe cross-sectional area ( $A$ ), and fluid density ( $\rho$ ) for a given flow stream must remain constant:

$$\rho_1 A_1 \bar{v}_1 = \rho_2 A_2 \bar{v}_2 = \cdots \rho_n A_n \bar{v}_n$$

Fluid continuity is an expression of a more fundamental law of physics: the *Conservation of Mass*. If we assign appropriate units of measurement to the variables in the continuity equation, we see that the units cancel in such a way that only units of mass per unit time remain:

$$\rho A \bar{v} = \left[ \frac{\text{kg}}{\text{m}^3} \right] \left[ \frac{\text{m}^2}{1} \right] \left[ \frac{\text{m}}{\text{s}} \right] = \left[ \frac{\text{kg}}{\text{s}} \right]$$

This means we may define the product  $\rho A \bar{v}$  as an expression of *mass flow rate*, or  $W$ :

$$W = \rho A \bar{v}$$

In order for the product  $\rho A \bar{v}$  to differ between any two points in a pipe, mass would have to mysteriously appear and disappear. So long as the flow is continuous (not pulsing), and the pipe does not leak, it is impossible to have different rates of mass flow at different points along the flow path without violating the Law of Mass Conservation. The continuity principle for fluid through a pipe is analogous to the principle of current being the same everywhere in a series-connected electric circuit, and for equivalently the same reason<sup>73</sup>.

<sup>73</sup>The conservation law necessitating equal current at all points in a series electric circuit is the *Law of Charge Conservation*, which states that electric charges cannot be created or destroyed.

We refer to a flowing fluid as *incompressible* if its density does not substantially change with modest changes in pressure<sup>74</sup>. For this limiting case,  $\rho$  is constant and the continuity equation simplifies to the following form:

$$A_1 \bar{v}_1 = A_2 \bar{v}_2$$

Examining this equation in light of dimensional analysis, we see that the product  $A\bar{v}$  is also an expression of flow rate:

$$A\bar{v} = \left[ \frac{\text{m}^2}{1} \right] \left[ \frac{\text{m}}{\text{s}} \right] = \left[ \frac{\text{m}^3}{\text{s}} \right]$$

Cubic meters per second is an expression of *volumetric flow rate*, often symbolized by the variable  $Q$ :

$$Q = A\bar{v}$$

The practical implication of this principle is that fluid velocity is inversely proportional to the cross-sectional area of a pipe. That is, fluid slows down when the pipe's diameter expands, and vice-versa. We readily see this principle manifest in the natural world: rivers run slowest where they are deep and wide, and run fastest where they are shallow and narrow.

More specifically, we may say that the average velocity of a fluid through a pipe varies inversely with the square of the diameter, since cross-sectional area is proportional to the square of the pipe diameter. For example, if fluid flows at a velocity of 2 feet per second through a 12-inch pipe, and that pipe extends to a narrower section only 6 inches (half the diameter of the wide section), the velocity at the narrower section will be *four times* as great (8 feet per second), since the area of that skinnier section is one-quarter the area of the wider section.

---

<sup>74</sup>Although not grammatically correct, this is a common use of the word in discussions of fluid dynamics. By definition, something that is “incompressible” *cannot* be compressed, but that is not how we are using the term here. We commonly use the term “incompressible” to refer to either a moving liquid (in which case the actual compressibility of the liquid is inconsequential) or a gas/vapor that *does not happen to undergo substantial compression or expansion as it flows through a pipe*. In other words, an “incompressible” flow is a moving fluid whose  $\rho$  does not substantially change, whether by actual impossibility or by circumstance.

For example, consider a pipe with an inside diameter of 8 inches (2/3 of a foot), passing a liquid flow of 5 cubic feet per minute. The average velocity ( $v$ ) of this fluid may be calculated as follows:

$$Q = A\bar{v}$$

$$\bar{v} = \frac{Q}{A}$$

Solving for  $A$  in units of square feet:

$$A = \pi r^2$$

$$A = \pi \left( \frac{1}{3} \text{ ft} \right)^2 = \frac{\pi}{9} \text{ ft}^2$$

Now, solving for average velocity  $\bar{v}$ :

$$\bar{v} = \frac{Q}{A} = \frac{\frac{5 \text{ ft}^3}{\text{min}}}{\frac{\pi}{9} \text{ ft}^2}$$

$$\bar{v} = \left( \frac{5 \text{ ft}^3}{\text{min}} \right) \left( \frac{9}{\pi \text{ ft}^2} \right)$$

$$\bar{v} = \frac{45 \text{ ft}}{\pi \text{ min}} = 14.32 \frac{\text{ft}}{\text{min}}$$

Thus, the average fluid velocity inside an 8-inch pipe passing a volumetric flow rate of 5 cubic feet per minute is 14.32 feet per minute.

### 2.11.12 Viscous flow

The pressure dropped by a slow-moving, viscous fluid through a pipe is described by the *Hagen-Poiseuille equation*. This equation applies only for conditions of low Reynolds number; i.e. when viscous forces are the dominant restraint to fluid motion through the pipe, and turbulence is nonexistent:

$$Q = k \left( \frac{\Delta P D^4}{\mu L} \right)$$

Where,

$Q$  = Flow rate (gallons per minute)

$k$  = Unit conversion factor =  $7.86 \times 10^5$

$\Delta P$  = Pressure drop (inches of water column)

$D$  = Pipe diameter (inches)

$\mu$  = Liquid viscosity (centipoise) – this is a temperature-dependent variable!

$L$  = Length of pipe section (inches)

### 2.11.13 Bernoulli's equation

*Bernoulli's equation* is an expression of the *Law of Energy Conservation* for an inviscid (frictionless) fluid stream, named after Daniel Bernoulli<sup>75</sup>. It states that the sum total energy at any point in a passive fluid stream (i.e. no pumps or other energy-imparting machines in the flow path, nor any energy-dissipating elements) must be constant. Two versions of the equation are shown here:

$$z_1 \rho g + \frac{v_1^2 \rho}{2} + P_1 = z_2 \rho g + \frac{v_2^2 \rho}{2} + P_2$$

$$z_1 + \frac{v_1^2}{2g} + \frac{P_1}{\gamma} = z_2 + \frac{v_2^2}{2g} + \frac{P_2}{\gamma}$$

Where,

$z$  = Height of fluid (from a common reference point, usually ground level)

$\rho$  = Mass density of fluid

$\gamma$  = Weight density of fluid ( $\gamma = \rho g$ )

$g$  = Acceleration of gravity

$v$  = Velocity of fluid

$P$  = Pressure of fluid

Each of the three terms in Bernoulli's equation is an expression of a different kind of energy, commonly referred to as *head*:

$z \rho g$       Elevation head

$\frac{v^2 \rho}{2}$       Velocity head

$P$       Pressure head

Elevation and Pressure heads are potential forms of energy, while Velocity head is a kinetic form of energy. Note how the elevation and velocity head terms so closely resemble the formulae for potential and kinetic energy of solid objects:

$E_p = mgh$       Potential energy formula

$E_k = \frac{1}{2}mv^2$       Kinetic energy formula

The only real differences between the solid-object and fluid formulae for energies is the use of mass *density* ( $\rho$ ) for fluids instead of mass ( $m$ ) for solids, and the arbitrary use of the variable  $z$  for height instead of  $h$ . In essence, the elevation and velocity head terms within Bernoulli's equation come from the assumption of individual fluid molecules behaving as miniscule solid masses.

---

<sup>75</sup>According to Ven Te Chow in *Open Channel Hydraulics*, who quotes from Hunter Rouse and Simon Ince's work *History of Hydraulics*, Bernoulli's equation was first formulated by the great mathematician Leonhard Euler and made popular by Julius Weisbach, not by Daniel Bernoulli himself.

It is very important to maintain consistent units of measurement when using Bernoulli's equation! Each of the three energy terms (elevation, velocity, and pressure) *must* possess the exact same units if they are to add appropriately<sup>76</sup>. Here is an example of dimensional analysis applied to the first version of Bernoulli's equation (using British units):

$$z\rho g + \frac{v^2\rho}{2} + P$$

$$[\text{ft}] \left[ \frac{\text{slug}}{\text{ft}^3} \right] \left[ \frac{\text{ft}}{\text{s}^2} \right] + \left[ \frac{\text{ft}}{\text{s}} \right]^2 \left[ \frac{\text{slug}}{\text{ft}^3} \right] + \left[ \frac{\text{lb}}{\text{ft}^2} \right] = \left[ \frac{\text{slug}}{\text{ft} \cdot \text{s}^2} \right]$$

As you can see, both the first and second terms of the equation (elevation and velocity heads) bear the same unit of slugs per foot-second squared after all the “feet” are canceled. The third term (pressure head) does not appear as though its units agree with the other two terms, until you realize that the unit definition of a “pound” is a slug of mass multiplied by the acceleration of gravity in feet per second squared, following Newton's Second Law of motion ( $F = ma$ ):

$$[\text{lb}] = [\text{slug}] \left[ \frac{\text{ft}}{\text{s}^2} \right]$$

Once we make this substitution into the pressure head term, the units are revealed to be the same as the other two terms, slugs per foot-second squared:

$$\left[ \frac{\text{lb}}{\text{ft}^2} \right] = \left[ \frac{\text{slug} \left[ \frac{\text{ft}}{\text{s}^2} \right]}{\text{ft}^2} \right] = \left[ \frac{\text{slug}}{\text{ft} \cdot \text{s}^2} \right]$$

In order for our British units to be consistent here, we must use *feet* for elevation, *slugs* per cubic *foot* for mass density, *feet* per *second* squared for acceleration, *feet* per *second* for velocity, and *pounds* per square *foot* for pressure. If one wished to use the more common pressure unit of PSI (pounds per square inch) with Bernoulli's equation instead of PSF (pounds per square foot), all the other units would have to change accordingly: elevation in *inches*, mass density in slugs per cubic *inch*, acceleration in *inches* per second squared, and velocity in *inches* per second.

Just for fun, we can try dimensional analysis on the second version of Bernoulli's equation, this time using metric units:

$$z + \frac{v^2}{2g} + \frac{P}{\gamma}$$

$$[\text{m}] + \left[ \frac{\left[ \frac{\text{m}}{\text{s}} \right]^2}{\left[ \frac{\text{m}}{\text{s}^2} \right]} \right] + \left[ \frac{\left[ \frac{\text{N}}{\text{m}^2} \right]}{\left[ \frac{\text{N}}{\text{m}^3} \right]} \right] = [\text{m}]$$

Here, we see that all three terms end up being cast in simple units of meters. That is, the fluid's elevation, velocity, and pressure heads are all expressed as simple elevations. In order for our metric

<sup>76</sup>Surely you've heard the expression, “Apples and Oranges don't add up.” Well, pounds per square inch and pounds per square foot don't add up either! A general mathematical rule in physics is that any quantities added to or subtracted from each other *must* bear the exact same units. This rule does not hold for multiplication or division, which is why we see units canceling in those operations. With addition and subtraction, no unit cancellation occurs.

units to be consistent here, we must use *meters* for elevation, *meters per second* for velocity, *meters per second squared* for acceleration, *pascals* (*newtons per square meter*) for pressure, and *newtons per cubic meter* for weight density.

Applying Bernoulli's equation to real-life applications can be a bit daunting, as there are so many different units of measurement to contend with, and so many calculations which must be precise in order to arrive at a correct final answer. The following example serves to illustrate how Bernoulli's equation may be applied to the solution of pressure at a point in a water piping system, assuming no frictional losses anywhere in the system:

We know without a doubt that Bernoulli's equation will be what we need to evaluate in order to solve for the unknown pressure  $P_2$ , but where do we begin? A good place to start is by writing the equation we know we will need, then identifying all known values and all unknown values:

$$z_1 \rho g + \frac{v_1^2 \rho}{2} + P_1 = z_2 \rho g + \frac{v_2^2 \rho}{2} + P_2$$

Here is a list of known values, given to us already:

Known quantity	Comments
$z_1$	0 ft (arbitrarily assigned as 0 height)
$z_2$	3 ft (if $z_1$ is 0 feet, then $z_2$ is 3 ft above it)
$v_1$	11 ft/s
$P_1$	46 PSI ( <i>need to convert into PSF so all units match</i> )
$g$	32.2. ft/s <sup>2</sup>

The conversion for  $P_1$  from units of PSI into units of PSF is quite simple: multiply 46 PSI by 144 to get 6624 PSF.

Here is a list of values unknown to us at this time:

Unknown quantity	Comments
$\rho$	(needs to be in units of slugs/ft <sup>3</sup> )
$v_2$	(needs to be in units of ft/s just like $v_1$ )
$P_2$	(the quantity we are ultimately solving for)

Now all we must do is solve for  $\rho$  and  $v_2$ , and we will be ready to use Bernoulli's equation to solve for  $P_2$ . The important of identifying all the known and unknown quantities *before* beginning any calculations cannot be overstated. Doing so allows us to *develop a plan* for solving the problem. Without a plan, one has no idea of where or how to proceed, which is a condition many students repeatedly find themselves in when solving physics-type problems.

We know that  $\rho$  is an expression of mass density for the fluid, and we were told the fluid in this example is water. Water has a maximum density of 62.4 pounds per cubic foot, but this figure is not usable in our chosen form of Bernoulli's equation because it is *weight* density ( $\gamma$ ) and not *mass* density ( $\rho$ ).

The relationship between weight density  $\gamma$  and mass density  $\rho$  is the exact same relationship between weight ( $F_W$ ) and mass ( $m$ ) in a gravitational field ( $g$ ). Newton's Second Law equation relating force to mass and acceleration ( $F = ma$ ) works well to relate weight to mass and gravitational acceleration:

$$F = ma$$

$$F_W = mg$$

Dividing both sides of this equation by volumetric units ( $V$ ) (e.g. cubic feet) gives us our relationship between  $\gamma$  and  $\rho$ :

$$\frac{F_W}{V} = \frac{m}{V}g$$

$$\gamma = \rho g$$

Water has a weight density of 62.4 pounds per cubic foot in Earth gravity (32.2 feet per second squared), so:

$$\rho = \frac{\gamma}{g}$$

$$\rho = \frac{62.4 \text{ lb/ft}^3}{32.2 \text{ ft/s}^2} = 1.94 \text{ slugs/ft}^3$$

Now we may calculate the total value for the left-hand side of Bernoulli's equation, representing the sum total of potential and kinetic heads for the fluid within the 10-inch pipe:

$$z_1 \rho g + \frac{v_1^2 \rho}{2} + P_1 = \text{Total head at 10-inch pipe}$$

Head	Calculation at 10 inch pipe	Value
$z_1 \rho g$	(0 ft) (1.94 slugs/ft <sup>3</sup> ) (32.2 ft/s <sup>2</sup> )	0 lb/ft <sup>2</sup>
$v_1^2 \rho / 2$	(11 ft/s) <sup>2</sup> (1.94 slugs/ft <sup>3</sup> ) / 2	117.4 lb/ft <sup>2</sup>
$P_1$	(46 lb/in <sup>2</sup> ) (144 in <sup>2</sup> /1 ft <sup>2</sup> )	6624 lb/ft <sup>2</sup>
<b>Total</b>	0 lb/ft <sup>2</sup> + 117.4 lb/ft <sup>2</sup> + 6624 lb/ft <sup>2</sup>	<b>6741.4 lb/ft<sup>2</sup></b>

Note the absolutely consistent use of units: all units of distance are *feet*. All units of mass as *slugs*. All units of time are *seconds*. Failure to maintain consistency of units will result in (often severely) incorrect results!<sup>77</sup>

---

<sup>77</sup>It is entirely possible to perform all our calculations using inches and/or minutes as the primary units instead of feet and seconds. The only caveat is that *all* units throughout all terms of Bernoulli's equation must be consistent. This means we would also have to express mass density in units of slugs per cubic *inch*, the acceleration of gravity in *inches* per second squared (or *inches* per *minute* squared), and velocity in units of *inches* per second (or *inches* per *minute*). The only real benefit of doing this is that pressure would remain in the more customary units of pounds per square *inch*. My personal preference is to do all calculations using units of feet and seconds, then convert pressures in units of PSF to units of PSI at the very end.

There is one more unknown quantity to solve for before we may calculate values at the 6-inch pipe, and that unknown quantity is  $v_2$ . We know that the Continuity equation gives us a mathematical relationship between volumetric flow ( $Q$ ), pipe area ( $A$ ), and velocity ( $v$ ):

$$Q = A_1 v_1 = A_2 v_2$$

Looking at this equation, the only variable we know the value of at this point is  $v_1$ , and we need to find  $v_2$ . However, if we could find the values of  $A_1$  and  $A_2$ , and/or  $Q$ , we would have the information we need to solve for  $v_2$ , which in turn would give us the information we would need to solve for  $P_2$  in Bernoulli's equation.

One way to approach this problem is to express the areas and velocities as ratios, eliminating  $Q$  entirely so all we need to find are  $A_1$  and  $A_2$ :

$$\frac{A_1}{A_2} = \frac{v_2}{v_1}$$

The area of a circular pipe is given by the basic equation  $A = \pi r^2$ . Since the problem gives us each pipe's diameter (10 inches and 6 inches), we know the radii (5 inches and 3 inches, respectively) which we may then plug into our ratio equation:

$$\frac{\pi(5 \text{ in})^2}{\pi(3 \text{ in})^2} = \frac{v_2}{v_1}$$

$$\frac{25}{9} = \frac{v_2}{v_1}$$

Knowing  $v_1$  has a value of 11 feet per second, the solution for  $v_2$  is now quite simple:

$$v_2 = 11 \text{ ft/s} \left( \frac{25}{9} \right)$$

$$v_2 = (11 \text{ ft/s})(2.778) = 30.56 \text{ ft/s}$$

Finally, we have all the pieces necessary to solve for  $P_2$  in the right-hand side of Bernoulli's equation:

$$z_2 \rho g + \frac{v_2^2 \rho}{2} + P_2 = \text{Total head at 6-inch pipe}$$

Head	Calculation at 6 inch pipe	Value
$z_2 \rho g$	(3 ft) (1.94 slugs/ft <sup>3</sup> ) (32.2 ft/s <sup>2</sup> )	187.4 lb/ft <sup>2</sup>
$v_2^2 \rho / 2$	(30.56 ft/s) <sup>2</sup> (1.94 slugs/ft <sup>3</sup> ) / 2	905.6 lb/ft <sup>2</sup>
$P_2$		(unknown)
<b>Total</b>	187.4 lb/ft <sup>2</sup> + 905.6 lb/ft <sup>2</sup> + $P_2$	<b>1093 lb/ft<sup>2</sup> + <math>P_2</math></b>

Knowing that the total head calculated at the first location was 6741.4 lb/ft<sup>2</sup>, and the Conservation of Energy requires total heads at both locations be equal (assuming no energy lost to fluid friction along the way),  $P_2$  must be equal to:

$$6741.4 \text{ lb/ft}^2 = 1093 \text{ lb/ft}^2 + P_2$$

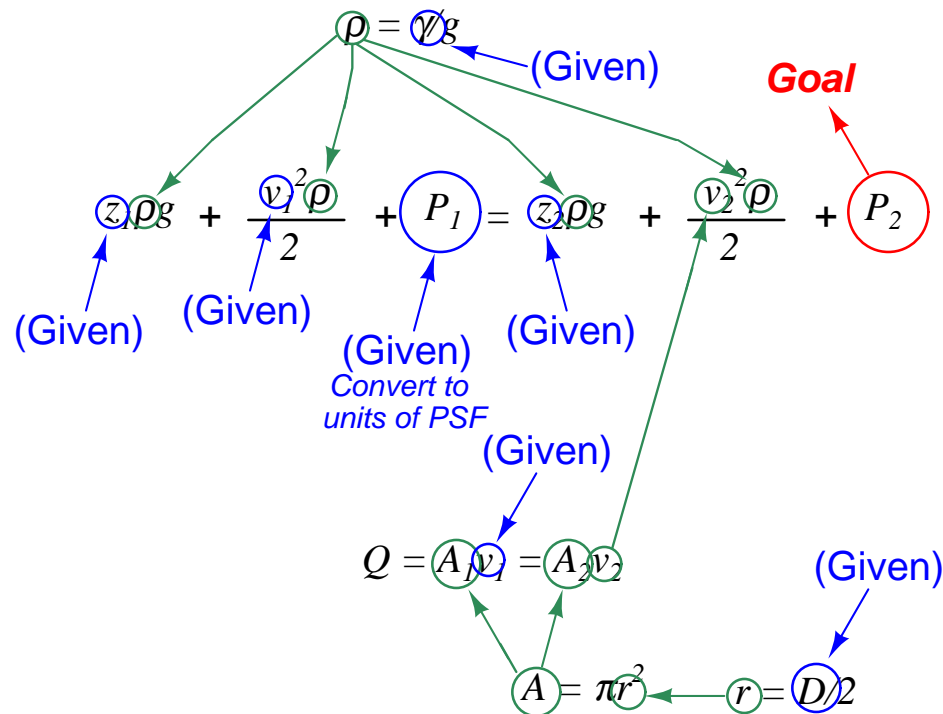

$$P_2 = 6741.4 \text{ lb/ft}^2 - 1093 \text{ lb/ft}^2 = 5648.3 \text{ lb/ft}^2$$

Converting pounds per square foot into the more customary unit of pounds per square inch (PSI):

$$P_2 = (5648.3 \text{ lb/ft}^2) \left( \frac{1 \text{ ft}^2}{144 \text{ in}^2} \right)$$

$$P_2 = 39.2 \text{ lb/in}^2$$

Before discussing the larger meaning of our solution, it would be good to review the problem-solving plan we followed to calculate  $P_2$ :

First, we identified Bernoulli's equation as being the central equation necessary for solving  $P_2$ . Then, we identified all the known variables within Bernoulli's equation given to us in the problem, and also if there were any unit-conversion operations necessary. Next, we identified any unknown variables necessary to solve for  $P_2$  in Bernoulli's equation. For each of those unknown variables, we found or developed equations to solve for them, based on variables known to us. The graphic shown above illustrates our plan of solution, with arrows showing the dependent relationships where equations supplied values for unknown quantities in other equations.

This is not just a problem-solving technique unique to Bernoulli's equation; it is a general strategy applicable to *any* type of problem where multiple equations must be used to solve for some quantity. The study of physics in general is filled with problems like this!

Note how our calculated value for  $P_2$  at the second gauge is so much lower than the pressure at the first gauge: 39.2 PSI compared to 46 PSI. This represents nearly a 7 PSI decrease in pressure! Note also how little vertical distance separates the two gauges: only 3 feet. Clearly, the change in elevation between those two points is insufficient to account for the large loss in pressure<sup>78</sup>. Given a 3 foot difference in elevation, one would expect a pressure reduction of about 1.3 PSI for a static column of water, but what we're seeing in this piping system is a pressure drop of nearly 7 PSI. The difference is due to an exchange of energy from potential to kinetic form, as the fluid enters a much narrower pipe (6 inches instead of 10) and must increase velocity.

Furthermore, if we were to increase the flow rate discharged from the pump, resulting in even more velocity through the narrow pipe, pressure at  $P_2$  might even drop lower than atmospheric. In other words, Bernoulli's equation tells us we can actually produce a *vacuum* by accelerating a fluid through a constriction. This principle is widely used in industry with devices known as *eductors* or *ejectors*<sup>79</sup>: tapered tubes through which fluid flows at high velocity to produce a vacuum at the throat.

This, in fact, is how a *carburetor* works in an older automobile engine to vaporize liquid gasoline fuel into a stream of air drawn into the engine: the engine's intake air passes through a venturi tube, where vacuum at the throat of the venturi produces enough negative pressure to draw liquid gasoline into the stream to produce a fine mist.

<sup>78</sup>A simple approximation for pressure loss due to elevation gain is approximately 1 PSI for every 2 vertical feet of water (1 PSI for every 27.68 inches to be more exact).

<sup>79</sup>Technically, an *eductor* uses a liquid such as water to generate the vacuum, while an *ejector* uses a gas or a vapor such as steam.

Ejectors use a high-velocity gas or vapor (e.g. superheated steam) to produce significant vacuums. Eductors use process liquid flow, such as the eductor shown in this next photograph where wastewater flow creates a vacuum to draw gaseous chlorine into the stream for biological disinfection:

Here, the eductor helps fulfill an important safety function. By creating a vacuum to draw toxic chlorine gas from the supply tank into the water stream, the chlorine gas piping may be continuously maintained at a slightly negative pressure throughout. If ever a leak were to develop in the chlorine system, this vacuum would cause ambient air to enter the chlorine pipe rather than toxic chlorine gas to exit the pipe, making a leak far less dangerous than if the chlorine gas piping were maintained in a pressurized state.

### 2.11.14 Torricelli's equation

The velocity of a liquid stream exiting from a nozzle, pressured solely by a vertical column of that same liquid, is equal to the free-fall velocity of a solid mass dropped from the same height as the top of the liquid column. In both cases, potential energy (in the form of vertical height) converts to kinetic energy (motion):

This was discovered by Evangelista Torricelli almost 100 years prior to Bernoulli's more comprehensive formulation. The velocity may be determined by solving for  $v$  after setting the potential and kinetic energy formulae equal to each other (since all potential energy at the upper height must translate into kinetic energy at the bottom, assuming no frictional losses):

$$mgh = \frac{1}{2}mv^2$$

$$gh = \frac{1}{2}v^2$$

$$2gh = v^2$$

$$v = \sqrt{2gh}$$

Note how mass ( $m$ ) simply disappears from the equation, neatly canceling on both sides. This means the nozzle velocity depends only on height, not the mass density of the liquid. It also means the velocity of the falling object depends only on height, not the mass of the object.

### 2.11.15 Flow through a venturi tube

If an incompressible fluid moves through a *venturi tube* (i.e. a tube purposefully built to be narrow in the middle), the continuity principle tells us the fluid velocity must increase through the narrow portion. This increase in velocity causes kinetic energy to increase at that point. If the tube is level, there will be negligible difference in elevation ( $z$ ) between different points of the tube's centerline, which means elevation head remains constant. According to the Law of Energy Conservation, some other form of energy must decrease to account for the increase in kinetic energy. This other form is the pressure head, which decreases at the throat of the venturi:

Ideally, the pressure downstream of the narrow throat should be the same as the pressure upstream, assuming equal pipe diameters upstream and down. However, in practice the downstream pressure gauge will show slightly less pressure than the upstream gauge due to some inevitable energy loss as the fluid passed through the venturi. Some of this loss is due to fluid friction against the walls of the tube, and some is due to viscous losses within the fluid driven by turbulent fluid motion at the high-velocity throat passage.

The difference between upstream and downstream pressure is called *permanent pressure loss*, while the difference in pressure between the narrow throat and downstream is called *pressure recovery*.

If we install vertical sight-tubes called *piezometers*<sup>80</sup> along a horizontal venturi tube, the differences in pressure will be shown by the heights of liquid columns within the tubes. Here, we assume an ideal (inviscid) liquid with no permanent pressure loss:

The height of liquid in each piezometer tube represents the amount of *potential energy*<sup>81</sup> in the fluid at that point along the venturi tube.

<sup>80</sup>A piezometer tube is nothing more than a manometer (minus the well or the other half of the U-tube).

<sup>81</sup>For a moving fluid, potential energy is the sum of fluid height and static pressure.

We may gain more insight into the nature of energy in this moving fluid stream if we add three more piezometers, each one equipped with its own *Pitot tube* facing upstream to “catch” the velocity of the fluid. Rather than represent potential energy by liquid height as the straight-tube piezometers do, the Pitot tube piezometers represent the *total energy* (potential plus kinetic) of the fluid. As such, the liquid heights in these new piezometers are all equal to each other, showing that total energy is indeed conserved at every point in the system:

$$z + \frac{v^2}{2g} + \frac{P}{\gamma} = (\text{constant})$$

Here, each of the “heads” represented<sup>82</sup> in Bernoulli’s equation are shown in relation to the different piezometer heights. The difference in liquid column height between each Pitot tube piezometer (potential + kinetic energy) and its corresponding straight-tube piezometer (potential energy alone) reflects the amount of kinetic energy possessed by the fluid stream at that point in the venturi tube.

<sup>82</sup>The form of Bernoulli’s equation with each term expressed in units of distance (e.g.  $z = [\text{feet}]$ ;  $\frac{v^2}{2g} = [\text{feet}]$ ;  $\frac{P}{\gamma} = [\text{feet}]$ ) was chosen so that the piezometers’ liquid heights would directly correspond.

In a real venturi tube, there is some energy permanently lost in the moving fluid due to friction. Consequently the piezometer measurements in a real venturi tube would look something like this:

The “energy line” is seen to slope downhill from inlet to outlet on the venturi tube, showing a degradation in total energy content from beginning to end.

## Chapter 3

# Chemistry

**Everything there is to know about chemistry** – excerpted from “Everything you need to know about school” in the September 16, 2008 edition of the Seattle periodical *The Stranger*:

Stuff is made up of different arrangements of atoms; atoms are made up of nucleus surrounded by buzzing electrons. The outer shell always wants to be filled with eight electrons. So, any arrangement that gets you there – sodium with chloride, oxygen with two hydrogens, carbon with four chlorides – will work. This is why the periodic table has eight columns and helium (with eight outer electrons of its own) doesn’t explode. Some arrangements adding up to eight shared electrons are happier than others. Chemical reactions rearrange from less stable to more stable arrangements on their own, giving off energy in the process. To make a less stable arrangement, you have to put in energy as payment. Chemistry is simply accounting: You must not gain or lose atoms at any point. Ignore the nuclear physicists at this point.

As suggested by this quote, chemistry is the study of matter (stuff) on an atomic scale. It is relevant to industrial instrumentation because so many industrial processes rely on specific chemical reactions to achieve desired outcomes, and we must use instruments to monitor and regulate these chemical reactions. Chemistry can be a confounding subject of study, principally because it seems to defy any simple rule. Many of the “rules” learned by chemistry students, such as the rule of eight electrons referenced in the humorous quote, are not general and in fact only apply to certain elements in the Periodic Table. It should be noted that helium is actually an exception to this rule (an atom of helium only has two electrons, not eight – but at least the quote was correct in saying helium doesn’t explode!). It should also be noted that only a small portion of the Periodic Table has eight columns – most of the table in fact has *eighteen* columns.

Perhaps the most accurate portion of the quote is where it tells us atoms are never lost or gained in a chemical reaction: every atom entering a reaction must somewhere exit that reaction. This simple rule goes by the clumsy name of *stoichiometry* and it is inviolable for all practical purposes. Chemistry, therefore, is the shuffling of atoms between different arrangements which we call *molecules*.

Chemistry is the study of matter: in particular how and why atoms join with one another to form molecules, and the processes by which molecules may be formed and re-formed. Any process where atoms either join with one another to form molecules, or break apart to become individual atoms, is called a *chemical reaction*. Applications of chemistry abound, from the formation of rocks and minerals in the Earth to industrial processes to the processes of organic life itself. Chemistry plays a particularly important role in industrial instrumentation in the form of devices called *analyzers* which exist to measure concentrations of certain chemicals. Analytical instrumentation is essential for industrial processes such as wastewater treatment, combustion, and fermentation to proceed safely and efficiently. Analyzers are also essential for quantitatively tracking pollutants emitted by industrial processes.

Like so many other areas of physical science, the patterns and limits we see in chemical reactions are dominated by two fundamental laws of physics: the *Conservation of Mass* and the *Conservation of Energy*. The particles of matter comprising atoms have the ability to store energy in potential form, and their tendency is to “seek” states having the lowest available energy<sup>1</sup>. The arrangement of electrons around the nucleus of an atom is largely dictated by the tendency of electrons to “prefer” stable energy states, and so is the formation of molecules (atoms bonded together): electrons seeking energy states least liable to disturbance. The rest, as they say, is mere detail.

We exploit this property of energy storage in the fuels we use. Atoms bound together to form molecules are in a lower energy state than when they exist as separate atoms. Therefore, an investment of energy is required to force molecules apart (into separate atoms), and energy is returned (released) when atoms join together to form molecules. The combustion of a *fuel*, for example, is nothing more than a process of the atoms in relatively unstable (high-energy) fuel molecules joining with oxygen atoms in air to form stable (low-energy) molecules such as water ( $\text{H}_2\text{O}$ ) and carbon dioxide ( $\text{CO}_2$ ).

Natural gas, for example, is a relatively stable combination of hydrogen (H) and carbon (C) atoms, mostly in the form of molecules with a 4:1 hydrogen-to-carbon ratio ( $\text{CH}_4$ ). However, when placed in the vicinity of free oxygen (O) atoms, and given enough energy (a spark) to cause the hydrogen and carbon atoms to separate from each other, the hydrogen atoms strongly bond with oxygen atoms to form water molecules ( $\text{H}_2\text{O}$ ), while the carbon atoms also strongly bond with oxygen atoms to form carbon dioxide molecules ( $\text{CO}_2$ ). These strong bonds formed between hydrogen, carbon, and oxygen in the water and carbon dioxide molecules are the result of electrons within those atoms seeking lower energy states than they possessed while forming molecules of natural gas ( $\text{CH}_4$ ). In other words, the electrons binding hydrogen and carbon atoms together to form natural gas are at higher energy states than the electrons binding hydrogen and carbon atoms to oxygen atoms to form water and carbon dioxide, respectively. As those electrons attain lower energy states, their difference of energy must go somewhere (since energy cannot be created or destroyed), and so the chemical reaction releases that energy in the forms of heat and light. This is what you see and feel in the presence of a natural gas flame: the heat and light emitted by hydrogen and carbon atoms joining with oxygen atoms.

---

<sup>1</sup>This generally means to seek the *lowest* gross potential energy, but there are important exceptions where chemical reactions actually proceed in the opposite direction (with atoms seeking *higher* energy states and absorbing energy from the surrounding environment to achieve those higher states). A more general and consistent understanding of matter and energy interactions involves a more complex concept called *entropy*, and a related concept known as *Gibbs Free Energy*.

The Law of Mass Conservation plays an important role in chemistry as well. When atoms join to form molecules, their masses add. That is, the mass of a molecule is precisely equal<sup>2</sup> to the mass of its constituent atoms. Furthermore, the total mass is unaffected when atoms separate and then re-join to form different molecules. In our natural gas combustion example, the mass of the CH<sub>4</sub> molecules plus the mass of the oxygen atoms they combust with precisely equals the sum total mass of the water and carbon dioxide molecules produced by the combustion. Another way of saying this is that all mass entering a chemical reaction must equal the mass exiting that same reaction. Chemical engineers apply this principle when they calculate *mass balance* in a chemical process: accounting for all mass entering and exiting the process based on the safe assumption that no mass will be gained or lost.

Too many other practical applications of chemistry exist to summarize in these pages, but this chapter aims to give you a foundation to understand basic chemistry concepts necessary to comprehend the function of certain instruments (notably *analyzers*) and processes.

---

<sup>2</sup>This statement is not perfectly honest. When atoms join to form molecules, the subsequent release of energy is translated into an incredibly small loss of mass for the molecule, as described by Albert Einstein's famous mass-energy equation  $E = mc^2$ . However, this mass discrepancy is so small (typically less than one part per *billion* of the original mass!), we may safely ignore it for the purposes of understanding chemical reactions in industrial processes. This is what the humorous quote at the start of this chapter meant when it said "ignore the nuclear physicists at this point".

### 3.1 Terms and Definitions

- *Atom*: the smallest unit of matter that may be isolated by chemical means.
- *Particle*: a part of an atom, separable from the other portions only by levels of energy far in excess of chemical reactions.
- *Proton*: a type of “elementary” particle, found in the nucleus of an atom, possessing a positive electrical charge.
- *Neutron*: a type of “elementary” particle, found in the nucleus of an atom, possessing no electrical charge, and having nearly the same amount of mass as a proton.
- *Electron*: a type of “elementary” particle, found in regions surrounding the nucleus of an atom, possessing a negative electrical charge, and having just a small fraction of the mass of a proton or neutron.
- *Element*: a substance composed of atoms all sharing the same number of protons in their nuclei (e.g. hydrogen, helium, nitrogen, iron, cesium, fluorine).
- *Atomic number*: the number of protons in the nucleus of an atom – this quantity defines the chemical identity of an atom.
- *Atomic mass* or *Atomic weight*: the total number of elementary particles in the nucleus of an atom (protons + neutrons) – this quantity defines the vast majority of an atom’s mass, since the only other elementary particle (electrons) are so light-weight by comparison to protons and neutrons.
- *Ion*: an atom or molecule that is not electrically balanced (i.e. equal numbers of protons and electrons).
  - *Cation*: a positively-charged ion, called a “cation” because it is attracted toward the negative electrode (cathode) immersed in a fluid solution.
  - *Anion*: a negatively-charged ion, called an “anion” because it is attracted toward the positive electrode (anode) immersed in a fluid solution.
- *Isotope*: a variation on the theme of an element – atoms sharing the same number of protons in their nuclei, but having different numbers of neutrons, are called “isotopes” (e.g. uranium-235 versus uranium-238).
- *Molecule*: the smallest unit of matter composed of two or more atoms joined by electron interaction in a fixed ratio (e.g. water:  $\text{H}_2\text{O}$ ). The smallest unit of a *compound*.
- *Compound*: a substance composed of identical molecules (e.g. pure water).
- *Isomer*: a variation on the theme of a compound – molecules sharing the same numbers and types of atoms, but having different structural forms, are called “isomers”. For example, the sugars glucose and fructose are isomers, both having the same formula  $\text{C}_6\text{H}_{12}\text{O}_6$  but having different molecular structures. An isomer is to a molecule as an isotope is to an atomic nucleus.

- *Mixture*: a substance composed of different atoms or molecules not electronically bonded to each other.
- *Solution*: an homogeneous mixture at the molecular level (different atoms/molecules thoroughly mixed together). A solution may be a gas, a liquid, or a solid (e.g. air, saltwater, steel).
  - *Solvent*: the majority element or compound in a solution. Chemists usually consider water to be the *universal solvent*.
  - *Solute*: the minority element or compound in a solution (may be more than one).
  - *Precipitate*: (noun) solute that has “fallen out of solution” due to the solution being saturated with that element or compound; (verb) the process of solute separating from the rest of the solution. (e.g. If you mix too much salt with water, some of the salt will *precipitate* out of the water to form a solid pile at the bottom.)
  - *Supernatant*: the solution remaining above the precipitate.
- *Suspension*: an heterogeneous mixture where separation occurs due to gravity (e.g. mud).
- *Colloid* or *Colloidal suspension*: an heterogeneous mixture where separation either does not occur or occurs at a negligible pace under the influence of gravity (e.g. milk).
  - *Aerosol*: A colloid formed of a solid or liquid substance dispersed in a gas medium.
  - *Foam*: A colloid formed of a gas dispersed in either a liquid or a solid medium.
  - *Emulsion*: A colloid formed of a liquid dispersed in either a liquid or a solid medium.
  - *Sol*: A colloid formed of a solid dispersed in either a liquid or a solid medium.

A tremendously simplified model of a common nitrogen atom is shown here, with 7 protons and 7 neutrons in the nucleus, and 7 electrons in “orbit” around the nucleus:

The atomic number of this atom (the number of protons in the nucleus) is seven, which is what defines it as nitrogen. The *atomic mass* of this atom (the sum of protons and neutrons in the nucleus) is fourteen. The chemical symbol for this atom is shown here:

The atomic number is redundant to the letter “N” for nitrogen, since only the element nitrogen can have an atomic number of seven. The atomic mass is only relevant when we need to distinguish one *isotope* of nitrogen from another (variations of elements having the same number of protons but different numbers of neutrons), and this is seldom because the chemical properties of isotopes are identical – only their masses differ. For these reasons, you will usually find no left-hand subscripts or superscripts placed near chemical symbols of elements in chemical expressions.

By contrast, subscripts and superscripts placed to the right of a chemical symbol have very important meanings in chemistry. A right-hand subscript refers to the number of atoms bound together to form a molecule. A right-hand superscript refers to the electrical charge possessed by an atom (or by a molecule) by virtue of the number of electrons not matching the number of protons:

An  $N_2$  molecule may be represented simplistically as follows, the two nitrogen atoms joined by a mutual sharing of three of its highest-energy (valence) electrons, shown in this illustration as those electrons residing in the largest-diameter “orbits”. Incidentally, this “triple bond” characterizing the nitrogen molecule is very strong (the more electrons participating in the joining of two atoms, the stronger the bond, all other factors being equal):

An  $N^{3-}$  ion is an atom of nitrogen having three more electrons than it normally would when electrically balanced:

A chemical *formula* is a written description of a molecule's constituent atoms. Ethanol (ethyl alcohol), for example, is a conglomerate of two carbon atoms, six hydrogen atoms, and one oxygen atom. One way to express this structure is to write the following formula for ethanol, the right-hand subscripts showing the relative quantities of atoms in each ethanol molecule:

This is called a *molecular formula*, because it shows the proportions of atom types comprising each molecule.

A more common way to write the formula for ethanol, though, is this:

Here, an attempt is made to show the physical structure of the ethanol molecule, where one of the hydrogen atoms is located further away from the others. This is called a *structural formula*. If more detail of the bonds between atoms in a molecule is needed, a semi-graphic representation called a *displayed formula* (also known as an *expanded structural formula*) may be used in lieu of a structural formula:

*Displayed formula for ethanol*  
(C<sub>2</sub>H<sub>5</sub>OH)

Each letter in a displayed formula represents a single atom within that molecule, and each line segment in a displayed formula represents a bond between two.

In organic chemistry – the study of molecules principally centered around *carbon* atoms – a special type of notation is used to show the structural detail of the molecule with fewer lines and letters than a displayed formula. This notation is called a *line drawing*, where each line segment represents a single electron bond<sup>4</sup> to a carbon atom, each vertex and line-end represents the location of a carbon atom, and any hydrogen atoms directly bound to a carbon atom are simply omitted for simplicity. Compare and contrast these displayed formulae and line drawings for a few different organic compounds:

An important principle in organic chemistry is that carbon atoms prefer to form exactly *four* bonds with surrounding atoms<sup>5</sup>. This fact is exploited in line-drawing notation where any bonds not explicitly shown at a vertex are assumed to be single-bonds with hydrogen atoms, enough of them to bring the total number of bonds with that carbon atom to four. Since a great many organic compounds are principally comprised of carbon and hydrogen, the line-drawing symbols for these molecules tend to be more lines than letters.

<sup>4</sup>One line represents a single bond, which is one electron shared per bound atom. Two parallel lines represent a *double bond*, where each carbon atom shares two of its valence electrons with the neighboring atom. Three parallel lines represent a triple bond, where each atom shares three of its outer electrons with the neighboring atom.

<sup>5</sup>Incidentally, nitrogen atoms preferentially form exactly *three* bonds, and oxygen atoms exactly *two* bonds. The reason for this pattern is the particular patterns of electrons orbiting each of these atoms, and their respective energy levels. For more information on this, see section 3.4 beginning on page 241.

Chemical engineers often perform mass and energy balance calculations for processes where *mixtures* of similar compounds exist. Wastewater treatment is one example, where an array of organic compounds must all be treated through oxidation (chemical reaction with oxygen). In such cases, it is common for chemical engineers to write formulae expressing the *average* ratios of elements, so that they may calculate the quantity of reactant(s) needed to complete the desired chemical reaction with compounds in the mixture. Primary sludge clarified from municipal wastewater, for example, may be represented by the *compositional formula*  $C_{22}H_{39}O_{10}N$ . This does not suggest the existence of some monstrous molecule consisting of twenty-two carbon atoms, thirty-nine hydrogen atoms, ten oxygen atoms, and a lone nitrogen atom somewhere in a sample of sludge, but rather that the combined *average* carbon, hydrogen, oxygen, and nitrogen quantities in that sludge exist in a variety of molecular forms in these approximate proportions. This aggregate formula expression helps the engineer quantify the gross chemical characteristics of the sludge, and from that determine how much oxygen will be necessary to completely oxidize it.

Sometimes, compositional formulae are written with non-integer subscripts. An example of this would be the compositional formula  $C_{4.8}H_{8.4}O_{2.2}$ , which also happens to be an average composition for municipal wastewater sludge (ignoring nitrogen content). The same formula could just as well have been written  $C_{48}H_{84}O_{22}$ , or even  $C_{24}H_{42}O_{11}$ , because these subscript values all express the exact same proportions.

All substances are comprised of various elements in various combinations and proportions. Elements may thus be thought of as the building-blocks of matter. A Periodic Table of the Elements is a table listing the known elements in order of their atomic numbers.

Multiple attributes appear for each element in the table. Two of these attributes – atomic number and atomic mass – are directly related to the number of particles in the nucleus of each atom. We will examine the table’s entry for the element *potassium* (K) to explore these concepts.

Potassium has an *atomic number* (number of protons in the nucleus of each potassium atom) of 19. This number defines the element. If we were somehow to add or subtract protons from the nucleus of a potassium atom<sup>6</sup>, it would cease being potassium and *transmute* into a different element. Note how *every* element in the table has its own unique atomic number, and how each of these numbers is whole (no fractions or decimals).

The *atomic mass* or *atomic weight* shown for potassium is 39.0983. This quantity is the sum of protons and neutrons found in the nucleus of each potassium atom. Like the atomic number (19), we would logically expect the atomic mass to be a whole number as well, since protons and neutrons

<sup>6</sup>The amount of energy required to rearrange particles in the nucleus for even just a single atom is *tremendous*, lying well outside the energy ranges of chemical reactions. Such energy levels are the exclusive domain of *nuclear* reactions and high-energy radiation (subatomic particles traveling at high velocity). The extremely large energy “investment” required to alter an atom’s nucleus is why atomic identities are so stable. This is precisely why alchemists of antiquity utterly failed to turn lead into gold: no materials, processes, or techniques they had at their disposal were capable of the targeted energy necessary to dislodge three protons from a nucleus of lead ( $_{82}\text{Pb}$ ) to that it would turn into a nucleus of gold ( $_{79}\text{Au}$ ). That, and the fact the alchemists had no clue about atomic structure to begin with, made their endeavor fruitless.

only come in whole quantities. The primary reason we see a non-whole number for potassium's atomic mass is that this table reflects the *average* atomic mass of potassium atoms as found in nature. Some potassium atoms have atomic masses greater than 39, and some have atomic masses less than 39. We know that the number of protons in every potassium atom is fixed (which is what gives potassium its elemental identity), which means the only quantity that may cause the atomic mass to vary is the number of *neutrons* in the nucleus. The most common form of potassium ( $^{39}\text{K}$ ) atom possesses 19 protons and 20 neutrons in its nucleus, giving it an atomic mass of 39 ( $19 + 20$ ). The next most common form of potassium found on Earth is ( $^{41}\text{K}$ ), possessing 19 protons and 22 neutrons.

We refer to atoms of the same element with differing atomic masses as *isotopes*. From a chemical perspective, isotopes are identical. That is to say, they engage in the exact same chemical reactions in the exact same manner. To use potassium as an example, an atom of  $^{39}\text{K}$  will join with a chlorine atom (Cl) to form the compound *potassium chloride* (KCl) just as readily as an atom of  $^{41}\text{K}$  will join with a chlorine atom to form the same compound. The three isotopes of hydrogen ( $^1\text{H}$ ,  $^2\text{H}$ , and  $^3\text{H}$ : hydrogen, deuterium, and tritium, respectively) are all chemically identical: all are highly flammable, combining with oxygen to create water ( $\text{H}_2\text{O}$ ). However, deuterium ( $^2\text{H}$ ) has twice the density of normal hydrogen ( $^1\text{H}$ ), while tritium ( $^3\text{H}$ ) has three times the density of normal hydrogen and is highly radioactive! Isotopes only differ in their mass and in their nuclear properties (such as *radioactivity*: the tendency for a nucleus to spontaneously decay, usually resulting in a loss or gain of protons that subsequently alters the identity of the decayed atom).

The Periodic Table is called “periodic” because its configuration reveals a repeating pattern of chemical behaviors approximately following atomic number. Horizontal rows in the table are called *periods*, while vertical columns are called *groups*. Elements in the same group (vertical column) share similar chemical reactivities – that is, they tend to engage in the same types of chemical reactions – despite having different masses and physical properties such as melting point, boiling point, etc. This *periodicity* is a function of how electrons are arranged around the nucleus of each atom, a subject we will explore in more detail later in this chapter. As mentioned previously, chemistry is the study of how atoms bond together to form molecules, and this bonding takes place through the interaction of the electrons surrounding the atoms' nuclei. It makes perfect sense, then, that the configuration of those electrons determine the chemical (bonding) properties of atoms.

Some periodic tables show the *first ionization energy* value for each element – the amount of energy required to force the first electron of an electrically balanced atom to separate from that atom – in addition to other attributes such as atomic number and atomic mass. If we note the ionization energies of the elements, reading each element in turn from left-to-right, starting with period 1 (hydrogen and helium) and progressing to subsequent periods, we see an interesting pattern:

Element	Period	First ionization energy (measured in “electron-volts”)
Hydrogen (H)	1	13.5984
Helium (He)	1	24.5874
Lithium (Li)	2	5.3917
Beryllium (Be)	2	9.3227
Boron (B)	2	8.2980
Carbon (C)	2	11.2603
Nitrogen (N)	2	14.5341
Oxygen (O)	2	13.6181
Fluorine (F)	2	17.4228
Neon (Ne)	2	21.5645
Sodium (Na)	3	5.1391
Magnesium (Mg)	3	7.6462
Aluminum (Al)	3	5.9858
Silicon (Si)	3	8.1517
Phosphorus (P)	3	10.4867
Sulfur (S)	3	10.3600
Chlorine (Cl)	3	12.9676
Argon (Ar)	3	15.7596
Potassium (K)	4	4.3407

First ionization energy represents the relative stability of the last electron balancing the electrical charge of an atom. We see from this table that 24.5874 electron-volts of energy is needed to remove one electron from an electrically-balanced atom of helium (changing He into  $\text{He}^{1+}$ ), while only 13.5984 electron-volts of energy is required to do the same to an atom of hydrogen. This tells us the electron configuration of helium is at a lower energy (and therefore more stable) than that of hydrogen.

The ionization energies increase with increasing atomic number (with an occasional down-step) until the last column of the period is reached, and then there is a comparatively enormous down-step in energy at the first column of a new period. This pattern is clearly evident when the first ionization energies are plotted against atomic number:

This periodicity suggests that as atoms grow in atomic number, the additional electrons do not simply pile on in random fashion or in a plain and simple progression from inner orbits to outer orbits. Rather, they “fill in” a structured energy pattern, with major changes in structure at the start of each new period. More details of this structured pattern will be explored later in this chapter.

The low ionization energy values for all the “Group 1” elements (far left-hand column) suggest they are relatively easy to positively ionize, and indeed we find this to be the case through experimentation. Hydrogen, lithium, sodium, potassium, and the rest all readily become positively-charged ions upon interaction with other atoms, since their low ionization energy values means they may easily lose an electron.

The high ionization energy values for all the “Group 18” elements (far right-hand column) suggest they possess a very stable electron structure, which is also verified by experiment. These are the *noble* elements, possessing very little reactive potential<sup>7</sup>.

Looking at the “Group 17” column, just to the left of the noble elements, we notice that they are all just one electron shy of the stable electron structure enjoyed by the noble atoms when in their electrically-balanced states. This suggests it might be easy to *add* one more electron to atoms of these elements, which (once again!) is a principle validated by experiment. Fluorine, chlorine, bromine, iodine, and even astatine<sup>8</sup> all readily ionize negatively, readily accepting an extra electron from surrounding atoms. As one might expect from this tendency, these elements readily bond through electrostatic attraction with the “Group 1” elements (hydrogen, lithium, sodium, potassium, etc.), each “Group 17” atom accepting an extra electron from each “Group 1” atom which readily provides it. Ordinary table salt (sodium chloride, or NaCl) is an example of a compound formed by this sort of bond.

<sup>7</sup>It used to be believed that these elements were completely *inert*: incapable of forming molecular bonds with other atoms. However, this is not precisely true, as some compounds are now known to integrate noble elements.

<sup>8</sup>All isotopes of astatine (At) are radioactive with very short half-lives, making this element difficult to isolate and study.

Thus, Group 1 and Group 17 elements are both highly reactive in a chemical sense, but in different ways. Group 1 elements easily form bonds with Group 17 elements, but Group 1 elements do not generally bond (solely) with other Group 1 elements, and likewise Group 17 elements do not generally bond (solely) with other Group 17 elements. It is the structure of the electrons surrounding each atom's nucleus that determines how those atoms will bond with other atoms.

## 3.4 Electronic structure

Earlier in this chapter you were shown a model of a nitrogen atom with a dense nucleus (comprised of protons and neutrons) surrounded by electrons whirling around like satellites around a planet. While there are some useful features of this model, it is largely in error. A more realistic view of atomic structure begins with the realization that electrons do not exist as discrete particles, but rather as wave packets. In a sense, they orbit the nucleus within certain *areas of probability*, as described by the principles of quantum mechanics. One way to envision this is to think of an electron's placement around the nucleus in the same way you might picture a city shrouded by a layer of fog. The electron does not have a discrete location (even though there *is* a discrete number of them found in every atom), but rather may be found anywhere within a certain region to varying degrees of probability.

Things get even stranger the more electrons there are in an atom. No two electrons may share the same quantum states in the same atom – a principle called the *Pauli Exclusion Principle*. This means the electrons surrounding a nucleus must exist in distinct patterns. Just a few of these patterns are shown here as *orbitals* (regions of high probability where up to two electrons may be found surrounding a nucleus):<sup>9</sup>

Electrons situate themselves around the nucleus of any atom according to one basic rule: the minimization of potential energy. That is, the electrons seek the lowest-energy positions available around the nucleus. Given the electrostatic attraction between negative electrons and the positive nucleus of an atom, there is potential energy stored in the “elevation” between an orbiting electron and the nucleus, just as there is gravitational potential energy in any object orbiting a planet. Electrons lose energy as they situate themselves closer to the nucleus, and it requires an external input of energy to move an electron farther away from its parent nucleus.

In a sense, most of chemistry may be explained by this principle of minimized potential energy. Electrons “want” to “fall” as close as they can to the positively-charged nucleus. However, there is limited “seating” around the nucleus. As described by Pauli’s Exclusion Principle, electrons cannot simply pile on top of each other in their quest for minimum energy, but rather must occupy certain regions of space allowed by their unique quantum states.

An analogy<sup>10</sup> for visualizing this is to picture an atom as if it were an amphitheater, with the stage being the nucleus and the concentric array of seats being places where electrons may reside. All spectators (electrons) desire to be as close to the stage (nucleus) in an amphitheater (atom) as possible, but since everyone cannot occupy the best seat, people are forced to choose seats at

<sup>9</sup>These orbitals just happen to be the 1s, 2p, 3d, and 4f orbitals, as viewed from left to right. In each case, the nucleus lies at the geometric center of each shape. In a real atom, all orbitals share the same center, which means any atom having more than two electrons (that’s all elements except for hydrogen and helium!) will have multiple orbitals around one nucleus. This four-set of orbital visualizations shows what some orbitals would look like if viewed in isolation.

<sup>10</sup>Please understand that like all analogies, this one merely illustrates a complex concept in terms that are easier to recognize. Analogies do not *explain* why things work, but merely liken an abstract phenomenon to something more accessible to common experience.

different positions around the stage. As a result, the inner seats fill first, with most empty seats being furthest away from the stage. The concept of energy fits neatly into this analogy as well: just as electrons give up *energy* to “fall into” lower-energy regions around the nucleus, people must give up *money* to purchase seats closest to the action on stage.

The energy levels available for orbiting electrons are divided into categories of *shells* and *subshells*. A “shell” (or, *principal quantum number*,  $n$ ) describes the main energy level of an electron. In our amphitheater analogy, this is equivalent to a *tier* or *seating level*. A “subshell” (or, *subsidiary quantum number*,  $l$ ) further divides the energy levels within each electron shell, and assigns different shapes to the electrons’ probability “clouds.” In the amphitheater analogy, a subshell would be a row of seats within a particular tier. To make the analogy accurate, we would have to imagine each row of seats in a tier having a different shape (not all arcs or straight lines), with varying degrees of viewing comfort afforded by each shape. The first row in each tier faces uniformly toward the stage, allowing easy viewing. Successive rows (subshells) in each tier (shell) contain more seats, but are bent in such a way that the stage is not as easy to view, making these rows less desirable to occupy. Electron subshells always have an even-numbered electron capacity, analogous to theater rows containing even-numbered quantities of seats, because atomic electrons tend to gather in pairs called *orbitals*.

Chemists identify electron shells both by number (the value of the quantum number  $n$ ) and/or by capital letters: the first shell by the letter K, the second by L, the third by M, and the fourth by N. Higher-order shells exist for atoms requiring<sup>11</sup> many electrons (high atomic number), and the lettering pattern is alphabetic (fifth shell is O, sixth is P, etc.). Each successive shell has a greater number of subshells available, like successive amphitheater tiers having more rows: the low-level tiers closest to the stage having the fewest rows, and the high-level tiers furthest from the stage having the most rows.

A numbering and lettering system is also used by chemists to identify subshells within each shell (the  $l$  quantum number value starting with zero, and lower-case letters beginning with “s”): the first subshell ( $l = 0$ ) in any shell represented by the letter s, the second ( $l = 1$ ) by p, the third ( $l = 2$ ) by d, the fourth ( $l = 3$ ) by f, and all others by successive lower-case letters of the alphabet<sup>12</sup>. Each subshell of each shell has an even-numbered capacity for electrons, since the electrons in each subshell are organized in “orbital” regions, each orbital handling a maximum of two<sup>13</sup> electrons. The number of orbitals per shell is equal to twice the  $l$  value plus one. An “s” subshell has one orbital holding up to two electrons. A “p” subshell has three orbitals holding up to six electrons total. A “d” subshell has five orbitals holding up to ten electrons total. An “f” subshell has seven orbitals holding up to 14 electrons total. A “g” subshell has nine orbitals holding up to 18 electrons total.

The number of subshells in any shell is the same as that shell’s  $n$  value. Thus, the first (K) shell has only one subshell, “s”. The second (L) shell has two subshells, an “s” and a “p”. The third (M) shell has three subshells available, an “s”, a “p”, and a “d”; and so on.

---

<sup>11</sup>Truth be told, higher-order shells exist even in simple atoms like hydrogen, but are simply not occupied by that atom’s electron(s) unless they are “excited” into a higher energy state by an external input of energy.

<sup>12</sup>The letters *s*, *p*, *d*, and *f* refer to the words *sharp*, *principal*, *diffuse*, and *fundamental*, used to describe the appearance of spectral lines in the early days of atomic spectroscopy research. Higher-order subshells are labeled alphabetically after *f*: *g*, *h*, and *i*.

<sup>13</sup>The two electrons of any orbital have opposite *spin* values.

This table shows the first few shells, their subshells, and electron capacities of each:

Shell ( $n$ value)	Subshell ( $l$ value)	Subshell electron capacity $= 2(2l + 1)$
$n = 1$ ; K	$l = 0$ ; s	$2 \times (2 \times 0 + 1) = 2$
$n = 2$ ; L	$l = 0$ ; s	$2 \times (2 \times 0 + 1) = 2$
	$l = 1$ ; p	$2 \times (2 \times 1 + 1) = 6$
$n = 3$ ; M	$l = 0$ ; s	$2 \times (2 \times 0 + 1) = 2$
	$l = 1$ ; p	$2 \times (2 \times 1 + 1) = 6$
	$l = 2$ ; d	$2 \times (2 \times 2 + 1) = 10$
$n = 4$ ; N	$l = 0$ ; s	$2 \times (2 \times 0 + 1) = 2$
	$l = 1$ ; p	$2 \times (2 \times 1 + 1) = 6$
	$l = 2$ ; d	$2 \times (2 \times 2 + 1) = 10$
	$l = 3$ ; f	$2 \times (2 \times 3 + 1) = 14$

Reviewing our amphitheater analogy, atomic shells are like seating tiers (levels), subshells are like rows of seats within each tier, and subshell electron capacity is like the number of seats in each row. This simple illustration shows an atom with three shells (K, L, and M) with the respective subshells (s, p, and d) represented by differently-shaded rings within each shell, having different numbers of places for electrons within each one:

This illustration is vastly over-simplified, failing to show the diverse shapes of each subshell, serving only to show how each successive shell grows in subshells and electron capacities.

The complete electron configuration for an atom may be expressed using *spectroscopic notation*, showing the shell numbers, subshell letters, and number of electrons residing within each subshell as a superscript. For example, the element helium (with an atomic number of 2) would be expressed as  $1s^2$ , with just two electrons in the “s” subshell of the first shell. The following table shows the electron structures of the first nineteen elements in the periodic table, from the element hydrogen (atomic number<sup>14</sup> = 1) to potassium (atomic number = 19):

Element	Atomic number	Electron configuration
Hydrogen	1	$1s^1$
Helium	2	$1s^2$
Lithium	3	$1s^2 2s^1$
Beryllium	4	$1s^2 2s^2$
Boron	5	$1s^2 2s^2 2p^1$
Carbon	6	$1s^2 2s^2 2p^2$
Nitrogen	7	$1s^2 2s^2 2p^3$
Oxygen	8	$1s^2 2s^2 2p^4$
Fluorine	9	$1s^2 2s^2 2p^5$
Neon	10	$1s^2 2s^2 2p^6$
Sodium	11	$1s^2 2s^2 2p^6 3s^1$
Magnesium	12	$1s^2 2s^2 2p^6 3s^2$
Aluminum	13	$1s^2 2s^2 2p^6 3s^2 3p^1$
Silicon	14	$1s^2 2s^2 2p^6 3s^2 3p^2$
Phosphorus	15	$1s^2 2s^2 2p^6 3s^2 3p^3$
Sulfur	16	$1s^2 2s^2 2p^6 3s^2 3p^4$
Chlorine	17	$1s^2 2s^2 2p^6 3s^2 3p^5$
Argon	18	$1s^2 2s^2 2p^6 3s^2 3p^6$
Potassium	19	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^1$

In order to avoid having to write unwieldy spectroscopic descriptions of each element’s electron structure, it is customary to write the notation only for subshells that are unfilled. For example, instead of writing the electron structure of the element aluminum<sup>15</sup> as  $1s^2 2s^2 2p^6 3s^2 3p^1$ , we might just as well write a condensed version showing only the last subshell ( $3p^1$ ), since all the previous subshells are completely full.

Another way to abbreviate the spectroscopic notation for elements is to condense all the shells below the newest (unfilled) shell as the corresponding noble element, in brackets. To use the example of aluminum again, we could write its spectroscopic notation as  $[\text{Ne}]3s^2 3p^1$  since its shell 1 and shell 2 configurations are completely described by the electron configuration of Neon.

<sup>14</sup>The atomic number is the quantity of protons found in an atom’s nucleus, and may only be a whole number. Since any electrically balanced atom will have the same number of electrons as protons, we may look at the atomic number of an element as being the number of electrons in each atom of that element.

<sup>15</sup>Building on the amphitheater analogy for one atom of the element aluminum, we could say that there are two electrons occupying the “s” seating row on the first level, plus two electrons occupying the “s” seating row on the second level, plus six electrons occupying the “p” seating row on the second level, plus two electrons occupying the “s” seating row on the third level, plus one electron occupying the “p” seating row on the third level.

Re-writing our electron shell table for the first nineteen elements using this condensed notation:

Element	Atomic number	Electron configuration
Hydrogen	1	$1s^1$
Helium	2	$1s^2$
Lithium	3	$[\text{He}]2s^1$
Beryllium	4	$[\text{He}]2s^2$
Boron	5	$[\text{He}]2s^22p^1$
Carbon	6	$[\text{He}]2s^22p^2$
Nitrogen	7	$[\text{He}]2s^22p^3$
Oxygen	8	$[\text{He}]2s^22p^4$
Fluorine	9	$[\text{He}]2s^22p^5$
Neon	10	$[\text{He}]2s^22p^6$
Sodium	11	$[\text{Ne}]3s^1$
Magnesium	12	$[\text{Ne}]3s^2$
Aluminum	13	$[\text{Ne}]3s^23p^1$
Silicon	14	$[\text{Ne}]3s^23p^2$
Phosphorus	15	$[\text{Ne}]3s^23p^3$
Sulfur	16	$[\text{Ne}]3s^23p^4$
Chlorine	17	$[\text{Ne}]3s^23p^5$
Argon	18	$[\text{Ne}]3s^23p^6$
Potassium	19	$[\text{Ar}]4s^1$

If we progress from element to element in increasing atomic number, we see that no new shell begins to form until after we reach the noble element for that period<sup>16</sup> at the far right-hand column. With the beginning of each new period at the far-left end of the Table, we see the beginning of the next higher-order electron shell. The shell(s) below are represented by whichever noble element shares that same configuration<sup>17</sup>, indicating a “noble core” of electrons residing in extremely stable (low-energy) regions around the nucleus.

<sup>16</sup>Recall the definition of a “period” in the Periodic Table being a horizontal row, with each vertical column being called a “group”.

<sup>17</sup>Building on the amphitheater analogy once again for one atom of the element aluminum, we could say that all seats within levels 1 and 2 are occupied (just like an atom of neon), plus two electrons occupying the “s” seating row on the third level, plus one electron occupying the “p” seating row on the third level.

The beginning of the next higher-order shell is what accounts for the periodic cycle of ionization energies we see in elements of progressing atomic number. The first electron to take residence in a new shell is very easy to remove, unlike the electrons residing in the “noble” configuration shell(s) below:

*Noble elements found at the end of each period have the most stable (i.e. difficult-to-ionize) electron configurations.*

Not only is the “noble core” notation convenient for tersely describing the electron structure of an element, but it also reveals an important concept in chemistry: the idea of *valence*. Electrons residing in lower-order shells are, by definition, at lower energy states than electrons residing in higher-order shells and are therefore much more difficult to dislodge. Therefore, the electrons in unfilled shells, being easier to dislodge, play a far greater role in chemical bonds than electrons residing in filled shells below. These “outer” electrons are called *valence electrons*, and their number determines how readily an atom will chemically interact with another atom. This is why elements found in the same group (having similar outer-electron configurations) bear similar chemical characteristics: the electrons lying below in the “noble core” configurations have little effect on how the atom will bond with other atoms. A lithium atom, with its outer-most electron configuration being  $2s^1$ , reacts in much the same way as an atom of sodium having an outer-most configuration of  $3s^1$ , and much the same as a potassium atom having an outer-most configuration of  $4s^1$ , all because those outer-shell electrons are the most available for interaction with electrons of other atoms.

If we examine the electron structures of atoms with successively greater atomic numbers (more protons in the nucleus, therefore more electrons in orbit to balance the electrical charge), we notice that the shells and subshells fill up in an interesting pattern. One might think that all the lower-order shells get completely filled before any electrons go into a higher-order shell – just as we might expect people to fill every seat in all the lower tiers of an amphitheater before filling seats in any of the higher tiers – but this is not always the case. Instead, the energy levels of subshells within shells is split, such that certain subshells within a higher shell will have a lower energy value than certain subshells within a lower shell. Referring back to our amphitheater analogy, where seating tiers represented shells and seat rows of various shape represented subshells, it is as though people choose to fill the more comfortable rows in higher-level tiers before sitting in the less-comfortable rows in lowest available tiers, the desire for comfort trumping the desire for proximity to the stage.

A rule commonly taught in introductory chemistry courses called the *Madelung rule* (also referred to as *Aufbau order*, after the German verb *aufbauen* meaning “to build up”) is that subshells fill with increasing atomic number in such an order that the subshell with the lowest  $n + l$  value, in the lowest shell, gets filled before any others.

The following graphic illustrates this ordering:

Madelung filling order:  $1s \rightarrow 2s \rightarrow 2p \rightarrow 3s \rightarrow 3p \rightarrow 4s \rightarrow 3d \rightarrow 4p \rightarrow 5s \rightarrow 4d \rightarrow 5p \rightarrow 6s \rightarrow 4f \rightarrow 5d \rightarrow 6p \rightarrow 7s \rightarrow 5f \rightarrow 6d \rightarrow 7p \rightarrow 8s \rightarrow (etc.)$

It should be noted that exceptions exist for this rule. We see one of those exceptions with the element chromium ( ${}_{24}\text{Cr}$ ). Strictly following the Madelung rule in progressing from vanadium (atomic number = 23, valence electron structure  $3d^3 4s^2$ ) to chromium (atomic number = 24), we would expect the next electron to take residence in the “3d” subshell making chromium’s valence structure be  $3d^4 4s^2$ , but instead we find *two more* electrons residing in chromium’s 3d subshell with one less in the 4s subshell ( $3d^5 4s^1$ ). The sequence resumes its expected progression with the next element, manganese (atomic number = 25, valence electron structure  $3d^5 4s^2$ ). The general principle

of energy minimization still holds true . . . it's just that the relative energies of succeeding subshells do not follow a simple rule structure. In other words, the Aufbau order is an over-simplified view of reality. To use the amphitheater analogy again, it's as if someone gave up one of the nice chairs in tier 4 to sit next to a friend who just occupied one of the less comfortable chairs in tier 3.

The practical importance of electron configurations in chemistry is the potential energy possessed by electrons as they reside in different shells and subshells. This is extremely important in the formation and breaking of chemical bonds, which occur due to the interaction of electrons between two or more atoms. A chemical bond occurs between atoms when the outer-most (valence) electrons of those atoms mutually arrange themselves in energy states that are collectively lower than they would be individually. The ability for different atoms to join in chemical bonds completely depends upon the default energy states of electrons in each atom, as well as the next available energy states in the other atoms. Atoms will form stable bonds only if the union allows electrons to assume stable (low-energy) levels. This is why different elements are very selective regarding which elements they will chemically bond with to form compounds: not all combinations of atoms result in favorable potential energy levels.

The amount of energy required to break a chemical bond (i.e. separate the atoms from each other) is the same amount of energy required to restore the atoms' electrons to their previous (default) states before they joined. This is the same amount of energy released by the atoms as they come together to form the bond. Thus, we see the foundation of the general principle in chemistry that forming chemical bonds releases energy, while breaking chemical bonds requires an input of energy from an external source. We also see in this fact an expression of the Conservation of Energy: the amount of energy "invested" in breaking bonds is precisely the same as the amount of energy "returned" when those same bonds re-form.

In summary, the whole of chemistry is a consequence of electrons not being able to assume arbitrary positions around the nucleus of an atom. Instead, they seek the lowest possible energy levels within a framework allowing them to retain unique quantum states. Atoms with mutually agreeable electron structures readily bond together to form molecules, and they release energy in the process of joining. Molecules may be broken up into their constituent atoms, if sufficient energy is applied to overcome the bond. Atoms with incompatible electron structures do not form stable bonds with each other.

## 3.5 Spectroscopy

Much of our knowledge about atomic structure comes from experimental data relating the interaction between *light* and atoms of the different elements. Light may be modeled as an electromagnetic wave, consisting of an oscillating electric field and an oscillating magnetic field. Like any wave, the relationship between propagation velocity, wavelength, and frequency is described by the following equation:

$$v = \lambda f$$

Where,

$v$  = Velocity of propagation (e.g. meters per second)

$\lambda$  = Wavelength (e.g. meters)

$f$  = Frequency of wave (e.g. Hz, or 1/seconds)

When applied to light waves, this equation is typically written as  $c = \lambda f$ , where  $c$  is the speed of light in a vacuum ( $\approx 3 \times 10^8$  meters per second): one of the fundamental constants of physics.

Light that is visible to the human eye has wavelengths approximately between 400 nm (400 *nanometers*) at the violet end of the spectrum and 700 nm at the red end of the spectrum. Given the speed of light, this equates to a frequency range for visible light between  $7.5 \times 10^{14}$  Hz and  $4.286 \times 10^{14}$  Hz.

A computer-generated image of the visible light spectrum (plus the ultraviolet and infrared regions outside of the visible range, shown in grey) appears here. A real spectrum may be generated by taking “white” light and passing it through either a prism or a diffraction grating so that the different wavelengths separate from each other:

Just as buoyant objects are moved up and down by waves of water, electrically-charged objects may be moved about by waves of electrical fields such as light. In the case of electrons, their positions around the nucleus of an atom may be altered if struck by light of the necessary wavelength.

One of the major breakthrough discoveries of modern physics was the realization that a ray of light could be modeled as a stream of *particles* – each of these “photon” particles possessing a definite amount of energy – in addition to being modeled as a continuous *wave* possessing a definite frequency. The combined work of physicists Max Planck in 1900 and Albert Einstein in 1905 resulted in the following equation relating a photon’s energy to its frequency:

$$E = hf$$

Where,

$E$  = Energy carried by a single “photon” of light (joules)

$h$  = Planck’s constant ( $6.626 \times 10^{-34}$  joule-seconds)

$f$  = Frequency of light wave (Hz, or 1/seconds)

We may re-write this equation to express a photon’s energy in terms of its wavelength ( $\lambda$ ) rather than its frequency ( $f$ ), knowing the equation relating those two variables for waves of light ( $c = \lambda f$ ):

$$E = \frac{hc}{\lambda}$$

Physicists knew that light carried energy, but now they understood that the energy carried by a beam of light was finely divided into fixed (“quantized”) amounts corresponding to the wavelength of each particle-wave (photon). That is to say, a beam of monochromatic (single-color, or single-wavelength) light consists of photons having exactly the same energies, and total beam power is simply a matter of how many of those photons per second pass by. Varying the intensity of a monochromatic light beam without changing its wavelength (color) only changes the number of photons per second, not the amount of energy carried by each photon.

If the amount of energy carried by a photon happens to match the energy required to make an atomic electron “jump” from one energy level to another within the atom, the photon will be consumed in the work of that task when it strikes the atom. Conversely, when that “excited” electron returns to its original (lower) energy level in the atom, it releases a photon of the same frequency as the original photon that excited the electron:

Since the energy levels available for an electron to “jump” within an atom are limited to certain fixed values by virtue of the atom’s shell and subshell structure, this means only certain specific frequencies or wavelengths of light will be able to make an electron of a particular atom move to new shells and/or subshells<sup>18</sup>. A startling consequence of this *quantum theory* of light was that the ability of a light beam to dislodge electrons from an atom depended on the *color* (wavelength or frequency) of the photons, and not the intensity (total power) of the light beam. A light beam consisting of photons with insufficient individual energy (i.e. frequency too low; wavelength too long; color too far shifted toward red if visible) is incapable of boosting electrons from a lower energy level to a higher energy level, no matter how intense that beam may be. This is analogous to shooting an armored target with slow-moving bullets: so long as the velocity (kinetic energy) of each bullet is insufficient to penetrate the armor, it does not matter how many of those low-energy bullets are fired at the target, or how frequently they are fired. However, just a single bullet with sufficient kinetic energy will be sufficient to penetrate the armor.

<sup>18</sup>This is the reason silicon-based photovoltaic solar cells are so inefficient, converting only a fraction of the incident light into electricity. The energy levels required to create an electron-hole pair at the P-N junction correspond to a narrow portion of the natural light spectrum. This means most of the photons striking a solar cell do *not* transfer their energy into electrical power because their individual energy levels are insufficient to create an electron-hole pair in the cell’s P-N junction. For photovoltaic cells to improve in efficiency, some way must be found to harness a broader spectrum of photon frequencies (light colors) than silicon P-N junctions can do, at least on their own.

The discovery of photons having discrete energy values was a major shift in scientific thought, setting physics down a new path of understanding matter and energy in *quantum* terms. It was this new quantum theory of matter and energy that led to the modern understanding of atomic electron structure, with all its shells, subshells, and orbitals. Later mathematical contributions to quantum theory from physicists such as Louis de Broglie, Werner Heisenberg, and especially Erwin Schrödinger provided tools to calculate the probability distributions of electrons within atoms. The oddly-shaped orbital electron “clouds” discussed earlier in this chapter are in fact solutions to Schrödinger’s wave equation for electrons at different energy levels:

This is why the notation used in the previous section to describe electron configurations (e.g.  $1s^2 2s^2 2p^1$ ) is called *spectroscopic* notation: the discovery of shells, subshells, and orbitals owes itself to the analysis of light wavelengths associated with different types of atoms, studied with a device called a *spectroscope* constructed to analyze the wavelengths of light across the visible spectrum. Just as the telescope was the first tool scientists used to explore outer space, the spectroscope was one of the first tools used by scientists to explore the “inner space” of atomic structure.

### 3.5.1 Emission spectroscopy

If we take a sample of atoms, all of the same element and at a low density<sup>19</sup> (e.g. a gas or vapor), and “excite” them with a source of energy such as an electric arc, we will notice those atoms emit colors of light that are characteristically unique to that element:

This phenomenon is used to make colored discharge (“neon”) lights. While neon gas glows with a characteristic pink-orange color, other gases glow with their own signature colors. By filling glass tubes with the right gas(es), a wide variety of colors may be produced.

These colors are unique to their respective gases because the unique electron configurations of each element creates a unique set of energy values between which atomic electrons of that element may “jump.” Since no two elements have the exact same electron configurations, no two elements will have the exact same set of available energy levels for their electrons to occupy. When excited electrons fall back into lower shell levels, the photons they emit will have distinct wavelengths. The result is an *emission spectrum* of light wavelengths, much like a “fingerprint” unique to that element. Indeed, just as fingerprints may be used to identify a person, the spectrum of light emitted by an “excited” sample of an element may be used to identify that element.

For example, we see here the emission spectrum for *hydrogen*, shown immediately below the continuous spectrum of visible light for convenient reference<sup>20</sup>:

Each of the colored “lines” in the emission spectrum for hydrogen represents the photon wavelength emitted when the excited electron loses energy and falls back into a lower-level position. The larger the energy difference between energy levels (i.e. the bigger the jump), the more energy the photon carries away, and consequently the shorter the wavelength (higher the frequency) of the photon. The violet color line, therefore, represents one of the larger “jumps” while the red color line represents one of the smaller. Hydrogen happens to emit four different wavelengths within the visible range (656 nm, 486 nm, 434 nm, and 410 nm), and many others outside the visible range.

<sup>19</sup>Solids and liquids tend to emit a broad spectrum of wavelengths when heated, in stark contrast to the distinct “lines” of color emitted by isolated atoms.

<sup>20</sup>To create these spectra, I used a computer program called *Spectrum Explorer*, or **SPEX**.

This next illustration shows a simplified view of a hydrogen atom, with the lowest-level shell ( $n = 1$ , K) representing the ground state and higher-level shells representing “excited” energy states for its single electron:

Wavelengths of light emitted when an excited electron falls from any high-level shell down to the second shell of hydrogen ( $n = 2$ ; L) are called the *Balmer series* of spectral lines. The four wavelengths previously mentioned are Balmer lines visible to the human eye: 410 nm resulting from an electron jumping from the sixth shell ( $n = 6$ ; P) to the second shell, 434 nm resulting from a transition between the fifth and second shells, 486 nm from a transition between the fourth and second shells, and finally the 656 nm wavelength resulting from a transition between the third and second shells. Other Balmer-series wavelengths exist<sup>21</sup> (electrons transitioning from even higher shells than the sixth, down to the second), but these wavelengths lie within the ultraviolet range and are therefore not visible to the human eye. Note the inverse relationship between jump distance and wavelength: the shortest “jump” (shell 3 to shell 2) yields the photon with the longest wavelength (656 nm). This is because the shortest jump represents the smallest energy change, which then

<sup>21</sup>Including wavelengths of 397 nm, 389 nm, and 384 nm.

results in a photon of comparatively little energy, having a low frequency and therefore a long wavelength.

You will note that the Balmer series of wavelengths do not involve an electron falling all the way back to the hydrogen atom's "ground state" (the normal, or un-excited state of shell  $n = 1$ , the "K" shell). Electrons falling down to the first shell ( $n = 1$ ; K) from any higher-level shells will also emit photons, but these photons will be of a far shorter wavelength (higher frequency, higher energy) than any in the Balmer series, owing to the larger energy gap between the first shell and all the others. This so-called *Lyman series* of light wavelengths lies within the region of wavelengths referred to as "far-ultraviolet," well outside the range of human vision.

This next graphic shows the emission spectra of several elements contrasted against a continuous spectrum covering both visible light and portions of the ultraviolet and infrared ranges:

Note how complex the emission spectra are for some of the elements. Since we know each spectral line represents a unique change in energy (i.e. a unique "jump distance" from one energy level to another), the multitude of lines we see for each element shows us the range of "jumps" possible within certain atoms. Note also how spectral lines for most elements (including hydrogen) extend past the visible light range. Lines in the ultraviolet range comes from large electron transitions, as electrons fall from high-level shells to low-level shells and lose much energy. Lines in the infrared range originate from small electron transitions, as electrons transition between adjacent shells and lose little energy.

Not only may the wavelengths of photons emitted from "excited" electrons returning to lower-energy conditions be used to positively identify different elements, but we may also use those wavelengths as universal standards, since the fundamental properties of elements are not liable to change. For example, the SI (Système International) definition for the base unit of the *meter* is standardized as 1650763.73 wavelengths of light emitted by a krypton-86 ( $^{86}\text{Kr}$ ) atom as its electrons transition between the  $2p^{10}$  and  $5d^5$  subshells<sup>22</sup>.

<sup>22</sup>The wavelength of this light happens to lie within the visible range, at approximately 606 nm. Note the shell levels involved with this particular electron transition: between  $2p^{10}$  and  $5d^5$ . Krypton in its ground (un-excited) state has a valence electron configuration of  $4p^6$ , which tells us the electron's transition occurs between an inner shell of the Krypton atom and an excited shell (higher than the ground-state outer shell of the atom). The wavelength of this photon (606 nm) resulting from a shell 5 to shell 2 transition also suggests different energy levels for those shells of a Krypton atom compared to shells 5 and 2 of a hydrogen atom. Recall that the Balmer line corresponding to a transition from  $n = 5$  to  $n = 2$  of a hydrogen atom had a wavelength value of 434 nm, a higher energy than 606 nm and therefore a larger jump between those corresponding shells.

### 3.5.2 Absorption spectroscopy

If we take a sample of atoms, all of the same element and at a low density (e.g. a gas or vapor), and pass a continuous (“white”) spectrum of light wavelengths through that sample, we will notice certain colors of light *missing* from the light exiting the sample:

Not only are these missing wavelengths characteristically unique to that element, but they are *the exact same wavelengths of light found in the emission spectrum for that element!* The same photon wavelengths produced by an atom when “excited” by an external energy source will be readily *absorbed* by that atom if exposed to them. Thus, the spectrum of light missing characteristic wavelengths after passing through a gas sample is called an *absorption spectrum*, and may be used to identify elements just as easily<sup>23</sup> as an emission spectrum.

The absorption spectrum of hydrogen gas is shown at the bottom of this three-spectrum graphic image, contrasted against the continuous spectrum of visible light (top) and the emission spectrum for hydrogen (middle):

Note how the four colored lines in the emission spectrum characteristic of hydrogen appear as *missing* colors (black lines) in the absorption spectrum. It is almost as though one hydrogen spectrum were a photographic “negative” of the other: each of the colors present in the emission spectrum is distinctly absent<sup>24</sup> in the absorption spectrum. Although the color patterns may be inverted, the positions of the lines within the spectrum are the same, and are *uniquely* representative of hydrogen.

The effect is analogous to fingerprints made two different ways: one by pressing a pre-inked finger onto a clean sheet of paper; the other by pressing a clean finger onto pre-inked paper. In the first method, the result is a set of dark ink-marks where the fingerprint ridges touched the paper to apply ink and light areas where skin and paper never touched. In the second method, the result is a set

<sup>23</sup>In fact, it is often easier to obtain an absorption spectrum of a sample than to create an emission spectrum, due to the relative simplicity of the absorption spectrometer test fixture. We don’t have to energize a sample to incandescence to obtain an absorption spectrum – all we must do is pass white light through enough of it to absorb the characteristic colors.

<sup>24</sup>One student described this to me as a “shadow” image of the hydrogen gas. The missing colors in the absorption spectrum are the *shadows* of hydrogen gas molecules blocking certain frequencies of the incident light from reaching the viewer.

of *inverse* ink-marks: light where the fingerprint ridges touched the paper to remove ink and dark where skin and paper never touched. The fingerprint patterns in both cases – if made using the same finger – will be identical in form, just inverted in color. Likewise, the *patterns* of emission and absorption spectroscopy will be the same for any given substance, just inverted in color: emission spectroscopy shows select wavelengths against an otherwise dark field, while absorption spectroscopy shows a nearly-full spectrum of color missing (the same) select wavelengths.

Individual atoms are not the only forms of matter possessing uniquely identifying spectra – many *molecules* have spectral “signatures” of their own as well. The absorption spectra for molecular substances are substantially more complex than the absorption spectra of pure elements, owing to the many more different ways in which light energy may be absorbed by a molecule. In addition to electron shell and subshell “jumps” capable of absorbing a photon’s energy, the atoms within a molecule are also able to vibrate, rotate, and twist about each other like mechanical oscillators. Photons of light possessing just the right frequencies are able to “excite” certain molecules in a manner not unlike AC electrical waveforms resonating with tuned LC (inductor-capacitor) circuits. Just as tuned LC circuits absorb and store energy at certain frequencies, molecular oscillators absorb and store energy from photons.

The multiplicity of energy-absorbing modes for certain molecules gives them wide *bands* of absorption in the light spectrum, not just thin “lines” as is the case with individual atoms. These bands are still unique to each molecule type, but they typically cover a far broader swath of wavelengths than is typical for atomic absorption spectra.

The absorption of ultraviolet light by ozone gas ( $O_3$ ) high in Earth’s atmosphere is an example of absorption spectroscopy on a grand scale. These molecules serve as a protective “blanket” against ultraviolet light rays from the sun which have detrimental effects on life (e.g. sunburn, skin cancer). The ozone does not absorb light in the visible spectrum, and so its protective effects are not visually apparent, but the attenuation of ultraviolet light is definitely measurable. This attenuation also covers far more than just one or two specific wavelengths of ultraviolet light, which is good for life on Earth because otherwise ozone wouldn’t offer much protection.

Many chemical substances of interest in process industries have well-known *absorption signatures* for ultraviolet and infrared light. This makes spectroscopy a powerful tool for the identification (and quantitative measurement) of chemical composition in process fluids, exhaust gases, and sometimes even in solid materials. For more detail on the practical application of spectroscopy to analytical measurement, refer to section 23.4 beginning on page 1805.

An interesting application of optical absorption is the detection of gas leaks using an infrared camera. Many industrial gases are strong absorbers of infrared light, which means if a leaking pipe or vessel is viewed through a camera sensitized to infrared light and there is sufficient ambient infrared light for viewing, the leaking gas will appear on the camera’s image as a dark cloud. The gas plume appears on the camera’s display the way steam or smoke appears to the naked eye. Several paraffinic hydrocarbon compounds such as methane, ethane, propane, butane, pentane, and hexane are detectable with infrared cameras sensitized to light wavelengths of 3.3 to 5 micrometers ( $\mu m$ ). Infrared cameras sensitized to longer wavelengths of light (10  $\mu m$  to 11  $\mu m$ ) are useful for detecting leaks of gases such as sulfur hexafluoride, ammonia, chlorine dioxide, FREON-12, and ethylene to name a few.

### 3.6 Formulae for common chemical compounds

Most of these formulae appear in *molecular chemical* form rather than structural form. For example, ethanol appears here as  $\text{C}_2\text{H}_6\text{O}$  rather than  $\text{C}_2\text{H}_5\text{OH}$ . Also, the entries for fructose and glucose are identical ( $\text{C}_6\text{H}_{12}\text{O}_6$ ) despite the two compounds having different structures. This means most of the formulae shown in this section merely represent the ratios of each element in a compound, making little or no attempt to convey the *structure* of the molecule.

It should be noted that this list is definitely *not* exhaustive, but merely attempts to show formulae for some common compounds.

- Acetone:  $\text{C}_3\text{H}_6\text{O}$
- Acetylene:  $\text{C}_2\text{H}_2$
- Alcohol, methyl (methanol):  $\text{CH}_4\text{O}$
- Alcohol, ethyl (ethanol):  $\text{C}_2\text{H}_6\text{O}$
- Alcohol, isopropyl (isopropanol):  $\text{C}_3\text{H}_8\text{O}$
- Alcohol, butyl (butanol):  $\text{C}_4\text{H}_{10}\text{O}$
- Alcohol, phenol:  $\text{C}_6\text{H}_6\text{O}$
- Aluminum oxide (alumina):  $\text{Al}_2\text{O}_3$
- Ammonia:  $\text{NH}_3$
- Ammonium carbonate:  $(\text{NH}_4)_2\text{CO}_3$
- Ammonium chloride (sal ammoniac):  $\text{NH}_4\text{Cl}$
- Ammonium nitrate:  $\text{N}_2\text{H}_4\text{O}_3$
- Aromatic hydrocarbons:
  - Acetylene:  $\text{C}_2\text{H}_2$
  - Ethylene:  $\text{C}_2\text{H}_4$
  - Propylene:  $\text{C}_3\text{H}_6$
  - Butylene:  $\text{C}_4\text{H}_8$
  - Benzene:  $\text{C}_6\text{H}_6$
  - Toluene:  $\text{C}_7\text{H}_8$
  - Styrene:  $\text{C}_8\text{H}_8$
  - Napthalene:  $\text{C}_{10}\text{H}_8$
- Calcium carbonate (limestone, marble):  $\text{CaCO}_3$
- Calcium chloride:  $\text{CaCl}_2$
- Calcium hydroxide:  $\text{Ca}(\text{OH})_2$

- Calcium oxide (lime or quicklime):  $\text{CaO}$
- Calcium sulfate (gypsum):  $\text{CaSO}_4$
- Carbon monoxide:  $\text{CO}$
- Carbon dioxide:  $\text{CO}_2$
- Carbon tetrachloride:  $\text{CCl}_4$
- Carbonic acid:  $\text{H}_2\text{CO}_3$
- Cellulose:  $(\text{C}_6\text{H}_{10}\text{O}_5)_n$
- Clay (or shale):  $\text{H}_4\text{Al}_2\text{Si}_2\text{O}_9$
- Copper oxide (cuprite):  $\text{Cu}_2\text{O}$
- Copper oxide (tenorite):  $\text{CuO}$
- Cyanic acid:  $\text{HOCN}$
- Dextrose (synonym for biological glucose):  $\text{C}_6\text{H}_{12}\text{O}_6$
- Ethyl mercaptan:  $\text{C}_2\text{H}_6\text{S}$
- Ethylene glycol:  $\text{C}_2\text{H}_6\text{O}_2$
- Ethylene oxide:  $\text{C}_2\text{H}_4\text{O}$
- Ferrous chloride:  $\text{FeCl}_2$
- Ferric chloride:  $\text{FeCl}_3$
- Formaldehyde:  $\text{CH}_2\text{O}$
- Folic acid:  $\text{C}_{19}\text{H}_{19}\text{N}_7\text{O}_6$
- Formaldehyde:  $\text{CH}_2\text{O}$
- Formic acid:  $\text{CH}_2\text{O}_2$
- Fructose (same molecular formula as glucose):  $\text{C}_6\text{H}_{12}\text{O}_6$
- Glycerol:  $\text{C}_3\text{H}_8\text{O}_3$
- Hydrazine:  $\text{N}_2\text{H}_4\text{N}$
- Hydrocyanic acid:  $\text{HCN}$
- Hydrofluoric acid:  $\text{HF}$
- Hydrochloric acid:  $\text{HCl}$
- Hydrogen peroxide:  $\text{H}_2\text{O}_2$

- Hydrogen sulfide:  $\text{H}_2\text{S}$
- Iron oxide:  $\text{Fe}_2\text{O}_3$
- Magnesium hydroxide (milk of magnesia):  $\text{Mg}(\text{OH})_2$
- Nitric acid:  $\text{HNO}_3$
- Nitric oxide:  $\text{NO}$
- Nitrogen dioxide:  $\text{NO}_2$
- Nitrogen trioxide:  $\text{NO}_2$
- Nitroglycerine:  $\text{C}_3\text{H}_5\text{N}_3\text{O}_9$
- Nitromethane:  $\text{CH}_3\text{NO}_2$
- Nitrous oxide:  $\text{N}_2\text{O}$
- Dinitrogen dioxide:  $\text{N}_2\text{O}_2$
- Dinitrogen trioxide:  $\text{N}_2\text{O}_3$
- Ozone:  $\text{O}_3$
- Paraffinic hydrocarbons:
  - Methane:  $\text{CH}_4$
  - Ethane:  $\text{C}_2\text{H}_6$
  - Propane:  $\text{C}_3\text{H}_8$
  - Butane:  $\text{C}_4\text{H}_{10}$
  - Pentane:  $\text{C}_5\text{H}_{12}$
  - Hexane:  $\text{C}_6\text{H}_{14}$
  - Heptane:  $\text{C}_7\text{H}_{16}$
  - Octane:  $\text{C}_8\text{H}_{18}$
  - Nonane:  $\text{C}_9\text{H}_{20}$
  - Decane:  $\text{C}_{10}\text{H}_{22}$
- Phosgene:  $\text{COCl}_2$
- Phosphoric acid:  $\text{H}_3\text{PO}_4$
- Potassium chloride:  $\text{KCl}$
- Potassium cyanide:  $\text{KCN}$
- Potassium hydroxide:  $\text{KOH}$
- Potassium sulfate:  $\text{K}_2\text{SO}_4$

- Silane:  $\text{SiH}_4$
- Silica:  $\text{SiO}_2$
- Silicon carbide:  $\text{SiC}$
- Sodium chloride (table salt):  $\text{NaCl}$
- Sodium hydroxide:  $\text{NaOH}$
- Sodium fluoride:  $\text{NaF}$
- Strychnine:  $\text{C}_{21}\text{H}_{22}\text{N}_2\text{O}_2$
- Sucrose:  $\text{C}_{12}\text{H}_{22}\text{O}_{11}$
- Sulfuric acid:  $\text{H}_2\text{SO}_4$
- Sulfur dioxide:  $\text{SO}_2$
- Sulfur hexafluoride:  $\text{SF}_6$
- Testosterone:  $\text{C}_{19}\text{H}_{28}\text{O}_2$
- Turpentine:  $\text{C}_{10}\text{H}_{16}$  (approx.)
- Zinc sulfate:  $\text{ZnSO}_4$

### 3.7 Molecular quantities

Sample sizes of chemical substances are often measured in *moles*. One mole of a substance is defined as a sample having  $6.022 \times 10^{23}$  (*Avogadro's number*) molecules<sup>25</sup>. This number is not arbitrary – it was chosen<sup>26</sup> such that 1 mole of carbon-12 ( $6.022 \times 10^{23}$  individual  $^{12}\text{C}$  atoms together in one sample) would have a mass of exactly 12 grams. In other words, Avogadro's number is a proportionality between an element's atomic mass (measured in *amu* or *Daltons*) and the mass of a sample (measured in *grams*).

With Avogadro's number defined as such, we may interpret any element's atomic mass value as a conversion factor relating moles to grams. For example, if we look up the element *potassium* in a periodic table, we see that it has an average atomic mass of 39.0983 amu (39.0983 Daltons) as found in nature. This means 1 mole of naturally-occurring potassium atoms equals 39.0983 grams of mass. Likewise, 5 moles of potassium atoms will have a mass of 195.4915 grams. Note the use of the equivalence 1 mol potassium = 39.0983 g as a “unity fraction” in the following calculation, used to cancel the given unit of moles to yield an answer in the unit of grams:

$$\left( \frac{5 \text{ mol potassium}}{1} \right) \left( \frac{39.0983 \text{ g}}{1 \text{ mol potassium}} \right) = 195.4915 \text{ g}$$

Molar quantities make it convenient to relate macroscopic samples of elements and compounds with each other. We know, for instance, that one mole of naturally occurring iron (Fe) atoms will have a mass of 55.8 grams, and that one mole of naturally occurring oxygen (O) atoms will have a mass of 16.0 grams, because the average atomic mass of naturally occurring iron is 55.8 amu, and the average atomic mass of naturally occurring oxygen is 16.0 amu. One mole of naturally occurring oxygen *molecules* ( $\text{O}_2$ ) will have a mass of 32.0 grams, since each molecule is a *pair* of oxygen atoms at 16 amu each, and “moles” counts the number of discrete entities which in the case of molecular oxygen is the number of  $\text{O}_2$  *molecules* rather than the number of O *atoms*. Applying the same reasoning, one mole of ozone ( $\text{O}_3$ ) molecules will have a mass of 48.0 grams.

The same mathematical proportions apply to compounds as they do to elements, since compounds are nothing more than different elements bound together in whole-number ratios, and the Conservation of Mass tells us a molecule cannot have a mass greater or less than the sum total of the constituent elements' masses. To illustrate this principle, we may calculate the mass of one mole of iron oxide ( $\text{Fe}_2\text{O}_3$ ), the principal component of *rust*:  $55.8 \times 2 + 16.0 \times 3 = 159.6$  grams. Likewise, we may calculate the mass of five moles of pure glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ ):  $5 \times (12.01 \times 6 + 1.01 \times 12 + 16.0 \times 6) = 900.9$  grams. The sum of the atomic masses of a molecule's constituent atoms is called the *molecular weight* or *formula weight* for that molecule. In the case of iron oxide, the molecular

<sup>25</sup>Truth be told, a “mole” is 602,200,000,000,000,000,000,000 counts of literally *any* discrete entities. Moles do not represent mass, or volume, or length, or area, but rather a *quantity of individual units*. There is nothing wrong with measuring the amount of eggs in the world using the unit of the mole, or the number of grains of sand in moles, or the number of bits in a collection of digital data. Think of “mole” as nothing more than a *really* big dozen, or more precisely, a really big *half*-dozen!

<sup>26</sup>Another way to define one mole is that it is the number of individual nucleons (i.e. protons and/or neutrons) necessary to comprise one gram of mass. Since protons and neutrons comprise the vast majority of an atom's mass, we may essentially ignore the mass of an atom's electrons when tabulating its mass and pay attention only to the nucleus. This is why one mole of Hydrogen atoms, each atom having just one lone proton in its nucleus, will have a combined mass of one gram. By extension, one mole of Carbon-12 atoms, each atom with 6 protons and 6 neutrons, will have a combined mass of twelve grams.

weight is 159.6 (typically rounded up to 160 grams per mole). In the case of glucose, the molecular weight is 180.18 (typically rounded down to 180 grams per mole).

When referring to liquid solutions, the concentration of a solute is often expressed as a *molarity*, defined as the number of moles of solute per liter of solution. Molarity is usually symbolized by an italicized capital letter *M*. It is important to bear in mind that the volume used to calculate molarity is that of the total solution (solute plus solvent) and not the solvent alone.

Suppose we had a solution of salt-water, comprised of 33.1 grams of table salt thoroughly mixed with pure water to make a total volume of 1.39 liters. In order to calculate the molarity of this solution, we first need to determine the equivalence between moles of salt and grams of salt. Since table salt is sodium chloride (NaCl), and we know the atomic masses of both sodium (23.0 amu) and chlorine (35.5 amu), we may easily calculate the mass of one mole of table salt:

$$1 \text{ mole of NaCl} = 23.0 \text{ g} + 35.5 \text{ g} = 58.5 \text{ g}$$

Another way to state this is to say that table salt (sodium chloride, or NaCl) has a molecular weight of 58.5 amu (58.5 grams of mass per mole).

We may use this equivalence as a unity fraction to help us convert the number of grams of table salt per unit volume of solution into a molarity (moles of table salt molecules per liter):

$$\left( \frac{33.1 \text{ g}}{1.39 \text{ l}} \right) \left( \frac{1 \text{ mol NaCl}}{58.5 \text{ g}} \right) = 0.407 \frac{\text{mol NaCl}}{\text{l}} = 0.407 \text{ M (NaCl)}$$

Another common expression for the concentration of a solute in either a liquid or a gas solution is related to the concept of *percent*, expressing the presence of the solute as a ratio of how many “parts” of solute exist per “parts” of solution. Earth’s atmosphere, for example, contains approximately 20.9% oxygen gas by volume. This means that for every 100 molecules found in a sample of air, approximately 21 of those are oxygen molecules. When the concentration of a solute is very small, however, percent becomes an awkward unit of measurement. In such cases it is common to see low concentrations of solute expressed as *parts per million* (ppm) or even *parts per billion* (ppb). The volumetric concentration of methane gas in Earth’s atmosphere is a good example where parts-per-million is a more appropriate expression than percent: for every million molecules found in a sample of air, approximately 2 of them are methane molecules (i.e. methane has an atmospheric concentration of 2 ppm). As a percentage, this equates to only 0.0002%.

We may use parts-per-unit concentration values as unity fractions just like molecular weights and just like molarity values, to relate total solution quantity to solute quantity. For example, if we need to calculate the total mass of hydrogen gas in a compressed air cylinder storing 47000 standard cubic feet of air, we could multiply the total volume of that air sample (47000 SCF) by the volumetric concentration of hydrogen naturally found in Earth’s atmosphere which is 0.5 ppm:

$$\left( \frac{47000 \text{ SCF air}}{1} \right) \left( \frac{0.5 \text{ parts hydrogen}}{1000000 \text{ parts air}} \right) = 0.0235 \text{ SCF hydrogen}$$

Note how the units of “parts” and “air” cancel out to leave “SCF hydrogen”.

An important caveat when using percent, ppm, or ppb is that we must clearly define the “parts” proportion as either being volume or mass. The concentration of hydrogen gas in the atmosphere (0.5 ppm) was specified as a *volumetric* concentration, and so it is appropriate to use this 0.5 ppm figure to calculate a proportion of the 47000 SCF total *volume*. If, however, we were given a ppm *mass* concentration for hydrogen, we could only use that figure in conjunction with a total *mass* quantity for the air sample.

The following photograph illustrates this concept, showing the label on a *calibration gas bottle* containing a certified mixture of gases used to check the accuracy of air-safety monitoring instruments. Note the concentrations of each gas type within the mixture – some expressed in percent, others in ppm – and how the label states “MOLE %” in the upper-right corner using large bold print to let you know the concentration values refer to molar quantities (e.g. 18% oxygen means 18% of the *molecules* contained in this bottle are oxygen molecules), which for gases closely corresponds to volumetric quantity rather than mass:

### 3.8 Stoichiometry

*Stoichiometry* is the accounting of atoms before and after a chemical reaction. It is an expression of the *Law of Mass Conservation*, in that elements are neither created nor destroyed in a chemical reaction, and that mass is an intrinsic property of every element. Thus, the numbers, types of atoms, and total mass exiting a chemical reaction (i.e. the “products” of that reaction) must be the same as the numbers, types of atoms, and total mass entering that chemical reaction (i.e. the “reactants”). For example, in the combustion of natural gas in an oxygen-rich environment, the fuel ( $\text{CH}_4$ ) and oxidizer ( $\text{O}_2$ ) are the reactants, while water vapor ( $\text{H}_2\text{O}$ ) and carbon dioxide gas ( $\text{CO}_2$ ) are the products:

Reactants	Products	Mass (per mole of $\text{CH}_4$ )
Carbon = $1 \times 1$	Carbon = $1 \times 1$	12 grams
Hydrogen = $1 \times 4$	Hydrogen = $2 \times 2$	4 grams
Oxygen = $2 \times 2$	Oxygen = $(1 \times 2) + (2 \times 1)$	64 grams

As you can see in this example, every single reactant atom (and its mass) entering the reaction is accounted for in the product molecules. The only exception to this rule is in *nuclear reactions* where elements transmute into different elements, with gains or losses in nuclear particles. No such transmutation occurs in any mere *chemical* reaction, and so we may safely assume equal numbers and types of atoms before and after any chemical reaction. Chemical reactions strictly involve re-organization of molecular bonds, with electrons as the constituent particles comprising those bonds. Nuclear reactions involve the re-organization of atomic nuclei (protons, neutrons, etc.), with far greater energy levels associated.

Often in chemistry, we know both the reactant and product molecules, but we need to determine their relative numbers before and after a reaction. The task of writing a general chemical equation and then assigning multiplier values for each of the molecules is called *balancing the equation*.

### 3.8.1 Balancing chemical equations by trial-and-error

Balancing a chemical equation is a task that may be done by trial-and-error. For example, let us consider the case of complete combustion for the hydrocarbon fuel *ethane* ( $\text{C}_2\text{H}_6$ ) with oxygen ( $\text{O}_2$ ). If combustion is complete, the only products will be water vapor ( $\text{H}_2\text{O}$ ) and carbon dioxide ( $\text{CO}_2$ ). The unbalanced equation representing all reactants and products for this reaction is shown here, along with a table showing the numbers of atoms on each side of the equation:

Reactants	Products
Carbon = 2	Carbon = 1
Hydrogen = 6	Hydrogen = 2
Oxygen = 2	Oxygen = 3

Clearly, this is not a balanced equation, since the numbers of atoms for each element are unequal between the two sides of the equation.

A good place to start in balancing this equation is to look for an element represented by only one molecule on each side of the equation. Carbon is an example (present in the ethane but not in the oxygen molecule on the left-hand side, and in the carbon dioxide but not the water on the right-hand side) and hydrogen is another.

Beginning with carbon, we see that each ethane molecule contains two carbon atoms while each carbon dioxide molecule contains just one carbon atom. Therefore, we may conclude that the ratio of carbon dioxide to ethane must be 2-to-1, no matter what the other ratios might be. So, we double the number of carbon dioxide molecules on the right-hand side and re-check our atomic quantities:

Reactants	Products
Carbon = 2	Carbon = 2
Hydrogen = 6	Hydrogen = 2
Oxygen = 2	Oxygen = 5

Next, we will balance the hydrogen atom numbers, since we know hydrogen is an element found in only one molecule on each side of the equation. Our hydrogen ratio is now 6:2 (left:right), so we know we need three times as many hydrogen-containing molecules on the right-hand side. Tripling the number of water molecules gives us:

Reactants	Products
Carbon = 2	Carbon = 2
Hydrogen = 6	Hydrogen = 6
Oxygen = 2	Oxygen = 7

Unfortunately, the numbers of oxygen atoms on each side of the equation are unequal, and it is not immediately obvious how to make them equal. We need five more atoms of oxygen on the left-hand side, but we cannot add exactly five more because oxygen atoms only come to us in pairs ( $\text{O}_2$ ), limiting us to even-number increments.

However, if we *double* all the other molecular quantities, it will make the disparity of oxygen atoms an even number instead of an odd number:

Reactants	Products
Carbon = 4	Carbon = 4
Hydrogen = 12	Hydrogen = 12
Oxygen = 2	Oxygen = 14

Now it is a simple matter to balance the number of oxygen atoms, by adding six more oxygen molecules to the left-hand side of the equation:

Reactants	Products
Carbon = 4	Carbon = 4
Hydrogen = 12	Hydrogen = 12
Oxygen = 14	Oxygen = 14

Now the equation is balanced: the quantities of each type of atom on both sides of the equation are equal.

### 3.8.2 Balancing chemical equations using algebra

A more mathematically sophisticated approach to stoichiometry involves the use of *simultaneous systems of linear equations*. The fundamental problem chemists must solve when balancing reaction equations is to determine the ratios of reactant and product molecules. If we assign a variable to each molecular quantity, we may then write a mathematical equation for each element represented by the reaction, and use algebra to solve for the variable values.

To illustrate, let us balance the equation describing the attack of aluminum metal's protective "passivation" layer of oxide by acid rain. When aluminum metal is exposed to oxygen, the outer surface of the metal quickly forms a layer of aluminum oxide ( $\text{Al}_2\text{O}_3$ ) which acts to impede further oxidation of the metal. This protective layer, however, may be attacked by the presence of sulfuric acid ( $\text{H}_2\text{SO}_4$ ). This acid finds its way into rainwater by way of sulfur compounds emitted during the combustion of sulfur-laden fuels. The products of this reaction between sulfuric acid and aluminum oxide are a sulfate molecule ( $\text{Al}(\text{SO}_4)_3$ ) and water ( $\text{H}_2\text{O}$ ), as illustrated in this *unbalanced* chemical equation:

This equation contains four different compounds (acid, aluminum oxide, sulfate, and water), which means we ultimately must solve for four different multiplier quantities. It also contains four different elements (H, S, O, and Al). Since the mathematical requirement for solving a system of linear equations is to have at least one equation per variable, it would first appear as though we could set up a  $4 \times 4$  matrix (four equations of four variables). However, this will not work. If we tried to solve for four unknown quantities, we would ultimately be foiled by an infinite number of solutions. This makes sense upon further inspection, since any stoichiometric solution to this chemical reaction will have an infinite number of correct *proportions* to satisfy it<sup>27</sup>. What we need to do is arbitrarily set one of these molecular quantities to a constant value (such as 1), then solve for the quantities of the other three. The result will be ratios or proportions of all the other molecules to the fixed number we assigned to the one molecule type.

---

<sup>27</sup>Take the combustion of hydrogen and oxygen to form water, for example. We know we will need two  $\text{H}_2$  molecules for every one  $\text{O}_2$  molecule to produce two  $\text{H}_2\text{O}$  molecules. However, *four* hydrogen molecules combined with *two* oxygen molecules will make *four* water molecules just as well! Similarly, *six* hydrogen molecules combined with *three* oxygen molecules also perfectly balance, making *six* water molecules. So long as we consider all three molecular quantities to be unknown, we will never be able to solve for just *one* correct answer, because there is no one correct set of absolute quantities, only one correct set of *ratios* or *proportions*.

As an example, I will choose to set the number of acid molecules to 1, and use the variables  $x$ ,  $y$ , and  $z$  to solve for the numbers of the other molecules (oxide, sulfate, and water, respectively):

1	$x$	=	$y$	$z$
H <sub>2</sub> SO <sub>4</sub>	Al <sub>2</sub> O <sub>3</sub>	→	Al <sub>2</sub> (SO <sub>4</sub> ) <sub>3</sub>	H <sub>2</sub> O

Now, I will write four algebraic equations, each algebraic equation representing the stoichiometric balance of a single element in the chemical equation. Focusing on the element hydrogen as an example, there will be *two* hydrogen atoms for every *one* molecule of acid,  $0x$  hydrogen atoms for every  $x$  molecules of aluminum oxide,  $0y$  atoms of hydrogen for every  $y$  molecules of aluminum sulfate, and  $2z$  atoms of hydrogen for every  $z$  molecules of water. The following table shows each of the four elements with their respective balance equations:

Element	Balance equation
Hydrogen	$2 + 0x = 0y + 2z$
Sulfur	$1 + 0x = 3y + 0z$
Oxygen	$4 + 3x = 12y + 1z$
Aluminum	$0 + 2x = 2y + 0z$

Simplifying each equation by eliminating all zero values and “1” coefficients:

Element	Balance equation
Hydrogen	$2 = 2z$
Sulfur	$1 = 3y$
Oxygen	$4 + 3x = 12y + z$
Aluminum	$2x = 2y$

We can see by examination of the first, second, and fourth equations that  $z$  must be equal to 1,  $y$  must be equal to  $\frac{1}{3}$ , and that  $x$  and  $y$  are equal to each other (therefore,  $x$  must be equal to  $\frac{1}{3}$  as well). Plugging these values into the variables of the third equation confirms this ( $4 + 1 = 4 + 1$ ). Thus, our solution to this multi-variable system of equations is:

$$x = \frac{1}{3} \quad y = \frac{1}{3} \quad z = 1$$

It makes little sense to speak of *fractions* of a molecule, which is what the values of  $x$  and  $y$  seem to suggest, but we must recall these values represent *proportions* only. In other words, we need only one-third as many oxide and sulfate molecules as acid and water molecules to balance this equation. If we multiply all these values by three (as well as the initial constant we chose for the number of acid molecules), the quantities will be whole numbers and the chemical reaction will still be balanced:

$$x = 1 \quad y = 1 \quad z = 3$$

Thus, our final (balanced) equation showing the attack of aluminum metal’s passivation layer by acid rain is as follows:

Another example to illustrate this method of balancing chemical equations is the oxidation of wastewater (sewage) sludge. Here, the reactant is not a single type of molecule, but rather a complex mixture of carbohydrates, proteins, fats, and other organic compounds. A practical way of dealing with this problem is to represent the average quantities of carbon, hydrogen, and oxygen in the form of a *compositional formula*<sup>28</sup> based on a gross analysis of the wastewater sludge:

We know that the products will be carbon dioxide and water, but the question is how much oxygen will be required to completely oxidize the mixture. The following (unbalanced) chemical equation shows the reactants and products:

The non-integer subscripts greatly complicate trial-and-error stoichiometry, but they pose absolutely no obstacle at all to simultaneous equations. Assigning variables  $x$ ,  $y$ , and  $z$  to the unknown molecular quantities:

1	$x$	=	$y$	$z$
$\text{C}_{4.8}\text{H}_{8.4}\text{O}_{2.2}$	$\text{O}_2$	$\rightarrow$	$\text{CO}_2$	$\text{H}_2\text{O}$

Now, we may write three algebraic equations, each representing the stoichiometric balance of one element in the chemical equation. The following table shows each of the three elements with their respective balance equations:

Element	Balance equation
Carbon	$4.8 + 0x = 1y + 0z$
Hydrogen	$8.4 + 0x = 0y + 2z$
Oxygen	$2.2 + 2x = 2y + 1z$

Simplifying each equation by eliminating all zero values and “1” coefficients:

Element	Balance equation
Carbon	$4.8 = y$
Hydrogen	$8.4 = 2z$
Oxygen	$2.2 + 2x = 2y + z$

We may tell from the first and second equations that  $y = 4.8$  and  $z = 4.2$ , which then leads to a solution of  $x = 5.8$  once the values for  $y$  and  $z$  have been inserted into the third equation. The final result is this balanced compositional equation for the oxidation of wastewater sludge:

My own personal experience with the use of simultaneous linear equations as a tool for stoichiometry is that it is much faster (especially when balancing complex reaction equations) than trial-and-error, and relatively easy to set up once the general principles are understood.

<sup>28</sup>Note that you cannot have a molecule comprised of 4.8 carbon atoms, 8.4 hydrogen atoms, and 2.2 oxygen atoms, since atoms exist in whole numbers only! This compositional formula merely shows us the *relative proportions* of each element in the complex mixture of molecules that make up sewage sludge.

### 3.8.3 Stoichiometric ratios

Regardless of the technique used to balance the equation for a chemical reaction, the most practical *purpose* of balancing the equation is to be able to relate the reactant and product quantities to each other. For instance, we may wish to know how much oxygen will be required to completely combust with a given quantity of fuel, so that we will be able to engineer a burner system capable of handling the necessary flow rates of fuel and oxygen. Balancing the chemical reaction is just the first part of the solution. Once we have a balanced equation, we need to consider the ratios of the substances to each other.

For example, let us consider the balanced (stoichiometric) chemical equation for the combustion of ethane fuel with pure oxygen:

From the balanced chemical equation we can see that for every 2 molecules of ethane, we will need 7 molecules of oxygen gas to completely combust, producing 6 molecules of water vapor and 4 molecules of carbon dioxide gas. The numerical multipliers preceding each molecule in the balanced equation tell us the *molar ratios* of those substances to each other. For oxygen to ethane the ratio is 7:2, for water to ethane the ratio is 6:2 (or 3:1), for carbon dioxide to water the ratio is 4:6 (2:3), etc. If for some reason we needed to calculate the number of moles of  $\text{CO}_2$  produced after burning 80 moles of ethane, we could easily calculate that by multiplying the 80 moles of ethane by the 2:4 (1:2) ethane-to-carbon dioxide ratio to arrive at a figure of 160 moles of  $\text{CO}_2$ . If we wished, we could even solve this using the same method of *unity fractions* we commonly apply in unit-conversion problems, writing the carbon dioxide-to-ethane ratio as a fraction of two equivalent quantities:

$$\left(\frac{80 \text{ mol ethane}}{1}\right) \left(\frac{4 \text{ molecules carbon dioxide}}{2 \text{ molecules ethane}}\right) = 160 \text{ mol carbon dioxide}$$

If any substances involved in the reaction happen to be gases at nearly the same pressure and temperature<sup>29</sup>, the molar ratios defined by the balanced equation will similarly define the *volumetric ratios* for those substances. For example, knowing our ideal oxygen-to-ethane molar ratio is 7:2 tells us that the volumetric flow rate of oxygen to ethane should also be (approximately) 7:2, assuming both the oxygen and ethane are gases flowing through their respective pipes at the same pressure and at the same temperature. Recall that the Ideal Gas Law ( $PV = nRT$ ) is approximately true for *any* gas far from its critical phase-change values. So long as pressure ( $P$ ) and temperature ( $T$ ) are the same for both gases, each gas's volume ( $V$ ) will be directly proportional to its molar quantity ( $n$ ), since  $R$  is a constant. This means any molar ratio ( $\frac{n_1}{n_2}$ ) for two gases under identical pressure and temperature conditions will be equal to the corresponding volumetric ratio ( $\frac{V_1}{V_2}$ ) for those gases.

---

<sup>29</sup>These assumptions are critically important to equating volumetric ratios with molar ratios. First, the compared substances must both be *gases*: the volume of one mole of steam is huge compared to the volume of one mole of liquid water. Next, we cannot assume temperatures and pressures will be the same after a reaction as before. This is especially true for our example here, where ethane and oxygen are *burning* to produce water vapor and carbon dioxide: clearly, the products will be at a greater temperature than the reactants!

It is important to understand that these molar ratios are not the same as the *mass* ratios for the reactants and products, simply because the different substances do not all have the same mass per mole.

If we regard each of the multipliers in the balanced equation as a precise molar quantity (i.e. exactly 2 moles of ethane, 7 moles of oxygen, etc.) and calculate the mass of the reactants, we will find this value precisely equal to the total mass of the products because the Law of Mass Conservation holds true for this (and all other) chemical reactions:

$$2\text{C}_2\text{H}_6 = 2[(12)(2) + (1)(6)] = 60 \text{ grams}$$

$$7\text{O}_2 = 7[(16)(2)] = 224 \text{ grams}$$

$$6\text{H}_2\text{O} = 6[(1)(2) + 16] = 108 \text{ grams}$$

$$4\text{CO}_2 = 4[12 + (16)(2)] = 176 \text{ grams}$$

Calculating mass based on 2 moles of ethane, we have a total reactant mass of 284 grams (60 grams ethane plus 224 grams oxygen), and a total product mass of 284 grams as well (108 grams water plus 176 grams carbon dioxide gas). We may write the mass ratios for this chemical reaction as such:

$$(\text{ethane}) : (\text{oxygen}) : (\text{water}) : (\text{carbon dioxide})$$

$$60 : 224 : 108 : 176$$

If for some reason we needed to calculate the mass of one of these substances in relation to the other for this reaction, we could easily do so using the appropriate mass ratios. For example, assume we were installing a pair of mass flowmeters to measure the mass flow rates of ethane and pure oxygen gas flowing into the combustion chamber of some industrial process. Supposing the ethane flowmeter had a calibrated range of 0 to 20 kg/min, what range should the oxygen's mass flowmeter be calibrated to in order to match in perfect stoichiometric ratio (so that when one flowmeter is at the top of its range, the other flowmeter should be also)?

The answer to this question is easy to calculate, knowing the required mass ratio of oxygen to ethane for this chemical reaction:

$$\left(\frac{20 \text{ kg ethane}}{1}\right) \left(\frac{224 \text{ g oxygen}}{60 \text{ g ethane}}\right) = 74.67 \text{ kg oxygen}$$

Therefore, the oxygen mass flowmeter should have a calibrated range of 0 to 74.67 kg/min. Note how the unit of mass used in the initial quantity (20 *kilograms* ethane) does not have to match the mass units used in our unity fraction (grams). We could have just as easily calculated the number of *pounds* per minute of oxygen given pounds per minute of ethane, since the mass ratio (like all ratios) is a unitless quantity<sup>30</sup>.

<sup>30</sup>Looking at the unity-fraction problem, we see that "grams" (g) will cancel from top and bottom of the unity fraction, and "ethane" will cancel from the given quantity and from the bottom of the unity fraction. This leaves "kilograms" (kg) from the given quantity and "oxygen" from the top of the unity fraction as the only units remaining after cancellation, giving us the proper units for our answer: *kilograms of oxygen*.

### 3.9 Energy in chemical reactions

A chemical reaction resulting in a net release of energy is called *exothermic*. Conversely, a chemical reaction requiring a net input of energy to occur is called *endothermic*. The relationship between chemical reactions and energy exchange corresponds to the breaking or making of chemical bonds. Atoms bonded together represent a lower state of total energy than those same atoms existing separately, all other factors being equal. Thus, when separate atoms join together to form a molecule, they go from a high state of energy to a low state of energy, releasing the difference in energy in some form (heat, light, etc.). Conversely, an input of energy is required to break that chemical bond and force the atoms to separate.

Chemical bonds are considered “strong” if a large input of energy is required to break them. “Weak” chemical bonds, by contrast, only require modest inputs of energy to disrupt. Thus, the strength of a bond is inversely proportional to the energy state of the molecule: atoms falling into very low energy states when joining together to form a molecule enjoy a strong bond because a large investment of energy is required to raise those atoms’ energy states high enough to sever their bond.

An example of a strong bond is that which exists between two atoms of hydrogen (H) and one atom of oxygen (O) when forming water ( $\text{H}_2\text{O}$ ). When hydrogen and oxygen atoms bond together to form water, they release energy. This, by definition, is an exothermic reaction, but we know it better as *combustion*: hydrogen is flammable in the presence of oxygen. A reversal of this reaction occurs when water is subjected to an electrical current, breaking water molecules up into hydrogen and oxygen gas molecules. This process of forced separation requires a substantial input of energy to accomplish, which by definition makes it an *endothermic* reaction. Specifically, the use of electricity to cause a chemical reaction is called *electrolysis*.

An even stronger bond is that formed between aluminum (Al) and oxygen (O) to make alumina ( $\text{Al}_2\text{O}_3$ ), a ceramic powder at room temperature. The energy state of this molecule is so low that the aluminum-oxygen bonds resist dissolution even at extremely high temperatures, explaining the high melting point and relative non-reactivity of this substance.

### 3.9.1 Heats of reaction and activation energy

The amount of energy exchanged (either absorbed or released) in a chemical reaction is often expressed as a numerical quantity to the right of the equation, labeled  $\Delta H$ , usually defined at a reference temperature of 298 Kelvin (25 degrees Celsius). A negative  $\Delta H$  value signifies an exothermic (heat-releasing) reaction, while a positive  $\Delta H$  value signifies an endothermic (heat-absorbing) reaction. The combustion of hydrogen and oxygen to form liquid water is an example of the former, and the electrolysis of water to yield hydrogen and oxygen gas is an example of the latter:

This energy value, commonly referred to as the *heat of reaction* or *enthalpy of reaction*, is expressed *per mole* of the reactants and products shown. The “−1” exponent applied to “mole” is simply a fancy way of saying “per mole”<sup>31</sup>, as an alternative to using a fraction bar.

While the mathematical sign of  $\Delta H$  may seem confusing at first (“Why is it *negative* when energy is *released*?”), it makes sense from the perspective of energy states before and after the reaction. In an exothermic (heat-releasing) reaction, the products are left at a lower state of energy than the reactants began with, and a negative value of  $\Delta H$  signifies this. The sign of  $\Delta H$ , then, is an expression of the change in energy state from reactants (input) to products (output), *not* an expression of the energy liberated from the reaction. Even though the term  $\Delta H$  is called the “heat of reaction” it really refers to the change in potential energy of the *matter* as a consequence of the chemical reaction.

---

<sup>31</sup>This notation is quite common in scientific and engineering literature, as a way to avoid having to typeset fractions in a text document. Instead of writing  $\frac{\text{kJ}}{\text{mol}}$  which requires a fraction bar, we may write  $\text{kJ mol}^{-1}$  which is mathematically equivalent. Another common example of this notation is to express frequency in the unit of  $\text{s}^{-1}$  (per second) rather than the unit of Hertz (Hz). Perhaps the most compelling reason to use negative exponents in unit expressions, though, is sociological: scientific studies have shown the regular use of this unit notation makes you appear 37.5% smarter than you actually are. Questioning statistical results of scientific studies, on the other hand, reduces your apparent intelligence by over 63%! Now, aren’t you glad you took the time to read this footnote?

The fact that hydrogen and oxygen as separate gases possess potential energy does not mean they are guaranteed to spontaneously combust when brought together. By analogy, just because rocks sitting on a hillside possess potential energy (by virtue of being elevated above the hill's base) does not mean all rocks in the world spontaneously roll downhill. Some rocks need a push to get started because they are caught on a ledge or resting in a depression on the hillside. Likewise, many exothermic reactions require an initial investment of energy before they can proceed. In the case of hydrogen and oxygen, what is generally needed is a spark to initiate the reaction. This initial requirement of input energy is called the *activation energy* of the reaction.

Activation energy may be shown in graphical form. For an exothermic reaction, it appears as a “hill” that must be climbed before the total energy can fall to a lower (than original) level:

For an endothermic reaction, activation energy is much greater, a part of which never returns but is stored in the reaction products as potential energy:

A *catalyst* is a substance that works<sup>32</sup> to minimize activation energy in a chemical reaction without being altered by the reaction itself. Catalysts are popularly used in industry to accelerate both exothermic and endothermic reactions, reducing the gross amount of energy that must be initially input to a process to make a reaction occur. A common example of a catalyst is the *catalytic converter* installed in the exhaust pipe of an automobile engine, helping to oxidize unburnt fuel molecules and certain combustion products such as carbon monoxide (CO) to compounds which are not as polluting. Without a catalytic converter, the exhaust gas temperature is not hot enough to overcome the activation energy of these reactions, and so they will not occur (at least not at the rate necessary to make a significant difference). The presence of the catalyst allows the reactions to progress quickly at typical engine exhaust temperatures.

<sup>32</sup>Just how catalysts perform this trick is a subject of continuing research. Catalysts used in industrial process industries are usually selected based on the results of empirical tests rather than by theory, since a general theoretical understanding of catalysis is lacking at this present time. Indeed, the specific selection of catalysts for high-value chemical processes is often a patented feature of those processes, reflecting the investment of time, finances, and effort finding a suitable catalyst for optimizing each chemical reaction.

The effect of a catalyst on activation energy may be shown by the following graphs, the dashed-line curve showing the energy progression with a catalyst and the solid-line curve showing the reaction progressing without the benefit of a catalyst:

It should be noted that the presence of a catalyst has absolutely no effect on the *net* energy loss or gain resulting from a chemical reaction. That is to say, the heat of reaction ( $\Delta H$ ) stands independent of catalytic assistance: with or without a catalyst, the difference in potential energy before and after a reaction will be the same<sup>33</sup>. The only difference a catalyst makes to a chemical reaction is how much energy must be *initially invested* to spark the reaction. To use the example of hydrogen and oxygen gas once again, the presence of a catalyst does not cause the combustion of hydrogen and oxygen to release more energy. All the catalyst does is make it easier for the combustion to begin.

<sup>33</sup>If this were not true, one could construct an over-unity ("perpetual motion") machine by initiating an endothermic reaction and then reversing that reaction (exothermic) using a catalyst in either or both portions of the cycle to reap a net energy release from the system. So trustworthy is the Law of Energy Conservation that we may safely invoke the impossibility of over-unity energy production as a *disproof* of any given hypothesis permitting it. In other words, if any hypothesis allows for an over-unity process (i.e. violates the Law of Energy Conservation), we may reject that hypothesis with confidence! This form of disproof goes by the name *reductio ad absurdum* (Latin: "reducing to an absurdity").

### 3.9.2 Heats of formation and Hess's Law

As we have seen, the formation of new chemical bonds between atoms is an energy-releasing process (i.e. exothermic), while the dissolution of chemical bonds is an energy-absorbing process (i.e. endothermic). Given the fact that the Law of Energy Conservation is universal, it stands to reason we ought to be able to mathematically balance the potential energy held by reactants, the potential energy held by the products, and the amount of energy either released or absorbed by the reaction.

Let us begin our exploration of this concept with the formation of carbon dioxide (CO<sub>2</sub>) from the combustion of elemental carbon (C) and oxygen molecules (O<sub>2</sub>):

As we can see, this reaction is exothermic<sup>34</sup>: the products have a lower energy than the reactants, losing 393.5 kilojoules of energy for every mole of carbon dioxide formed by this reaction.

If we are to account for all the energy entering and exiting a chemical reaction, we must have some means of quantifying the amount of energy stored within both the reactants and the products as well as the amount of energy released or absorbed by the reaction itself. Quantifying the amount of chemical potential possessed by atoms and molecules is difficult if not impossible to do in any absolute sense, and so the common practice is to arbitrarily assign an energy value of *zero* to chemical elements in their normal states at standard temperature and pressure (293.15 Kelvin and 1 atmosphere, abbreviated “STP”). This point of reference will be the norm for any subsequent determinations of chemical potential energy. The *standard heat of formation* or *standard enthalpy of formation* ( $\Delta H_f^\circ$ , or sometimes  $\Delta_f H^\circ$ ) for any substance is thus defined as the amount of energy gained or lost when one mole of that substance is formed from its constituent elements at STP. A superscripted “o” symbol represents conditions of standard temperature and pressure.

We know that the *phase* of a substance (i.e. solid, liquid, gas) affects how much energy it contains, and therefore in order to accurately account for all energy we must represent the phase of each substance when we specify heats of formation. Since the natural state of carbon is solid (s) at STP while the natural state of oxygen is gas (g) at STP, we will represent those states as letters within parentheses when defining their heats of formation:

$$\Delta H_f^\circ (\text{C}, \text{s}) = 0 \text{ kJ mol}^{-1} \quad \text{Heat of formation for solid carbon at STP}$$

$$\Delta H_f^\circ (\text{O}_2, \text{g}) = 0 \text{ kJ mol}^{-1} \quad \text{Heat of formation for gaseous oxygen at STP}$$

It takes no gain or loss of energy at all to form solid carbon (C) or gaseous oxygen molecules (O<sub>2</sub>) at STP because those elements are already in those forms at STP. The only way we will ever have a non-zero  $\Delta H_f^\circ$  value is if the substance in question is a compound (i.e. comprised of multiple elements joined by chemical bonds) or if the substance in question is an element in some unusual energy state (e.g. ionization).

---

<sup>34</sup>The heat-releasing nature of this reaction should be evident by inspection of the reaction equation alone, without reference to the  $\Delta H$  figure. Note how the carbon (C) and oxygen (O<sub>2</sub>) begin as separate entities, but end up as one combined molecule (CO<sub>2</sub>). Since we know the formation of new chemical bonds is exothermic, this reaction between carbon and oxygen to produce carbon dioxide must therefore be exothermic.

Since we already know the combustion of one atom of carbon with one molecule of oxygen liberates 393.5 kilojoules of heat energy, we may conclude the heat of formation for carbon dioxide gas (cooled down to the standard temperature of 293.15 Kelvin) must be  $-393.5 \text{ kJ mol}^{-1}$ , since this is precisely how much energy is liberated when carbon dioxide is formed from its constituent elements. Representing all these figures in a table helps us make sense of it all:

Reactant	Reactant	Reaction	Product
C(s)	O <sub>2</sub> (g)	→	CO <sub>2</sub> (g)
$\Delta H_f^\circ = 0 \text{ kJ mol}^{-1}$	$\Delta H_f^\circ = 0 \text{ kJ mol}^{-1}$	$\Delta H^\circ = -393.5 \text{ kJ mol}^{-1}$	$\Delta H_f^\circ = -393.5 \text{ kJ mol}^{-1}$

Stated verbally, the combined heats of formation for all reactants plus the heat of reaction yields the combined heats of formation for all products. Put into simpler terms, the energy contained by the reactants plus the change in energy wrought by the reaction gives us the energy left<sup>35</sup> inside the products. The mathematical formulation of this principle is as follows:

$$\Sigma [\Delta H_f^\circ (\text{Reactants})] + \Delta H^\circ (\text{Reaction}) = \Sigma [\Delta H_f^\circ (\text{Products})]$$

The practical application of this is that we may calculate<sup>36</sup> the exact amount of heat liberated or absorbed by *any* chemical reaction, if only we know in advance the heats of formation for all the reactants and products. Fortunately for our reference, chemists have tabulated standard heats of formation for a great many substances.

*Hess's Law* states that this accounting of energy is true regardless of the reaction path. For example, if the combustion of carbon with oxygen proceeds in one step ( $\text{C} + \text{O}_2 \rightarrow \text{CO}_2$ ), the overall heat of reaction will be precisely the same as for any other series of steps resulting in the same product(s) from the same reactant(s), for example the partial combustion of carbon to form carbon monoxide ( $\text{C} + \text{O} \rightarrow \text{CO}$ ) followed by the subsequent combustion of carbon monoxide ( $\text{CO} + \text{O} \rightarrow \text{CO}_2$ ). Just as we saw with catalytically-aided chemical reactions, the total heat of reaction is strictly a function of the reactants and the products, not of any process or path by which the reaction may proceed. The Law of Energy Conservation is indeed iron-clad!

<sup>35</sup>At first it may seem non-sensical for the carbon dioxide product of this reaction to have a *negative* energy, until you realize the zero values given to both the carbon and oxygen reactants are entirely arbitrary. Viewed in this light, the negative heat of formation for CO<sub>2</sub> is nothing more than a *relative* expression of chemical potential energy in reference to the elements from which CO<sub>2</sub> originated. Therefore, a negative  $\Delta H_f^\circ$  value for any molecule simply tells us that molecule has less energy (i.e. is more stable) than its constituent elements.

<sup>36</sup>We may also readily tell whether any given reaction will be exothermic or endothermic, based on the mathematical sign of this  $\Delta H$  value.

Let us investigate a practical application where we employ heats of formation to calculate the heat of a chemical reaction. In this case, we will consider the combustion of propane fuel gas ( $\text{C}_3\text{H}_8$ ) in the presence of pure oxygen gas ( $\text{O}_2$ ), producing liquid water ( $\text{H}_2\text{O}$ ) and gaseous carbon dioxide ( $\text{CO}_2$ ) as products:

To begin, we must identify the standard heats of formation for each of these substances at STP from a suitable reference<sup>37</sup>:

- Propane gas  $\Delta H_f^\circ = -103.8 \text{ kJ mol}^{-1}$
- Oxygen gas  $\Delta H_f^\circ = 0 \text{ kJ mol}^{-1}$
- Water  $\Delta H_f^\circ = -285.8 \text{ kJ mol}^{-1}$
- Carbon dioxide gas  $\Delta H_f^\circ = -393.5 \text{ kJ mol}^{-1}$

Setting these quantities into a table for ease of organization (all heats of formation given in units of kilojoules per mole):

Reactant	Reactant	Reaction	Product	Product
$\text{C}_3\text{H}_8(\text{g})$	$5\text{O}_2(\text{g})$	$\rightarrow$	$4\text{H}_2\text{O}(\text{l})$	$3\text{CO}_2(\text{g})$
$(1)(-103.8)$	$(5)(0)$	$\Delta H^\circ$	$(4)(-285.8)$	$(3)(-393.5)$

Solving for the unknown heat of reaction ( $\Delta H^\circ$ ):

$$\Sigma [\Delta H_f^\circ (\text{Reactants})] + \Delta H^\circ (\text{Reaction}) = \Sigma [\Delta H_f^\circ (\text{Products})]$$

$$[(1)(-103.8) + (5)(0)] + \Delta H^\circ = [(4)(-285.8) + (3)(-393.5)]$$

$$[-103.8] + \Delta H^\circ = [-1143.2 + -1180.5]$$

$$[-103.8] + \Delta H^\circ = [-2323.7]$$

$$\Delta H^\circ = -2323.7 + 103.8$$

$$\Delta H^\circ = -2219.9 \text{ kJ per mole of propane fuel}$$

The large, negative value of  $\Delta H^\circ$  tells us the reaction of propane with oxygen will be highly exothermic.

<sup>37</sup>Of course, it is not necessary to look up  $\Delta H_f^\circ$  for oxygen gas, as that is an element in its natural state at STP and therefore its standard heat of formation is defined to be zero. The heat of formation for carbon dioxide gas may be found from the preceding example, while the heat of formation for water may be found in the “Heats of Reaction and Activation Energy” subsection of this book. The only substance in this list of which the heat of formation is not defined as zero or given in this book is propane. Note that many thermochemical reference books will give heats of formation in units of *kilocalories* per mole rather than kilojoules per mole. The conversion factor between these is 1 calorie = 4.184 joules.

### 3.11 Ions in liquid solutions

Many liquid substances undergo a process whereby their constituent molecules split into positively and negatively charged ion pairs, the positively-charged ion called a *cation* and the negatively-charged ion called an *anion*<sup>38</sup>. Liquid *ionic* compounds<sup>39</sup> split into ions completely or nearly completely, while only a small percentage of the molecules in a liquid *covalent* compound<sup>40</sup> split into ions. The process of neutral molecules separating into ion pairs is called *dissociation* when it happens to ionic compounds, and *ionization* when it happens to covalent compounds.

Molten salt (NaCl) is an example of the former, while pure water (H<sub>2</sub>O) is an example of the latter. In liquid salt, practically every NaCl molecule splits up into an Na<sup>+</sup> and Cl<sup>-</sup> ion pair, whereas with liquid water only a very small percentage of molecules split up into positively and negatively charged ions – most remain as whole H<sub>2</sub>O molecules. All the ions present in molten salt serve as electrical charge carriers, making molten salt a very good conductor of electricity. The scarcity of ions in a sample of pure water explains why it is often considered an insulator. In fact, the electrical conductivity of a liquid substance is the definitive test of whether it is an ionic or a covalent (“molecular”) substance.

The few water molecules that do ionize split into positive hydrogen ions<sup>41</sup> (H<sup>+</sup>) and negative hydroxyl ions (OH<sup>-</sup>). At room temperature, the concentration of hydrogen and hydroxyl ions in a sample of pure water is quite small: a molarity of 10<sup>-7</sup> M (moles of hydrogen ions per liter of solution) each.

Given the fact that pure water has a mass of 1 kilogram (1000 grams) per liter, and one mole of pure water has a mass of 18 grams, we must conclude that there are approximately 55.56 moles of water molecules in one liter (55.56 M). If only 10<sup>-7</sup> moles of those molecules ionize at room temperature, that represents an extremely small percentage of the total:

$$\frac{10^{-7} \text{ mol hydrogen ions}}{55.56 \text{ mol solution}} = 0.0000000018 = 0.00000018\% = 0.0018 \text{ ppm (parts per million)}$$

It is not difficult to see why pure water is such a poor conductor of electricity. With so few ions available to act as charge carriers, pure water is practically an insulator. The vast majority of water molecules remain un-ionized and therefore cannot transport electric charges from one point to another.

The molarity of both hydrogen and hydroxyl ions in a pure water sample increases with increasing temperature. For example, at 60 °C, the molarity of hydrogen and hydroxyl ions increases to 3.1 ×

---

<sup>38</sup>These names have their origin in the terms used to classify positive and negative electrodes immersed in a liquid solution. The positive electrode is called the “anode” while the negative electrode is called the “cathode.” An *anion* is an ion attracted to the anode. A *cation* is an ion attracted to the cathode. Since opposite electrical charges tend to attract, this means “anions” are negatively charged and “cations” are positively charged.

<sup>39</sup>Ionic compounds are formed when oppositely charged atomic ions bind together by mutual attraction. The distinguishing characteristic of an ionic compound is that it is a conductor of electricity in its pure, liquid state. That is, it readily separates into anions and cations all by itself. Even in its solid form, an ionic compound is already ionized, with its constituent atoms held together by an imbalance of electric charge. Being in a liquid state simply gives those atoms the physical mobility needed to dissociate.

<sup>40</sup>Covalent compounds are formed when electrically neutral atoms bind together by the mutual sharing of valence electrons. Such compounds are not good conductors of electricity in their pure, liquid states.

<sup>41</sup>Actually, the more common form of positive ion in water is *hydronium*: H<sub>3</sub>O<sup>+</sup>, but we often simply refer to the positive half of an ionized water molecule as hydrogen (H<sup>+</sup>).

$10^{-7} M$ , which is still only 0.0056 parts per million, but definitely larger than the concentration at room temperature (25 °C).

The electrical conductivity of water may be greatly enhanced by dissolving an ionic compound in it, such as table salt. When dissolved, the table salt molecules ( $\text{NaCl}$ ) immediately dissociate into sodium cations ( $\text{Na}^+$ ) and chlorine anions ( $\text{Cl}^-$ ), becoming available as charge carriers for an electric current. In industry, we may exploit this relationship between electrical conductivity and ionic dissociation to detect the presence of ionic compounds in otherwise pure water.

### 3.12 pH

Hydrogen ion activity in aqueous (water-solvent) solutions is a very important parameter for a wide variety of industrial processes. A number of reactions important to chemical processing are inhibited or significantly slowed if the hydrogen ion activity of a solution lies outside a narrow range. Some additives used in water treatment processes (e.g. flocculants) will fail to function efficiently if the hydrogen ion activity in the water is not kept within a certain range. Alcohol and other fermentation processes strongly depend on tight control of hydrogen ion activity, as an incorrect level of ion activity will not only slow production but may also spoil the product. The concentration of active hydrogen ions<sup>42</sup> in a solution is always measured on a logarithmic scale, and referred to as *pH*.

pH is mathematically defined as the negative common logarithm of active hydrogen ion concentration in a solution<sup>43</sup>. Hydrogen ion concentration is expressed as a molarity (number of moles of ions per liter of total liquid solution volume), with “pH” being the unit of measurement for the logarithmic result:

$$\text{pH} = -\log[\text{H}^+]$$

For example, an aqueous solution with an active hydrogen concentration of 0.00044 *M* has a pH value of 3.36 pH.

Water is a covalent compound, and so there is little ionization of water molecules in liquid form. Most of the molecules in a sample of pure water remain as whole molecules ( $\text{H}_2\text{O}$ ) while a very small percentage ionize into positive hydrogen ions ( $\text{H}^+$ ) and negative hydroxyl ions ( $\text{OH}^-$ ). The mathematical product of hydrogen and hydroxyl ion molarity in water is known as the *ionization constant* ( $K_w$ ), and its value varies with temperature:

$$K_w = [\text{H}^+] \times [\text{OH}^-]$$

At 25 degrees Celsius (room temperature), the value of  $K_w$  is very nearly equal to  $1.0 \times 10^{-14}$ . Since each one of the water molecules that does ionize in this absolutely pure water sample separates into exactly one hydrogen ion ( $\text{H}^+$ ) and one hydroxyl ion ( $\text{OH}^-$ ), the molarities of hydrogen and hydroxyl ions must be equal to each other. The equality between hydrogen and hydroxyl ions in a pure water sample means that pure water is *neutral*, and that the molarity of hydrogen ions is equal to the square root of  $K_w$ :

$$[\text{H}^+] = \sqrt{K_w} = \sqrt{1.0 \times 10^{-14}} = 1.0 \times 10^{-7} \text{ M}$$

---

<sup>42</sup>Free hydrogen ions ( $\text{H}^+$ ) are rare in a liquid solution, and are more often found attached to whole water molecules to form a positive ion called *hydronium* ( $\text{H}_3\text{O}^+$ ). However, process control professionals usually refer to these positive ions simply as “hydrogen” even though the truth is a bit more complicated.

<sup>43</sup>The letter “p” refers to “potential,” in reference to the logarithmic nature of the measurement. Other logarithmic measurements of concentration exist for molecular species, including  $\text{pO}_2$  and  $\text{pCO}_2$  (concentration of oxygen and carbon dioxide molecules in a liquid solution, respectively).

Since we know pH is defined as the negative logarithm of hydrogen ion activity, and we can be assured all hydrogen ions present in a pure water sample will be “active” since there are no other positive ions to interfere with them, the pH value for water at 25 degrees Celsius is:

$$\text{pH of pure water at } 25\text{ }^{\circ}\text{C} = -\log(1.0 \times 10^{-7} M) = 7.0 \text{ pH}$$

As the temperature of a pure water sample changes, the ionization constant changes as well. Increasing temperature causes more of the water molecules to ionize into  $\text{H}^+$  and  $\text{OH}^-$  ions, resulting in a larger  $K_w$  value and a lower pH value. The following table shows  $K_w$  and pH values for pure water at different temperatures:

Temperature	$K_w$	pH
0 °C	$1.139 \times 10^{-15}$	7.47 pH
5 °C	$1.846 \times 10^{-15}$	7.37 pH
10 °C	$2.920 \times 10^{-15}$	7.27 pH
15 °C	$4.505 \times 10^{-15}$	7.17 pH
20 °C	$6.809 \times 10^{-15}$	7.08 pH
25 °C	$1.008 \times 10^{-14}$	6.998 pH
30 °C	$1.469 \times 10^{-14}$	6.92 pH
35 °C	$2.089 \times 10^{-14}$	6.84 pH
40 °C	$2.919 \times 10^{-14}$	6.77 pH
45 °C	$4.018 \times 10^{-14}$	6.70 pH
50 °C	$5.474 \times 10^{-14}$	6.63 pH
55 °C	$7.296 \times 10^{-14}$	6.57 pH
60 °C	$9.614 \times 10^{-14}$	6.51 pH

This means that while any pure water sample is *neutral* (an equal number of positive hydrogen ions and negative hydroxyl ions) at any temperature, the pH value of pure water actually changes with temperature, and is only equal to 7.0 pH<sup>44</sup> at one particular (“standard”) temperature: 25 °C. Based on the  $K_w$  values shown in the table, pure water will be 6.51 pH at 60 °C and 7.47 pH at freezing.

---

<sup>44</sup>Often, students assume that the 7 pH value of water is an arbitrary assignment, using water as a universal standard just like we use water as the standard for the Celsius temperature scale, viscosity units, specific gravity, etc. However, this is not the case here. Pure water at room temperature just happens to have an hydrogen ion molarity equivalent to a (nearly) round-number value of 7 pH.

If we add an electrolyte to a sample of pure water, molecules of that electrolyte will separate into positive and negative ions<sup>45</sup>. If the positive ion of the electrolyte happens to be a hydrogen ion ( $\text{H}^+$ ), we call that electrolyte an *acid*. If the negative ion of the electrolyte happens to be a hydroxyl ion ( $\text{OH}^-$ ), we call that electrolyte a *caustic*, or *alkaline*, or *base*. Some common acidic and alkaline substances are listed here, showing their respective positive and negative ions in solution:

**Sulfuric acid** is an *acid* (produces  $\text{H}^+$  in solution)

**Nitric acid** is an *acid* (produces  $\text{H}^+$  in solution)

**Hydrocyanic acid** is an *acid* (produces  $\text{H}^+$  in solution)

**Hydrofluoric acid** is an *acid* (produces  $\text{H}^+$  in solution)

**Lithium hydroxide** is a *caustic* (produces  $\text{OH}^-$  in solution)

**Potassium hydroxide** is a *caustic* (produces  $\text{OH}^-$  in solution)

**Sodium hydroxide** is a *caustic* (produces  $\text{OH}^-$  in solution)

**Calcium hydroxide** is a *caustic* (produces  $\text{OH}^-$  in solution)

When an acid substance is added to water, some<sup>46</sup> of the acid molecules dissociate into positive hydrogen ions ( $\text{H}^+$ ) and negative ions (the type of negative ions depending on what type of acid it is). This increases the molarity of hydrogen ions (the number of moles of  $\text{H}^+$  ions per liter of solution), therefore driving the pH value of the solution down to a smaller number. For example, a sample of acid added to a sample of neutral water at room temperature (7 pH) will drive the pH value down below 7 due to the increasing molarity of hydrogen ions in the solution. The addition of hydrogen ions to the solution also decreases the molarity of hydroxyl ions (the number of moles of  $\text{OH}^-$  ions per liter of solution) because some of the water's  $\text{OH}^-$  ions combine with the acid's  $\text{H}^+$  ions to form deionized water molecules ( $\text{H}_2\text{O}$ ).

If an alkaline substance (otherwise known as a *caustic*, or a *base*) is added to water, some<sup>47</sup> of the alkaline molecules dissociate into negative hydroxyl ions ( $\text{OH}^-$ ) and positive ions (the type of positive ions depending on what type of alkaline it is). This increases the molarity of  $\text{OH}^-$  ions in

<sup>45</sup>If the electrolyte is considered *strong*, all or nearly all of its molecules will dissociate into ions. A *weak* electrolyte is one where only a mere portion of its molecules dissociate into ions.

<sup>46</sup>For “strong” acids, all or nearly all molecules dissociate into ions. For “weak” acids, just a portion of the molecules dissociate.

<sup>47</sup>For “strong” bases, all or nearly all molecules dissociate into ions. For “weak” bases, just a portion of the molecules dissociate.

the solution, as well as decreases the molarity of hydrogen ions (again, because some of the caustic's  $\text{OH}^-$  ions combine with the water's  $\text{H}^+$  ions to form deionized water molecules,  $\text{H}_2\text{O}$ ). This decrease in hydrogen ion molarity will raise the pH value of the solution. For example, if we were to add a sample of caustic to a sample of neutral water at room temperature (7 pH), the pH of the solution would increase with the decreasing hydrogen ion molarity.

The result of this complementary effect (increasing one type of water ion, decreasing the other) keeps the overall ionization constant relatively constant, at least for dilute solutions. In other words, the addition of an acid or a caustic to water may change  $[\text{H}^+]$ , but it has little effect on  $K_w$ .

A simple way to envision this effect is to think of a laboratory balance scale, balancing the number of hydrogen ions in a solution against the number of hydroxyl ions in the same solution:

When the solution is pure water, this imaginary scale is balanced (neutral), with  $[\text{H}^+] = [\text{OH}^-]$ . Adding an acid to the solution tips the scale to the left (lower pH value), while adding a caustic to the solution tips the scale to the right (higher pH value)<sup>48</sup>.

---

<sup>48</sup>It should be noted that the solution never becomes *electrically* imbalanced with the addition of an acid or caustic. It is merely the balance of hydrogen to hydroxyl ions we are referring to here. The net electrical charge for the solution should still be zero after the addition of an acid or caustic, because while the balance of hydrogen to hydroxyl ions does change, that electrical charge imbalance is made up by the other ions resulting from the addition of the electrolyte (anions for acids, cations for caustics). The end result is still one negative ion for every positive ion (equal and opposite charge numbers) in the solution no matter what substance(s) we dissolve into it.

If an electrolyte has no effect on either the hydrogen and hydroxyl ion activity of an aqueous solution, we call it a *salt*. The following is a list of some common salts, showing their respective ions in solution:

**Potassium chloride** is a *salt* (produces neither  $\text{H}^+$  nor  $\text{OH}^-$  nor  $\text{O}^{2-}$  in solution)

**Sodium chloride** is a *salt* (produces neither  $\text{H}^+$  nor  $\text{OH}^-$  nor  $\text{O}^{2-}$  in solution)

**Zinc sulfate** is a *salt* (produces neither  $\text{H}^+$  nor  $\text{OH}^-$  nor  $\text{O}^{2-}$  in solution)

The addition of a salt to an aqueous solution should have no effect on pH, because the ions created neither add to nor take away from the hydrogen ion activity<sup>49</sup>.

Acids and caustics tend to neutralize one another, the hydrogen ions liberated by the acid combining (and canceling) with the hydroxyl ions liberated by the caustic. This process is called *pH neutralization*, and it is used extensively to adjust the pH value of solutions. If a solution is too acidic, just add caustic to raise its pH value. If a solution is too alkaline, just add acid to lower its pH value.

The result of a perfectly balanced mix of acid and caustic is deionized water ( $\text{H}_2\text{O}$ ) and a salt formed by the combining of the acid's and caustic's *other* ions. For instance, when hydrochloric acid ( $\text{HCl}$ ) and potassium hydroxide ( $\text{KOH}$ ) neutralize one another, the result is water ( $\text{H}_2\text{O}$ ) and potassium chloride ( $\text{KCl}$ ), a salt. This production of salt is a necessary side-effect of pH neutralization, which may require addressing in later stages of solution processing. Such neutralizations are exothermic, owing to the decreased energy states of the hydrogen and hydroxyl ions after combination. Mixing of pure acids and caustics together without the presence of substantial quantities of water (as a solvent) is often violently exothermic, presenting a significant safety hazard to anyone near the reaction.

Both acidic and caustic solutions pose safety hazards to human and animal life. Concentrated acids will cause burns to living tissue, while concentrated caustics chemically reduce fat within tissue to *soap*. These hazards are not just related to external skin contact, but also to internal contact in the form of ingestion or inhalation.

For more information on pH and its measurement, refer to section 23.2 beginning on page 1761 discussing different technologies for measuring the concentration of hydrogen ions in liquid solutions.

---

<sup>49</sup>Exceptions do exist for strong concentrations, where hydrogen ions may be present in solution yet unable to react because of being “crowded out” by other ions in the solution.

## Chapter 4

# DC electricity

## 4.1 Electrical voltage

*Voltage* is the amount of *specific potential energy* available between two points in an electric circuit. Potential energy is energy that is potentially available to do work. Looking at this from a classical physics perspective, potential energy is what we accumulate when we lift a weight above ground level, or when we compress a spring:

In either case, potential energy is calculated by the work done in exerting a force over a parallel distance. In the case of the weight, potential energy ( $E_p$ ) is the simple product of weight (gravity  $g$  acting on the mass  $m$ ) and height ( $h$ ):

$$E_p = mgh$$

Energy calculations for springs are more complex than for weights. The force exerted by the spring against the compressing motion increases with compression ( $F = kx$ , where  $k$  is the elastic constant of the spring). It does not remain steady as the force of weight does for the lifted mass. Therefore, the potential energy equation is nonlinear:

$$E_p = \frac{1}{2}kx^2$$

Releasing the potential energy stored in these mechanical systems is as simple as dropping the mass, or letting go of the spring. The potential energy will return to the original condition (zero) when the objects are at rest in their original positions. If either the mass or the spring were attached to a machine to harness the return-motion, that stored potential energy could be used to do useful tasks.

Potential energy may be similarly defined and quantified for *any* situation where we exert a force over a parallel distance, regardless of where that force or the motivating distance comes from. For instance, the static cling you experience when you pull a wool sock out of a clothes dryer is an example of a force. By pulling that sock away from another article of clothing against the force of “static cling,” you are doing *work*, and storing *potential energy* in the tension between that sock and the rest of the clothing. In a similar manner, that stored energy could be released to do useful tasks if we placed the sock in some kind of machine harnessing the sock’s motion as it returns to its original position on the pile of laundry, pulled by the force of static electrical attraction.

If we make use of non-mechanical means to move electric charge from one location to another, the result is no different. Moving attracting charges apart from one another means doing *work* (a force exerted over a parallel distance) and storing potential energy in that physical tension. When we use chemical reactions to move electrons from one metal plate to another in a solution, or when we spin a generator and electro-magnetically motivate electrons to seek other locations, we impart potential energy to those electrons. We could express this potential energy in the same unit as we do for mechanical systems (the *Joule*). However, it is actually more useful to express the potential energy in an electric system in terms of how many joules are available per a specific quantity of electric charge (a certain number of electrons). This measure of *specific* potential energy is simply called *electric potential* or *voltage*, and we measure it in units of *Volts*, in honor of the Italian physicist Alessandro Volta, inventor of the first electrochemical battery.

$$1 \text{ Volt} = \frac{1 \text{ Joule of potential energy}}{1 \text{ Coulomb of electric charge}}$$

In other words, if we forced 1 Coulomb's worth of electrons ( $6.24 \times 10^{18}$  of them, to be exact) away from a positively-charged place, and did one Joule's worth of work in the process, we would have generated one Volt of electric potential.

Electric potential (voltage) and potential energy share a common, yet confusing property: both quantities are fundamentally *relative* between two physical locations. There is really no such thing as specifying a quantity of potential energy at a single location. The amount of potential energy in any system is always relative between two different points. If I lift a mass off the ground, I can specify its potential energy, *but only in relation to its former position on the ground*. The amount of energy that mass is potentially capable of releasing by free-fall depends on how far it could possibly fall. To illustrate, we will perform some “thought experiments” where we lift a 1 kilogram mass 1 meter off the ground and then drop that mass to assess its energy. That 1-kilo mass weighs 9.81 Newtons on Earth, and the distance lifted was 1 meter, so the potential energy stored in the mass is 9.81 joules, right? Consider the following scenario:

If we drop the mass over the spot we first lifted it from, it will release all the potential energy we invested in it: 9.81 joules. From this example it seems very clear that the mass possessed 9.81 joules of potential energy when lifted. However, the situation becomes more complicated if we carry the mass over to the table and release it there. Since the mass can now only fall *half* a meter, it will only release 4.9 joules of energy in the process. How much potential energy did the mass have while suspended above that table? If you argue that the mass possessed a full 9.81 joules of potential energy at that original height, then why can't we realize that full potential when dropped over the table? Can we really say that an object possess potential energy if we cannot realize that potential?

Next, imagine lifting the 1 kg mass 1 meter off the ground, and then carrying it over the edge of a cliff with a 300 meter drop. If we were to release the mass here, it would fall a full 301 meters before hitting the ground. This represents *2.95 kilojoules (kJ)* of energy! How can we possibly argue that the mass had a potential energy of 9.81 joules when lifted one meter off the ground, and then without imparting any more energy to that mass we suddenly are able to realize over 300 times as much energy?

The answer to this paradox is that potential energy is always *relative* between the object's initial height and its height after falling. It is technically incorrect to say that the mass possesses 9.81 joules of potential energy when lifted 1 meter off the ground, as though potential energy were an absolute

quantity. Instead, it is more accurate to say that the mass *gained* 9.81 joules of potential energy after being lifted 1 meter off the ground, implying that the mass could have possessed potential energy (with reference to the cliff's bottom) even while sitting on the ground (above the cliff).

Likewise, electrical voltage (as an expression of potential energy) is a quantity relative between two points. Electrical voltage is symbolized by the variable  $V$  and measured in the unit of the *Volt*. Just as we must know the mass's position relative to its falling point before we can quantify its potential energy, we must know an electric charge's position relative to its return point before we can quantify its voltage. Consider a series of batteries<sup>1</sup> connected as shown:

The voltage as measured between any two points directly across a single battery will be 1.5 volts:

$$V_{AB} = 1.5 \text{ volts}$$

$$V_{BC} = 1.5 \text{ volts}$$

$$V_{CD} = 1.5 \text{ volts}$$

If, however, we span more than one battery with our voltmeter connections, our voltmeter will register more than 1.5 volts:

$$V_{AC} = 3.0 \text{ volts}$$

$$V_{BD} = 3.0 \text{ volts}$$

$$V_{AD} = 4.5 \text{ volts}$$

**Thus we see there is no such thing as “voltage” at a single point in a circuit.** The concept of voltage has meaning only *between* pairs of points in a circuit, just as the concept of potential energy for a mass has meaning only *between* two physical locations: where the mass is, and where it may potentially fall.

<sup>1</sup>A *battery* is an electrochemical device producing an electrical voltage as the result of a chemical reaction.

Things get interesting when we connect voltage sources in different configurations. Consider the following example, identical to the previous illustration except the middle battery has been reversed:

Note the “+” and “-” signs next to the ends of the batteries. These signs show the *polarity* of each battery’s voltage. Also note how the two voltmeter readings are different from before. Here we see an example of *negative potential* with the middle battery connected in opposition to the other two batteries. While the top and bottom batteries are both “lifting” electric charges to greater potential (going from point **D** to point **A**), the middle battery is decreasing potential from point **C** to point **B**. It’s like taking a step forward, then a step back, then another step forward. Or, perhaps more appropriately, like lifting a mass 1.5 meters up, then setting it down 1.5 meters, then lifting it 1.5 meters up again. The first and last steps accumulate potential energy, while the middle step releases potential energy.

This explains why it is important to install multiple batteries the same way into battery-powered devices such as radios and flashlights. The batteries’ voltages are supposed to add to make a larger total required by the device. If one or more batteries are placed backwards, potential will be lost instead of gained, and the device will not receive enough voltage.

Here we must pay special attention to how we use our voltmeter, since polarity matters. All voltmeters are standardized with two colors for the test leads: red and black. To make sense of the voltmeter's indication, especially the positive or negative *sign* of the indication, we must understand what the red and black test lead colors mean:

A positive reading indicates a **gain**  
in potential from black to red.

A negative reading indicates a **loss**  
in potential from black to red.

Connecting these test leads to different points in a circuit will tell you whether there is potential gain or potential loss from one point (black) to the other point (red).

## 4.2 Electrical current

*Current* is the name we give to the motion of electric charges from a point of high potential to a point of low potential. All we need to form an electric current is a source of potential (voltage) and some electric charges that are free to move between the poles of that potential. For instance, if we connected a battery to two metal plates, we would create an electric field between those plates, analogous to a gravitational field except it only acts on electrically charged objects, while gravity acts on anything with mass. A free charge placed between those plates would “fall” toward one of the plates just as a mass would fall toward a larger mass:

*An electric charge will "fall" in an electric field just as a mass will fall in a gravitational field.*

Some solid substances, most notably metals, have very mobile electrons. That is, the outer (valence) electrons are very easily dislodged from the parent atoms to drift to and fro throughout the material. In fact, the electrons within metals are so free that physicists sometimes refer to the structure of a metal as atomic nuclei “floating in a sea of electrons”. The electrons are almost fluid in their mobility throughout a solid metal object, and this property of metals may be exploited to form definite pathways for electric currents. This is why electrical wires are made of metal such as copper or aluminum: substances with a high degree of electron mobility. Any substance whose electrons are mobile is called a *electrical conductor*, while any substance lacking mobile electrons is called an *electrical insulator*.

If the poles of a voltage source are joined by a conductor, the free electrons within that conductor will drift toward the positive pole (electrons having a negative charge, opposite charges attracting one another). For each electron reaching the positive pole, an electron exits the negative pole of the source to replenish the total number of electrons in the flow:

If the source of this voltage is continually replenished by chemical energy, mechanical energy, or some other form of energy, the free electrons will continually loop around this circular path. We call this unbroken path an *electric circuit*. The drifting motion of electrons in a circuit has the same average rate of flow (current) at all points in that circuit, because there is only one pathway for the current. You may think of this like liquid flowing through a circular loop of pipe: since there is only one pathway for the liquid to flow, the rate of flow at all points in that pathway must be the same.

We typically measure the amount of current in a circuit by the unit of *Amperes*, or *Amps* for short (named in honor of the French physicist André Ampère, and symbolize it in formulae using the variable  $I$ ). One ampere of current is equal to one coulomb of electric charge ( $6.24 \times 10^{18}$  electrons) moving past a point in a circuit for every second of time.

Like masses falling toward a source of gravity, these electrons continually “fall” toward the positive pole of a voltage source. After arriving at that source, the energy imparted by that source “lifts” the electrons to a higher potential state where they once again “fall down” to the positive pole through the circuit.

Like rising and falling masses in a gravitational field, these electrons act as carriers of energy within the electric field of the circuit. This is very useful, as we can use them to convey energy from one place to another, using metal wires as conduits for this energy. This is the basic idea behind electric power systems: a source of power (a *generator*) is turned by some mechanical engine (windmill, water turbine, steam engine, etc.), creating an electric potential. This potential is then used to motivate free electrons inside the metal wires to drift in a common direction. The electron drift is conveyed in a circuit through long wires, where they can do useful work at a *load* device such as an electric motor, light bulb, or heater.

Given the proper metal alloys, the friction that electrons experience within the metal wires may be made very small, allowing nearly all the energy to be expended at the load (motor), with very little wasted along the path (wires). This makes electricity the most efficient means of energy transport known.

The electric currents common in electric power lines may range from hundreds to thousands of amperes. The currents conveyed through power receptacles in your home typically are no greater than 20 amperes. The currents in the small battery-powered circuits you will build are even less: fractions of an ampere. For this reason, we commonly use the metric prefix *milli* (one one-thousandth) to express these small currents. For instance, 10 milliamperes is 0.010 amperes, and 500 milliamperes is one-half of an ampere.

### 4.2.1 Electron versus conventional flow

When Benjamin Franklin proposed his single-fluid theory of electricity, he defined “positive” and “negative” as the surplus and deficiency of electric charge, respectively. These labels were largely arbitrary, as Mr. Franklin had no means of identifying the actual nature of electric charge carriers with the primitive test equipment and laboratory techniques of his day. As (bad) luck would have it, his hypothesis was precisely opposite of the truth for metallic conductors, where electrons are the dominant charge carrier.

This means that in an electric circuit consisting of a battery and a light bulb, electrons slowly move from the negative side of the battery, through the metal wires, through the light bulb, and on to the positive side of the battery as such:

Unfortunately, scientists and engineers had grown accustomed to Franklin’s false hypothesis long before the true nature of electric current in metallic conductors was discovered. Their preferred notation was to show electric current flowing from the positive pole of a source, through the load, returning to the negative pole of the source:

This relationship between voltage polarity marks and conventional flow current tends to make more intuitive sense than electron flow notation, because it is reminiscent of fluid pressure and flow direction:

If we take the “+” sign to represent *more* pressure and the “-” sign to represent *less* pressure, it makes perfect sense that fluid should move from the high-pressure (discharge) port of the pump through the hydraulic “circuit” and back to the low-pressure (suction) port of the pump. It also makes perfect sense that the upstream side of the valve (a fluid restriction) will have a greater pressure than the downstream side of the valve. In other words, conventional flow notation best honors Mr. Franklin’s original intent of modeling current as though it were a fluid, even though he was later proven to be mistaken in the case of metallic conductors where electrons are the dominant charge carrier.

This convention was so well-established in the electrical engineering realm that it held sway despite the discovery of electrons. Engineers, who create the symbols used to represent the electronic devices they invent, consistently chose to draw arrows in the direction of conventional flow rather than electron flow. In each of the following symbols, the arrow heads point in the direction that *positive* charge carriers would move (opposite the direction that electrons actually move):

This stands in contrast to electronics technicians, who historically have been taught using electron flow notation. I remember sitting in a technical school classroom being told by my teacher to always imagine the electrons moving *against the arrows* of the devices, and wondering why it mattered.

It is truly a sad situation when the members of two branches within the same field do not agree on something as fundamental as the convention used to denote flow in diagrams. It is even worse when people within the field argue over which convention is best. So long as one is consistent with their convention and with their thinking, *it does not matter!* Many fine technologists may be found on either side of this “fence,” and some are adept enough to switch between both without getting confused.

My personal preference is conventional flow notation. The only objective arguments I have in favor of this preference are as follows:

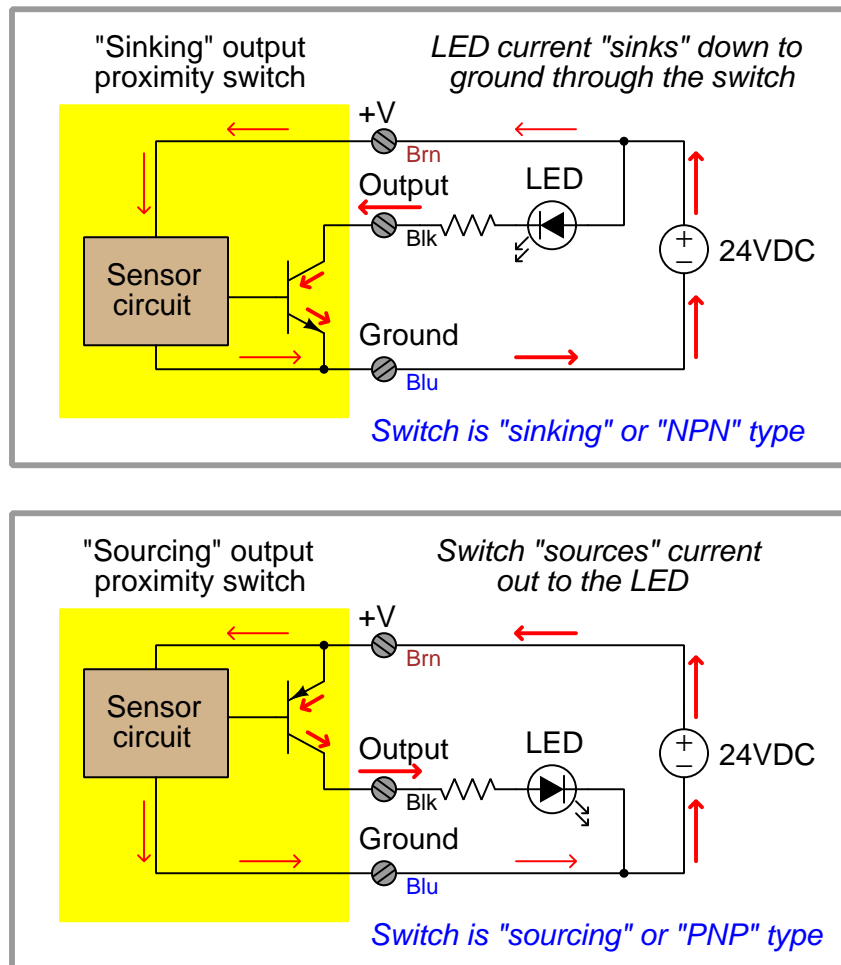

- Conventional flow notation is a closer analogue to fluid flow in pneumatic, hydraulic, and process flow systems. Since instrument technicians need to understand the relationships between pressure and flow in fluid systems as well as electrical circuits, using conventional flow notation for electrical circuits helps to reinforce these analogous concepts.
- Conventional flow notation is the *standard* for modern manufacturers' documentation (reference manuals, troubleshooting guides, datasheets, etc.)<sup>2</sup>.
- Conventional flow notation is consistent with the “right-hand rule” for vector cross products (which are essential for understanding electromagnetics at advanced academic levels). The so-called “left-hand rule” taught to students learning electron flow notation is mathematically wrong, and must be un-learned if the student ever progresses to the engineering level in his or her studies.
- Conventional flow notation matches all device arrows; no need to “go against the arrow” when tracing current in a schematic diagram.
- Conventional flow notation makes sense of the descriptive terms *sourcing* and *sinking*.

This last point merits further investigation. The terms “sourcing” and “sinking” are often used in the study of digital electronics to describe the direction of current in a switching circuit. A circuit that “sources” current to a load is one where the direction of conventional flow points outward from the sourcing circuit to the load device. These terms are also used to characterize the DC input and output modules of certain industrial control equipment such as programmable logic controllers (PLCs), and so any technologist working with such equipment will need to properly identify and connect these module types based on the directions of electric current for which they are designed.

---

<sup>2</sup>I have yet to read a document of any kind written by an equipment manufacturer using electron flow notation, and this is after scrutinizing literally hundreds of documents looking for this exact detail! For the record, though, most technical documents do not bother to draw a direction for current at all, leaving it to the imagination of the reader instead. It is only when a direction must be drawn that one sees a strong preference in industry for conventional flow notation.

For example, here are two schematic diagrams showing two different kinds of electronic proximity switch. The first switch *sinks* current in from the LED through its output terminal, through its transistor, and down to ground. The second switch *sources* current from the positive supply terminal through its transistor and out to the LED through its output terminal (note the direction of the thick arrow near the output screw terminal in each circuit):

These terms simply make no sense when viewed from the perspective of electron flow notation. If you were to actually trace the directions of the electrons, you would find that a device "sourcing" current has electrons flowing *into* its connection terminal, while a device "sinking" current sends electrons *out* to another device where they travel (up) to a point of more positive potential.

In fact, the association between conventional flow notation and sourcing/sinking descriptions is so firm that I have yet to see a professionally published textbook on digital circuits that uses electron flow<sup>3</sup>. This is true even for textbooks written for technicians and not engineers!

<sup>3</sup>If by chance I have missed anyone's digital electronics textbook that does use electron flow, please accept my

Once again, though, it should be understood that either convention of current notation is adequate for circuit analysis. I dearly wish this horrible state of affairs would come to an end, but the plain fact is it will not. Electron flow notation may have the advantage of greater correspondence to the actual state of affairs (in the vast majority of circuits), but conventional flow has the weight of over a hundred years of precedent, cultural inertia, and convenience. No matter which way you choose to think, at some point you will be faced with the opposing view.

Choose the notation you like best, and may you live long and prosper.

### 4.3 Electrical sources and loads

By definition, a *source* is a device delivering energy into a system, while a *load* is a device extracting energy from a system. Examples of typical electrical sources include generators, photovoltaic cells, thermopiles, and primary-cell batteries. These devices create electrical voltage, which in turn motivates electrical current to flow in a circuit. Examples of typical electrical loads include resistors, lamps, and electric motors. These devices resist the flow of electrical current through them, creating a voltage *drop* as a result.

In a working circuit, electrical sources and loads may be easily distinguished by comparison of their current directions and voltage polarities. An electrical source always manifests a voltage polarity in a direction *aiding* the direction of charge flow; i.e. a source is “pushing” the current along. An electrical load always manifests a voltage polarity in a direction *opposing* the direction of charge flow; i.e. a load “resists” the current.

The way in which we designate the direction of current (charge flow) becomes very important here. Since there are two commonly accepted notations – electron flow and “conventional” flow, exactly opposite of each other – it is easy to become confused.

---

apologies. I can only speak of what I have seen myself.

First we see a diagram showing a source and a load, using electron flow notation. Electrons, being negatively charged particles, are repelled by the negative (−) poles of both source and load, and attracted to the positive (+) poles of both source and load. The difference between source and load is that the source device *motivates* the flow of electrons while the load device *resists* the flow of electrons:

Electrons are repelled by the (−) poles  
and attracted to the (+) poles

In the case of the source (battery), the polarity of the voltage works *for* the direction of charge motion. In the case of the load (resistor), the polarity of the voltage drop works *against* the direction of charge motion.

Next we see a diagram showing the same source and load, this time using “conventional” flow notation to designate the direction of current. Here we must imagine positively-charged carriers moving through the wires instead of electrons. These positive charge carriers are repelled by any positive (+) pole and attracted to any negative (−) pole. Viewed in this light, we see the exact same principle at work: the source device is seen to *motivate* the flow of these positive charge carriers while the load device *resists* the flow:

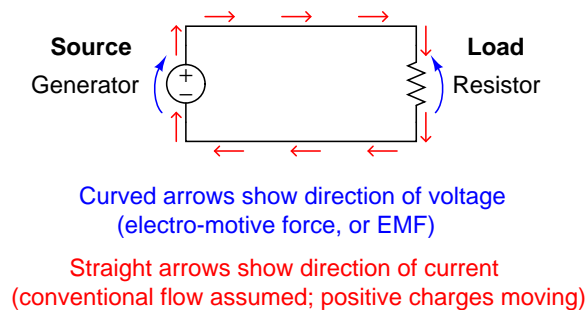

Positive charge carriers are repelled by the  
(+) poles and attracted to the (−) poles

Despite using a different notation for charge motion, the concept of source and load remains the same. In the case of the source (battery), the polarity of the voltage works *for* the direction of charge motion. In the case of the load (resistor), the polarity of the voltage drop works *against* the direction of charge motion.

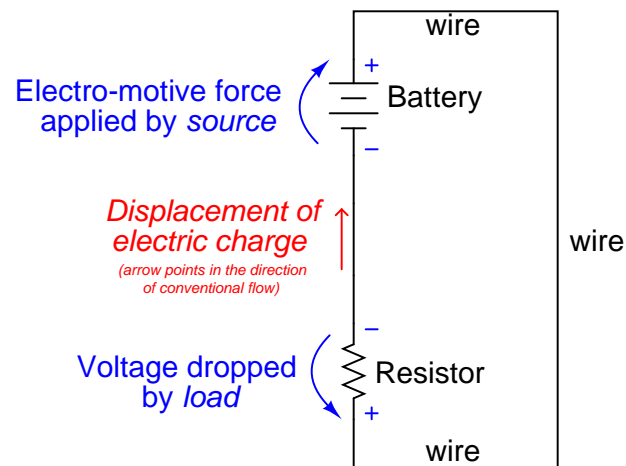

An alternative notation for voltage (other than using “+” and “−” symbols) that many students find particularly illustrative is the use of curved arrows, where the tip of the curved arrow is the positive pole and the tail of the curved arrow is the negative pole. This notation is intended to be used when the direction of current (using “straight” or “angular” arrows) is shown using conventional flow notation:

Using arrows to represent voltage polarity in addition to using arrows to represent current direction is highly intuitive. It shows which way each component in the DC circuit is “pushing” in relation to the flow of charge carriers. Note how the source’s voltage arrow points in the same direction as the current: this means the source is motivating the current, causing charge carriers to flow in this circuit. Note how the resistor’s voltage arrow points opposite to the direction of current: this means the resistor is opposing the current, in a sense “fighting against” the flow of charge carriers. This comparison of voltage-arrow versus current-arrow direction makes the distinction between sources and loads rather obvious: sources push in the direction of current while loads push against the direction of current.

I personally lament the obscurity of this “curved-arrow” notation for voltage, as it greatly aids comprehension of this critically important distinction between sources and loads. When the voltage and current arrows point in the same direction, it means the component in question is motivating charge carriers along and therefore imparts energy to the circuit. When voltage and current arrows point in opposite directions, it means the component in question opposes charge carrier motion and therefore acts to extract energy from the circuit.

This directly relates to the fundamental physics concept of *work*, specifically in relation to the mathematical sign of work being a function of the relative angle between force and displacement. When a force acts in the same direction as motion, the work done is positive; when a force acts in the opposite direction as motion, the work done is negative:

$W_{\text{battery}}$  = positive value, because its force is in the same direction as the current

$W_{\text{resistor}}$  = negative value, because its force opposes the direction of the current

Positive work represents an infusion of energy into a system (source), while negative work represents an extraction of energy from that system (load).

If we examine a hydraulic system, where a pump pushes fluid around a pipe loop and an orifice (called a “restrictor”) restricts the flow of this fluid, we see this same concept in action: the pump’s pressures at its discharge and suction ports work *for* the direction of fluid flow, while the pressures at the upstream and downstream ports of the restrictor work *against* the direction of fluid flow. The pump acts as a power *source* in this hydraulic “circuit” (infusing energy into the system) while the restrictor acts as a power *load* (extracting energy from the system):

We may even see this concept revealed in a simple mechanical system where work is being done. Examine the case of a crane lifting a heavy weight into the air, shown below. As the crane lifts the weight upward, the crane’s upward force on the weight is clearly working *for* the direction of motion, while the weight’s downward force against the crane is clearly working *against* the direction of motion:

Thus, the crane is doing positive work (acting as a *source*, infusing potential energy into the weight) while the weight is doing negative work (acting as a *load*, absorbing potential energy from the crane). A mathematically rigorous way to demonstrate this is to calculate the work done by each using the formula  $W = \vec{F} \cdot \vec{x}$  or  $W = Fx \cos \theta$ . Since the crane’s force and motion vectors both point in the same direction,  $\theta = 0$  and work is a positive quantity  $Fx$ . The weight’s force vector, however, points  $180^\circ$  away from the motion vector, and so its work calculation is  $Fx \cos(180^\circ)$  or  $-Fx$ .

Some electric components have the ability to act as sources and loads at different times. Both capacitors (see section 4.12 starting on page 346) and inductors (see section 4.13 starting on page 350) have the ability to temporarily contribute to and extract energy from electrical circuits, both having the ability to act as energy *storage* devices. One of the key concepts necessary to grasp the energy-storing abilities of capacitors and inductors is being able to recognize sources and loads at a glance based on the relationship between voltage polarity and charge motion. A set of three schematic diagrams shows how a capacitor is able to play the role of either source or load depending on what other component it is connected to:

Rechargeable batteries (called “secondary-cell” batteries as opposed to “primary-cell” batteries which cannot be recharged) may also behave as either sources or loads depending on external conditions. If a secondary-cell battery is connected to a resistor, the battery will discharge its energy (i.e. act as a source) while the resistor will dissipate that energy (i.e. act as a load). If a depleted secondary-cell battery is connected to an electrical generator of greater voltage, the generator will source energy to the battery while the re-charging battery will load down the generator (i.e. conventional flow entering the battery’s positive terminal and exiting the negative terminal).

Another practical benefit of clearly comprehending the distinction between electrical sources and electrical loads is being able to understand and troubleshoot 4-20 mA signal “loop” circuits used extensively in industrial instrumentation, especially circuits containing 2-wire (“loop-powered”) process transmitters. A “2-wire transmitter” is a device designed to regulate the amount of electrical current through it to a value determined by some physical variable such as a sensed pressure, temperature, or flow rate. The purpose of such a device is to represent that physical measurement in the form of an electric current that may be carried far distances through wires. What makes this device so troublesome for people to understand is that despite its function to *set* the value of current in the circuit, it is actually an electrical *load* and not an electrical *source* as one might assume. That is, a 2-wire transmitter relies wholly on some other source of electrical power in the circuit to function, although the transmitter solely defines how much current will flow in the circuit by virtue of its function as a regulator. For more information on this subject, refer to section 13.5 starting on page 891.

## 4.4 Electrical power

Since we often use electricity to convey energy from one location to another, it is important to be able to quantify and calculate the rate at which energy is delivered by an electric circuit. The *rate* at which energy transfers from one location to another is technically referred to as *power* ( $P$ ), and it is typically<sup>4</sup> measured in the unit of the *watt* (1 watt = 1 joule of energy per second of time).

The total amount of power (energy per unit time) carried by an electric current is proportional to the strength of that current as well as the amount of potential (voltage) between the poles of the electrical source. Thus, power is equal to the product of current and voltage in a formula called *Joules' Law*:

$$P = IV$$

Where,

$P$  = Power in watts (joules of energy per second of time)

$I$  = Current in amperes

$V$  = Voltage in volts

We may prove the correctness of this formula by verifying all the units of measurement agree:

$$P = IV$$

$$[\text{Watts}] = [\text{Amperes}] \times [\text{Volts}] \quad \text{or} \quad [\text{W}] = [\text{A}][\text{V}]$$

$$\left[ \frac{\text{Joules}}{\text{Seconds}} \right] = \left[ \frac{\text{Coulombs}}{\text{Seconds}} \right] \times \left[ \frac{\text{Joules}}{\text{Coulombs}} \right] \quad \text{or} \quad \left[ \frac{\text{J}}{\text{s}} \right] = \left[ \frac{\text{C}}{\text{s}} \right] \left[ \frac{\text{J}}{\text{C}} \right]$$

Note how the basic units for power (joules per second) are indeed equal to the product of voltage (joules per coulomb) and current (coulombs per second). This process of checking for agreement between units of measurement in a physics formula is called *dimensional analysis*.

---

<sup>4</sup>Although the unit of the “watt” is commonly used for electrical power, other units are valid as well. The British unit of *horsepower* is every bit as valid for expressing electrical power as “watts,” although this usage is less common. Likewise, the “watt” may be used to express measurements of non-electrical power as well, such as the mechanical power output of an engine. European automobile manufacturers, for example, rate the power output of their cars’ engines in *kilowatts*, as opposed to American automobile manufacturers who rate their engines in *horsepower*. This choice of units is strictly a cultural convention, since any valid unit for power may be applied to any form of energy rate.

## 4.5 Electrical resistance and Ohm's Law

To review, *voltage* is the measure of potential energy available to electric charges. *Current* is the uniform drifting of electric charges in response to a voltage. We can have a voltage without having a current, but we cannot have a current without first having a voltage to motivate it<sup>5</sup>. Current without voltage would be equivalent to motion without a motivating force.

When electric charges move through a material such as metal, they will naturally encounter some friction, just as fluid moving through a pipe will inevitably encounter friction<sup>6</sup>. We have a name for this friction to electrical charge motion: *resistance*. Like voltage and current, resistance has its own special unit of measurement: the *ohm*, named in honor of the German physicist Georg Simon Ohm.

At this point it would be good to summarize and compare the symbols and units we use for voltage, current, and resistance:

Quantity	Algebraic symbol	Unit	Unit abbreviation
Voltage	$V$ (or $E$ )	Volt	V
Current	$I$	Ampere (or Amp)	A
Resistance	$R$	Ohm	$\Omega$

Ohm defined resistance as the mathematical ratio between applied voltage and resulting current. This formula became known as *Ohm's Law*, perhaps the most basic formula in all of electrical science (shown here in three different forms, each one solving for a different variable):

$$R = \frac{V}{I} \qquad V = IR \qquad I = \frac{V}{R}$$

Verbally expressed, resistance is how much voltage it takes to force a certain rate of current through a conductive material. Many materials have relatively stable resistances, while others do not. Devices called *resistors* are sold which are manufactured to possess a very precise amount of resistance, for the purpose of limiting current in circuits (among other things).

Here is an example of Ohm's Law in action: calculate the amount of current in a circuit with a voltage source of 25 V and a total resistance of 3500  $\Omega$ . Taking 25 volts and dividing by 3500 ohms, you should arrive at a result of 0.007143 amperes, or 7.143 milliamperes (7.143 mA).

One of the most challenging aspect of Ohm's Law is remembering to *keep all variables in context*. This is a common problem for many students when studying physics as well: none of the equations learned in a physics class will yield the correct results unless all the variables relate to the same object or situation. For instance, it would make no sense to try to calculate the kinetic energy of a moving object ( $E = \frac{1}{2}mv^2$ ) by taking the mass of one object ( $m$ ) and multiplying it by the square of the velocity of some *other* object ( $v^2$ ). Likewise, with Ohm's Law, we must make sure the voltage, current, and resistance values we are using all relate to the same portion of the same circuit.

---

<sup>5</sup>Except in the noteworthy case of *superconductivity*, a phenomenon occurring at extremely low temperatures.

<sup>6</sup>Except in the noteworthy case of *superfluidity*, another phenomenon occurring at extremely low temperatures.

If the circuit in question has only one source of voltage, one resistance, and one path for current, we cannot mis-apply Ohm's Law. Expressing the previous example in a schematic diagram:

*Note: arrows point in the direction of conventional flow*

However, if we look at a more complex circuit, we encounter the potential for mis-application of Ohm's Law because we have multiple resistances in the circuit rather than just one resistance:

Which resistance do we use to calculate current in this circuit? Do we divide our 25 volts by 3500 ohms like we did last time, or do we divide it by 1500 ohms, or something entirely different? The answer to this question lies in the identification of voltages and currents. We know that the 25 volt potential will be impressed across the *total* of the two resistances  $R_1$  and  $R_2$ , and since there is only one path for current they must share the same current. Thus, we actually have *three* voltages ( $V_1$ ,  $V_2$ , and  $V_{total}$ ), *three* resistances ( $R_1$ ,  $R_2$ , and  $R_{total}$ ), and only *one* current ( $I$ ):

*Note: arrows point in the direction of conventional flow*

Using the  $V = IR$  form of Ohm's Law to relate these three voltages ( $V_1$ ,  $V_2$ , and  $V_{total}$ ) to the one current ( $I$ ), we end up with three equations for this circuit:

$$V_1 = IR_1$$

$$V_2 = IR_2$$

$$V_{total} = IR_{total} = I(R_1 + R_2)$$

We can only solve for one unknown variable at a time in any equation. This means we cannot solve for  $V_1$  yet, because although we do know the value of resistor  $R_1$  (3500 ohms), we do not yet know the circuit's current ( $I$ ). Likewise for  $V_2$ , because we do not yet know the value of  $I$ . However, the third equation is solvable, since we happen to know the total voltage as well as both resistor values, leaving circuit current  $I$  as the only unknown variable. Manipulating this equation and solving for  $I$ :

$$I = \frac{V_{total}}{R_{total}} = \frac{V_{total}}{R_1 + R_2} = \frac{25 \text{ V}}{3500 \Omega + 1500 \Omega} = 0.005 \text{ A} = 5 \text{ mA}$$

Now that we know the amount of current in this circuit, we may solve for  $V_1$  and  $V_2$  in the other equations to find that the voltage across resistor  $R_1$  is 17.5 volts, and that the voltage across resistor  $R_2$  is 7.5 volts.

## 4.6 Series versus parallel circuits

In addition to Ohm's Law, we have a set of rules describing how voltages, currents, and resistances relate in circuits comprised of multiple resistors. These rules fall neatly into two categories: *series* circuits and *parallel* circuits. The two circuit types are shown here, with squares representing any type of two-terminal electrical component:

**Series circuit**

**Parallel circuit**

The defining characteristic of a series electrical circuit is it provides just one path for current. This means there can be only one value for current anywhere in the circuit, the exact same current for all components at any given time<sup>7</sup>. The principle of current being the same everywhere in a series circuit is actually an expression of a more fundamental law of physics: the *Conservation of Charge*, which states that electric charge cannot be created or destroyed. In order for current to have different values at different points in a series circuit indefinitely, electric charge would have to somehow appear and disappear to account for greater rates of charge flow in some areas than in others. It would be the equivalent of having different rates of water flow at different locations along one length of pipe<sup>8</sup>.

<sup>7</sup>Interesting exceptions do exist to this rule, but only on very short time scales, such as in cases where we examine the a transient (pulse) signal nanosecond by nanosecond, and/or when very high-frequency AC signals exist over comparatively long conductor lengths.

<sup>8</sup>Those exceptional cases mentioned earlier in the footnote are possible only because electric charge may be temporarily stored and released by a property called *capacitance*. Even then, the law of charge conservation is not violated because the stored charges re-emerge as current at later times. This is analogous to pouring water into a bucket: just because water is poured into a bucket but no water leaves the bucket does not mean that water is magically disappearing. It is merely being stored, and can re-emerge at a later time.

Series circuits are defined by having only one path for current, and this means the steady-state current in a series circuit must be the same at all points of that circuit. It also means that the sum of all voltages dropped by load devices must equal the sum total of all source voltages, and that the total resistance of the circuit will be the sum of all individual resistances:

The defining characteristic of a parallel circuit, by contrast, is that all components share the same two equipotential points. “Equipotential” simply means “at the same potential” which points along an uninterrupted conductor must be<sup>9</sup>. This means there can be only one value of voltage anywhere in the circuit, the exact same voltage for all components at any given time<sup>10</sup>. The principle of voltage being the same across all parallel-connected components is (also) an expression of a more fundamental law of physics: the *Conservation of Energy*, in this case the conservation of specific potential energy which is the definition of voltage. In order for voltage to differ between parallel-connected components, the potential energy of charge carriers would have to somehow appear and disappear to account for lesser and greater voltages. It would be the equivalent of having a “high spots” and “low spots” of water mysteriously appear on the quiet surface of a lake, which we know cannot happen because water has the freedom to move, meaning any high spots would rush to fill any low spots<sup>11</sup>.

<sup>9</sup>An ideal conductor has no resistance, and so there is no reason for a difference of potential to exist along a pathway where nothing stands in the way of charge motion. If ever a potential difference developed, charge carriers within the conductor would simply move to new locations and neutralize the potential.

<sup>10</sup>Again, interesting exceptions do exist to this rule on very short time scales, such as in cases where we examine the a transient (pulse) signal nanosecond by nanosecond, and/or when very high-frequency AC signals exist over comparatively long conductor lengths.

<sup>11</sup>The exceptional cases mentioned in the previous footnote exist only because the electrical property of *inductance* allows potential energy to be stored in a magnetic field, manifesting as a voltage different along the length of a conductor. Even then, the Law of Energy Conservation is not violated because the stored energy re-emerges at a later time.

The sum of all component currents must equal the total current in a parallel circuit, and total resistance will be *less* than the smallest individual resistance value:

The rule for calculating total resistance in a parallel circuit perplexes many students with its weird compound reciprocal notation. There is a more intuitive way to understand this rule, and it involves a different quantity called *conductance*, symbolized by the letter  $G$ .

Conductance is defined as the reciprocal of resistance; that is, a measure of how *easily* electrical charge carriers may move through a substance. If the electrical resistance of an object doubles, then it now has *half* the conductance it did before:

$$G = \frac{1}{R}$$

It should be intuitively apparent that conductances add in parallel circuits. That is, the total amount of conductance for a parallel circuit must be the sum total of all individual conductances, because the addition of more conductive pathways must make it easier overall for charge carriers to move through the circuit. Thus,

$$G_{\text{total}} = G_1 + G_2 + \dots + G_n$$

The formula shown here should be familiar to you. It has the same form as the total resistance formula for series circuits. Just as resistances add in series (more series resistance makes the overall resistance to current increase), conductances add in parallel (more conductive branches makes the overall conductance increase).

Knowing that resistance is the reciprocal of conductance, we may substitute  $\frac{1}{R}$  for  $G$  wherever we see it in the conductance equation:

$$\frac{1}{R_{\text{total}}} = \frac{1}{R_1} + \frac{1}{R_2} + \dots + \frac{1}{R_n}$$

Now, to solve for  $R_{total}$ , we need to reciprocate both sides:

$$R_{total} = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \cdots + \frac{1}{R_n}}$$

For both series and parallel circuits, total power dissipated by all load devices is equal to the total power delivered by all source devices. The configuration of a circuit is irrelevant to the balance between power supplied and power lost, because this balance is an expression of the Law of Energy Conservation.

## 4.7 Kirchhoff's Laws

Two extremely important principles in electric circuits were codified by Gustav Robert Kirchhoff in the year 1847, known as *Kirchhoff's Laws*. His two laws refer to voltages and currents in electric circuits, respectively.

Kirchhoff's Voltage Law states that the algebraic sum of all voltages in a closed loop is equal to zero. Another way to state this law is to say that for every rise in potential there must be an equal fall, if we begin at any point in a circuit and travel in a loop back to that same starting point.

An analogy for visualizing Kirchhoff's Voltage Law is hiking up a mountain. Suppose we start at the base of a mountain and hike to an altitude of 5000 feet to set up camp for an overnight stay. Then, the next day we set off from camp and hike farther up another 3500 feet. Deciding we've climbed high enough for two days, we set up camp again and stay the night. The next day we hike down 6200 feet to a third location and camp once gain. On the fourth day we hike back to our original starting point at the base of the mountain. We can summarize our hiking adventure as a series of rises and falls like this:

Day	Path	Altitude gain/loss
Day 1	A to B	+5000 feet
Day 2	B to C	+3500 feet
Day 3	C to D	-6200 feet
Day 4	D to A	-2300 feet
(Total)	ABCD A	0 feet

Of course, no one would tell their friends they spent *four days hiking a total altitude of 0 feet*, so people generally speak in terms of the *highest* point reached: in this case 8500 feet. However, if we track each day's gain or loss in algebraic terms (maintaining the mathematical sign, either positive or negative), we see that the end sum is zero (and indeed *must always be zero*) if we finish at our starting point.

If we view this scenario from the perspective of potential energy as we lift a constant mass from point to point, we would conclude that we were doing work on that mass (i.e. investing energy in it by lifting it higher) on days 1 and 2, but letting the mass do work on us (i.e. releasing energy by lowering it) on days 3 and 4. After the four-day hike, the net potential energy imparted to the mass is zero, because it ends up at the exact same altitude it started at.

Let's apply this principle to a real circuit, where total current and all voltage drops have already been calculated for us:

Arrow shows current in the direction of conventional flow notation

If we trace a path ABCDEA, we see that the algebraic voltage sum in this loop is zero:

Path	Voltage gain/loss
A to B	− 4 volts
B to C	− 6 volts
C to D	+ 5 volts
D to E	− 2 volts
E to A	+ 7 volts
ABCDEA	0 volts

We can even trace a path that does not follow the circuit conductors or include all components, such as EDCBE, and we will see that the algebraic sum of all voltages is still zero:

Path	Voltage gain/loss
E to D	+ 2 volts
D to C	− 5 volts
C to B	+ 6 volts
B to E	− 3 volts
EDCBE	0 volts

Kirchhoff's Voltage Law is often a difficult subject for students, precisely because voltage itself is a difficult concept to grasp. Remember that there is no such thing as voltage at a single point; rather, voltage exists only as a *differential* quantity. To intelligently speak of voltage, we must refer to either a *loss* or *gain* of potential between **two points**.

Our analogy of altitude on a mountain is particularly apt. We cannot intelligently speak of some point on the mountain as having a specific altitude unless we assume a point of reference to measure from. If we say the mountain summit is 9200 feet high, we usually mean 9200 feet *higher than sea level*, with the level of the sea being our common reference point. However, our hiking adventure where we climbed 8500 feet in two days did not imply that we climbed to an absolute altitude of 8500 feet above sea level. Since I never specified the sea-level altitude at the base of the mountain,

it is impossible to calculate our absolute altitude at the end of day 2. All you can tell from the data given is that we climbed 8500 feet *above* the mountain base, wherever that happens to be with reference to sea level.

So it is with electrical voltage as well: most circuits have a point labeled as *ground* where all other voltages are referenced. In DC-powered circuits, this ground point is often the negative pole of the DC power source<sup>12</sup>. Voltage is fundamentally a quantity relative between two points: a measure of how much potential has *increased* or *decreased* moving from one point to another.

Kirchhoff's Current Law is a much easier concept to grasp. This law states that the algebraic sum of all currents at a junction point (called a *node*) is equal to zero. Another way to state this law is to say that for every electron entering a node, one must exit somewhere.

An analogy for visualizing Kirchhoff's Current Law is water flowing into and out of a “tee” fitting:

So long as there are no leaks in this piping system, every drop of water entering the tee must be balanced by a drop exiting the tee. For there to be a continuous mis-match between flow rates would imply a violation of the Law of Mass Conservation.

---

<sup>12</sup>But not always! There do exist positive-ground systems, particularly in telephone circuits and in some early automobile electrical systems.

Let's apply this principle to a real circuit, where all currents have been calculated for us:

*Arrows show currents in the direction of conventional flow notation*

At nodes where just two wires connect (such as points A, B, and C), the amount of current going in to the node exactly equals the amount of current going out (4 mA, in each case). At nodes where three wires join (such as points D and E), we see one large current and two smaller currents (one 4 mA current versus two 2 mA currents), with the directions such that the sum of the two smaller currents form the larger current.

Just as the balance of water flow rates into and out of a piping “tee” is a consequence of the Law of Mass Conservation, the balance of electric currents flowing into and out of a circuit junction is a consequence of the Law of *Charge* Conservation, another fundamental conservation law in physics.

## 4.8 Circuit fault analysis

Perhaps the most valuable skill an instrument technician can possess is the ability to efficiently diagnose malfunctioning systems: determining in as short a time as possible the cause of a system's malfunction. Since most instrumentation and control systems are based on electricity, a solid understanding of electrical faults is the foundation of this skill set. In this section we will explore the two basic types of electrical faults (*opens* and *shorts*) and analyze their respective effects in DC circuits.

An *open* is an electrical fault whereby the pathway for electrical current is broken, thus preventing the passage of current. A *short* is an electrical fault whereby two points in a circuit that are supposed to be separated are joined together by a conductive pathway. It should be noted that this definition for the word “short” both is technical and specific. This is important to understand, as many people tend to use the word “short” to refer to any electrical problem in general. In technical parlance, a “short” fault is the exact opposite of an “open” fault, and should never be confused one for the other.

Let us examine the effects of both faults in a simple two-resistor DC circuit. We will begin with an analysis of the circuit in a healthy condition, showing all values of voltage and current:

Being a series circuit, the current is the same through all components while the two loads' voltage drops add to equal the source voltage.

Now suppose resistor  $R_1$  fails open. We know that a continuous electric current is able to exist only where there is a continuous path for that current. If a component fails open, the continuity of the circuit will be broken, and current must halt. Since this is a series circuit, if current halts in one location it must likewise halt in all locations:

We would still expect to measure 15 volts between test points A and B because it is the nature of a voltage source to maintain a constant voltage across its terminals (i.e. to maintain the same amount of energy difference per unit charge from one side to the other). We may apply Ohm's Law to calculate the voltage across the healthy resistor  $R_2$ : since  $V = IR$  and  $I = 0$ , we may safely conclude that  $V = 0$  for resistor  $R_2$ .

Unfortunately, we cannot apply Ohm's Law to the failed resistor  $R_1$  since the resistance of any failed-open component is infinite. Infinities do not lend themselves to arithmetic calculations (how much is zero times infinity?), and so we must find some other way to determine the voltage dropped across the open  $R_1$ . Here we find that Kirchhoff's Voltage Law applies very nicely: if we know that the algebraic sum of all voltages in a loop must equal zero, and we know all but one of the voltages in the loop BACDB, we may calculate the last voltage by simple addition and subtraction:

Path	Voltage gain/loss	Reason
B to A	+ 15 volts	Source voltage value
A to C	<b>−15 volts</b>	Necessary to satisfy KVL
C to D	0 volts	These points are equipotential
D to B	0 volts	Ohm's Law: $V = 0 \text{ amps} \times 500 \text{ ohms}$
BACDB	0 volts	KVL sum = 0

Clearly, the voltage between points A and C (across the failed-open  $R_1$ ) must be  $-15$  volts in order to satisfy Kirchhoff's Voltage Law. The negative sign of  $V_{AC}$  tells us that point C must be at a lesser potential than point A (i.e. A is positive and C is negative).

Let us suppose now resistor  $R_1$  fails shorted. This means its two terminals are now directly connected to each other rather than being separated by 1000 ohms of electrical resistance. In other words, the two terminals of resistor  $R_1$  have been made *equipotential* by the shorted fault. By extension, this forces points A and C to be equipotential as well. Since points C and D are already equipotential to each other by virtue of the wire connecting them, points A through D must now be equipotential.

If points A through D are all equipotential, it means the right-hand terminal of resistor  $R_2$  is directly connected to the positive terminal of the 15 volt source. The left-hand terminal of  $R_2$  is already equipotential with the negative terminal of the source. This means the shorted fault at  $R_1$  has placed the full source potential across resistor  $R_2$ . An analysis using Kirchhoff's Law confirms this:

Path	Voltage gain/loss	Reason
B to A	+ 15 volts	Source voltage value
A to C	0 volts	Shorting points makes them equipotential
C to D	0 volts	These points are equipotential
D to B	-15 volts	Necessary to satisfy KVL
BACDB	0 volts	KVL sum = 0

The negative sign of  $V_{DB}$  tells us that point B must be at a lesser potential than point D (i.e. D is positive and B is negative). Calculating the amount of current in this circuit is now a simple matter of applying Ohm's Law to resistor  $R_2$ . Given a 15 volt potential across it and 500 ohms of resistance, the current is equal to 30 milliamps:

All DC circuit fault analysis reduces to these simple principles: *open* faults directly affect current by interrupting the continuity of the circuit, while *shorted* faults directly affect voltage by making points equipotential to each other that were not equipotential before. The rest is merely applying Kirchhoff's and Ohm's Laws to determine consequences of the fault throughout the circuit.

## 4.9 Bridge circuits

A *bridge* circuit is basically a pair of voltage dividers where the circuit output is taken as the difference in potential between the two dividers. Bridge circuits may be drawn in schematic form in an H-shape or in a diamond shape, although the diamond configuration is more common:

The voltage source powering the bridge circuit is called the *excitation* source. This source may be DC or AC depending on the application of the bridge circuit. The components comprising the bridge need not be resistors, either: capacitors, inductors, lengths of wire, sensing elements, and other component forms are possible, depending on the application.

Two major applications exist for bridge circuits, which will be explained in the following subsections.

### 4.9.1 Component measurement

Bridge circuits may be used to test components. In this capacity, one of the “arms” of the bridge circuit is comprised of the component under test, while at least one of the other “arms” is made adjustable. The common *Wheatstone bridge* circuit for resistance measurement is shown here:

Fixed resistors  $R_1$  and  $R_2$  are of precisely known value and high precision. Variable resistor  $R_{\text{adjust}}$  has a labeled knob allowing for a person to adjust and read its value to a high degree of precision. When the ratio of the variable resistance to the specimen resistance equals the ratio of the two fixed resistors, the sensitive galvanometer will register exactly zero volts regardless of the excitation source’s value. This is called a *balanced* condition for the bridge circuit:

$$\frac{R_1}{R_2} = \frac{R_{\text{adjust}}}{R_{\text{specimen}}}$$

When the two resistance ratios are equal, the voltage drops across the respective resistances will also be equal. Kirchhoff’s Voltage Law declares that the voltage differential between two equal and opposite voltage drops must be zero, accounting for the meter’s indication of balance.

It would not be inappropriate to relate this to the operation of a laboratory balance-beam scale, comparing a specimen of unknown mass against a set of known masses. In either case, the instrument is merely comparing an unknown quantity against an (adjustable) known quantity, indicating a condition of equality between the two:

Many legacy instruments were designed around the concept of a *self-balancing* bridge circuit, where an electric servo motor drove a potentiometer to achieve a balanced condition against the voltage produced by some process sensor. Analog electronic paper chart recorders often used this principle. Almost all pneumatic process instruments use this principle to translate the force of a sensing element into a variable air pressure.

Modern bridge circuits are mostly used in laboratories for extremely precise component measurements. Very rarely will you encounter a Wheatstone bridge circuit used in the process industries.

### 4.9.2 Sensor signal conditioning

A different application for bridge circuits is to convert the output of an electrical sensor into a voltage signal representing some physical measurement. This is by far the most popular use of bridge measurement circuits in industry, and here we see the same circuit used in an entirely different manner from that of the balanced Wheatstone bridge circuit.

Here, the bridge will be balanced only when  $R_{\text{sensor}}$  is at one particular resistance value. Unlike the Wheatstone bridge, which serves to measure a component's value when the circuit is balanced, this bridge circuit will probably spend most of its life in an unbalanced condition. The output voltage changes as a function of sensor resistance, which makes that voltage a reflection of the sensor's physical condition. In the above circuit, we see that the output voltage increases (positive on the top wire, negative on the bottom wire) as the resistance of  $R_{\text{sensor}}$  increases.

One of the most common applications for this kind of bridge circuit is in strain measurement, where the mechanical strain of an object is converted into an electrical signal. The sensor used here is a device known as a *strain gauge*: a folded wire designed to stretch and compress with the object under test, altering its electrical resistance accordingly. Strain gauges are typically quite small, as shown by this photograph:

Strain gauges are useful when bonded to metal specimens, providing a means of electrically sensing the strain (“stretching” or “compressing” of that specimen). The following bridge circuit is a typical application for a strain gauge:

When the specimen is stretched along its long axis, the metal wires in the strain gauge stretch with it, increasing their length and decreasing their cross-sectional area, both of which work to

increase the wire's electrical resistance. This stretching is microscopic in scale, but the resistance change is measurable and repeatable within the specimen's elastic limit. In the above circuit example, stretching the specimen will cause the voltmeter to read upscale (as defined by the polarity marks). Compressing the specimen along its long axis has the opposite effect, decreasing the strain gauge resistance and driving the meter downscale.

Strain gauges are used to precisely measure the strain (stretching or compressing motion) of mechanical elements. One application for strain gauges is the measurement of strain on machinery components, such as the frame components of an automobile or airplane undergoing design development testing. Another application is in the measurement of force in a device called a *load cell*. A "load cell" is comprised of one or more strain gauges bonded to the surface of a metal structure having precisely known elastic properties. This metal structure will stretch and compress very precisely with applied force, as though it were an extremely stiff spring. The strain gauges bonded to this structure measure the strain, translating applied force into electrical resistance changes.

You can see what a load cell looks like in the following photograph:

Strain gauges are not the only dynamic element applicable to bridge circuits. In fact, any resistance-based sensor may be used in a bridge circuit to translate a physical measurement into an electrical (voltage) signal. Thermistors (changing resistance with temperature) and photocells (changing resistance with light exposure) are just two alternatives to strain gauges.

It should be noted that the amount of voltage output by this bridge circuit depends both on the amount of resistance change of the sensor *and* the value of the excitation source. This dependency on source voltage value is a major difference between a sensing bridge circuit and a Wheatstone (balanced) bridge circuit. In a perfectly balanced bridge, the excitation voltage is irrelevant: the output voltage is zero no matter what source voltage value you use. In an unbalanced bridge circuit, however, source voltage value matters! For this reason, these bridge circuits are often rated in terms of how many millivolts of output they produce *per volt of excitation* per unit of physical measurement (microns of strain, newtons of stress, etc.).

An interesting feature of a sensing bridge circuit is its ability to cancel out unwanted variables. In the case of a strain gauge, for example, mechanical strain is not the only variable affecting gauge resistance. Temperature also affects gauge resistance. Since we do not wish our strain gauge to also act as a thermometer (which would make measurements very uncertain – how would we differentiate the effects of changing temperature from the effects of changing strain?), we must find some way to nullify resistance changes due solely to temperature, such that our bridge circuit will respond only to changes in strain. The solution is to creatively use a “dummy” strain gauge as another arm of the bridge:

The “dummy” gauge is attached to the specimen in such a way that it maintains the same temperature as the active strain gauge, yet experiences no strain. Thus, any *difference* in gauge resistances must be due solely to specimen strain. The differential nature of the bridge circuit naturally translates the differential resistance of the two gauges into one voltage signal representing strain.

If thermistors are used instead of strain gauges, this circuit becomes a differential temperature sensor. Differential temperature sensing circuits are used in solar heating control systems, to detect when the solar collector is hotter than the room or heat storage mass being heated.

Sensing bridge circuits may have more than one active “arm” as well. The examples you have seen so far in this section have all been *quarter-active* bridge circuits. It is possible, however, to incorporate more than one sensor into the same bridge circuit. So long as the sensors’ resistance changes are coordinated, their combined effect will be to increase the sensitivity (and often the linearity as well) of the measurement.

For example, *full-active bridge* circuits are sometimes built out of four strain gauges, where each strain gauge comprises one arm of the bridge. Two of the strain gauges must compress and the other two must stretch under the application of the same mechanical force, in order that the bridge will become unbalanced with strain:

Not only does a full-active bridge circuit provide greater sensitivity and linearity than a quarter-active bridge, but it also *naturally* provides temperature compensation without the need for “dummy” strain gauges, since the resistances of all four strain gauges will change by the same proportion if the specimen temperature changes.

## 4.10 Null-balance voltage measurement

A number of different sensors used in instrumentation generate DC voltage signals proportional to the process variable of interest. We call such sensors *potentiometric*, which literally means “voltage-measuring”. Thermocouples are one type of potentiometric sensor, used to measure temperature. Photodiodes are another, used to measure light intensity. Glass pH electrodes are yet another, used to measure the hydrogen ion activity in a liquid solution. It should be obvious that accurate voltage measurement is critical for any instrument based on a potentiometric sensor, for if our measurement of that sensor’s output voltage is not accurate, we will surely suffer inaccurate measurement of any process variable proportional to that voltage (e.g. temperature, light, pH).

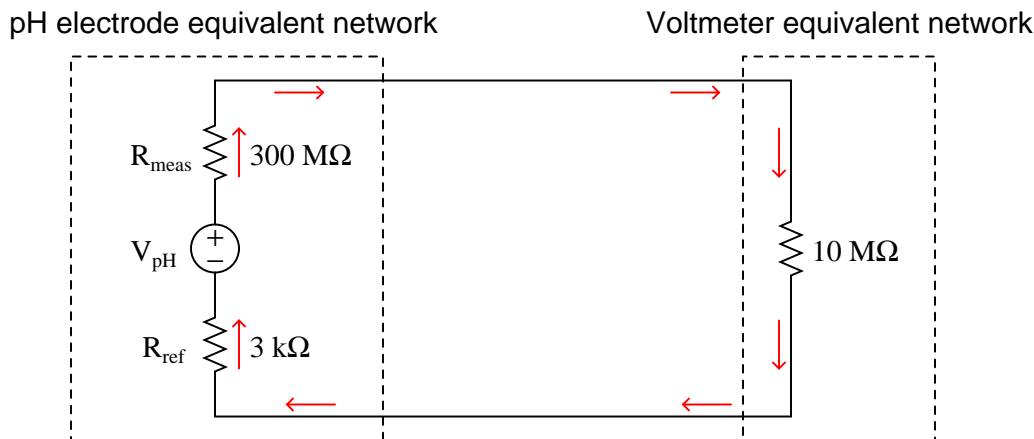

One common obstacle to accurate sensor voltage measurement is the internal resistance of the sensor itself. We will explore this concept by way of a practical example: trying to measure the voltage output by a pH electrode pair using a standard digital voltmeter. A pictorial diagram shows the basic concept, where a voltmeter is connected to a pH electrode pair immersed in a liquid solution:

Hydrogen ions within the liquid solution penetrate the round glass bulb of the measurement electrode, generating a potential difference approximately equal to 59 millivolts per pH unit of deviation from 7 pH (neutral). The reference electrode serves the simple purpose of completing the electrical circuit from the voltmeter’s terminals to both sides of the glass bulb (inside and outside).

What should be an elementary task is complicated by the fact that the glass bulb of the measurement electrode has an incredibly high electrical resistance, typically on the order of *hundreds* of mega-ohms. When connected to a common digital multimeter having an input resistance in the order of *tens* of mega-ohms, the voltmeter acts as a rather “heavy” electrical load which causes the measured voltage to be far less than what the glass electrode is actually producing.

If we sketch an equivalent electrical schematic of these components, the problem becomes more evident. Red arrows in this schematic depict the flow of electrical current (conventional notation):

Only a small fraction of the glass electrode's voltage ( $V_{pH}$ ) will actually be seen at the voltmeter's terminals due to this loading effect. We may treat the voltmeter's internal resistance of 10 MΩ as one resistance in a voltage divider network, the two probe resistances being the other two divider resistances:

$$V_{meter} = V_{pH} \left( \frac{10 \text{ M}\Omega}{300 \text{ M}\Omega + 10 \text{ M}\Omega + 3 \text{ k}\Omega} \right)$$

Supposing the pH-sensing glass bulb outputs 100 millivolts, the voltmeter in this circuit would only register a reading of 3.226 millivolts: just a *few percent* of the actual sensor's potentiometric output. While this is a rather extreme example, it should be clear to see that any potentiometric circuit of the same form will suffer some degree of measurement inaccuracy due to this effect – the only question being how much error.

Lying at the heart of this problem is the fact that voltmeters necessarily draw some electric current in the act of measuring a voltage. It is this current draw, no matter how slight, that causes a voltmeter to register something other than a perfect facsimile of the sensor's voltage signal. The solution to this problem, then, is to minimize or eliminate this current draw. In other words, we need our voltmeter to have as much internal resistance as possible (ideally, an *infinite* amount of internal resistance).

Modern field-effect transistor amplifier circuits go a long way toward addressing this problem by allowing us to manufacture voltmeters having internal resistances in the *trillions* of ohms. So long as the voltmeter's internal resistance far overshadows (i.e. “swamps”) the signal source's resistance, loading errors will be held to a minimum.

In the days before high-resistance semiconductor amplifier circuits, special voltmeters called *vacuum-tube voltmeters* (VTVMs) were used whenever voltages needed to be measured from high-resistance potentiometric sensors.

Prior to the advent of electronic vacuum tubes, though, it was impossible to mitigate the problem of voltmeter loading simply by selecting a better-quality voltmeter. Un-amplified voltmeters rely on the passage of a small current from the source under test to drive their indicating mechanisms. Without this small current drawn from the circuit, the voltmeter simply would not function at all. How then did early experimenters and electrical metrologists overcome this problem of loading?

An ingenious solution to the problem of voltmeter loading is the so-called *null-balance* method of voltage measurement. This technique added two components to the measurement circuit: a highly sensitive ammeter called a *galvanometer* and a variable DC voltage source. Using our pH measurement circuit as an example, a null-balance arrangement would look something like this:

Operation of this circuit follows these two steps:

- Adjust the variable DC voltage source until the galvanometer registers exactly zero (i.e. no current)
- Read the voltmeter to see what the pH sensor's voltage is

So long as the galvanometer registers zero (a “null” condition), there will be no electric current passing through the large resistances of the pH sensor's electrodes because the pH sensor's voltage is perfectly balanced against the variable supply's voltage. With no current passing through those high resistances, they will drop no voltage whatsoever. Thus,  $V_{pH}$  must be equal to the voltage of the variable DC source, which the voltmeter registers accurately because its current requirements are met by the variable source and not the pH sensor. The only way this measurement technique can fail in its objective is if the galvanometer is not able to precisely detect a condition of zero current. So long as the galvanometer faithfully tells us when we have reached a condition of zero current, we may measure the voltage of the pH sensor using *any* DC voltmeter regardless of its internal resistance.

Special null-balance voltmeter instruments were manufactured with precision variable voltage sources built into them, called *differential voltmeters*. One such instrument was the Fluke model 801, a gold-plated version of which is shown here in Fluke's museum of measurement:

Note the center-zero analog meter on the face of this instrument, performing the function of the sensitive galvanometer in our schematic diagram. A set of five knobs oriented vertically on the face of this instrument, each one showing one digit of a 5-digit number, adjusted the DC voltage output by the internal voltage source. When the “null” meter registered zero, it meant the voltage of the source or circuit under test was precisely equal to the voltage dialed up by these five knobs. Differential voltmeters such as the Fluke 801 used amplifier circuits to make this “null” detector ultra-sensitive, in order to achieve the most accurate condition of balance between the variable DC voltage source and the source under test possible.

## 4.11 Electromagnetism

The fundamental principle of *electromagnetism* is that an electric current will create a magnetic field at right angles to the direction of the current. If the electric current travels in a straight path, the lines of magnetic flux will form concentric circles around that path. If the electric current travels in a circular path (i.e. through a loop or coil of wire), the magnetic lines of flux will form straight lines down the center of the coil, wrapping around at the ends to form a complete loop of its own:

Magnetic field strength is directly proportional to the amount of current in the conductor (and also directly proportional to the number of “turns” in a coiled wire), such that the unit of measurement<sup>13</sup> for magnetic field strength is the *amp-turn*.

<sup>13</sup>Both in the British system of measurement *and* the SI metric system of measurement! The older metric system (called “CGS” for Centimeter-Gram-Second) had a special unit of measurement called the *Gilbert* for expressing magnetic field strength, with 1 Gilbert (Gb) equal to 0.7958 Amp-turns (At).

The directly proportional relationship between current intensity and magnetic field strength is exploited by *clamp-on ammeters*, which are able to measure electric current without the need for contact with the conductor:

The following photograph shows how particles of steel align with the circular magnetic field surrounding one of the electric cables of an electric arc welder on a job site:

Very strong magnetic fields may be generated with wire *coils*, since the magnetic fields surrounding each “turn” of wire in a coil tend to overlap constructively, supporting one another to form a stronger total field. The magnetic field from a wire coil may be so strong, in fact, that it is useful for creating an attractive force upon a ferrous<sup>14</sup> object (called an *armature*) strong enough to move mechanisms. This arrangement of a wire coil and an iron armature is called a *solenoid*<sup>15</sup>.

<sup>14</sup>The term “ferrous” simply refers to any substance containing the element *iron*. This includes steel, which is a combination of iron and carbon.

<sup>15</sup>The word “solenoid” may also be used to describe a wire coil with no armature, but the more common industrial use of the word refers to the complete arrangement of coil and movable armature.

A practical example of a solenoid is a *solenoid valve*: a mechanical valve opened and/or closed by the application of electric current through the coil:

When the coil is energized by an external source of electric current, the magnetic field attracts the movable armature, thereby actuating the valve. A spring typically returns the valve mechanism back to its original position upon de-energization of the coil.

Another very practical application of electromagnetism are *electric motors*, which use magnetic fields generated by wire coils to twist a mechanical shaft and perform useful work.

In the DC motor design, electric current creates a magnetic field in the armature coil which reacts against the magnetic fields of the permanent magnets to twist the armature about its axis. Every half-turn, the brushes break and re-make contact with the commutator bars, reversing the direction of current through the armature coil to keep it spinning in the same direction.

In the AC motor design, alternating current (continually reversing direction many times per second) creates an alternating magnetic field in a set of stationary wire coils called *stator* windings.

This alternating magnetic field causes a rotor to spin at speed proportional to the frequency of the magnetic field's reversals.

Both electric current and magnetic field lines are *vectors*, having both magnitude and direction. As we have seen already, there is a perpendicular relationship between these two vectors. This relationship may be visualized by a simple rule called the *right-hand rule*, whereby the fingers and thumb of a human right hand represent the vector orientations of current and magnetism (or vice-versa). Using the right-hand rule, digits representing current direction assume the use of *conventional flow* rather than electron flow<sup>16</sup>, while digits representing magnetism point in the direction of “North.”

To use this rule, curl the four fingers of your right hand such that they point toward the palm of that hand, and extend your right thumb so that it points perpendicularly to your curled fingers. Your right hand should look like this:

Your curled fingers will represent one set of vectors, while your thumb points in the direction of the other. Whether the fingers represent current and the thumb magnetism, or whether the fingers represent magnetism and the thumb current, is irrelevant: the rule works both ways.

---

<sup>16</sup>There is also a left-hand rule for fans of electron flow, but in this book I will default to conventional flow. For a more complete discussion on this matter, see section 4.2.1 beginning on page 301.

This flexibility makes the right-hand rule easy to apply to different situations such as these:

*Thumb represents current vector*  
*Fingers represent magnetic field vectors*

*Fingers represent current vectors*  
*Thumb represents magnetic field vector*

**Note: red arrows point in the direction of conventional current flow**

Physicists have devised a convention for clearly illustrating the directions of perpendicular vectors (arrows) without resorting to illustrations drawn in 3-dimensional perspective. The following two-dimensional illustration shows the magnetic field surrounding a straight, current-carrying wire. The magnetic field, of course, encircles the wire. This is shown by the alternating “dot” and “cross” symbols above and below the wire, representing arrow heads (circles with dots) coming “out” of the page directly at the reader, and representing arrow tails (circles with crosses) headed straight into the page away from the reader:

The same notation may be used to show the perpendicular relationship between current and magnetic flux lines for a coiled conductor. Here, the arrow “tips” and “tails” represent current (conventional flow) entering and exiting the page, while the horizontal arrow represents magnetic field direction:

Note how the individual magnetic fields surrounding each wire in the coil all have their arrows pointing to the right in the coil’s interior, and to the left at the coil’s exterior. This shows how the individual magnetic loops constructively add to generate a large magnetic field through the center of the coil, looping around back to the other end of the coil.

## 4.12 Capacitors

Any two electrical conductors separated by an insulating medium possess the characteristic called *capacitance*: the ability to store energy in the form of an electric field created by a voltage between those two conductors. Capacitance is symbolized by the capital letter  $C$  and is measured in the unit of the *Farad* (F). The relationship between capacitance, stored electric charge ( $Q$ ), and voltage ( $V$ ) is as follows:

$$Q = CV$$

For example, a capacitance having a value of 33 microfarads charged to a voltage of 5 volts would store an electric charge of 165 microcoulombs.

*Capacitors* are devices expressly designed and manufactured to possess capacitance. They are constructed of a “sandwich” of conductive plates separated by an insulating *dielectric*. Capacitors have maximum voltage ratings as well as capacitance ratings. Here are some schematic symbols for capacitors:

Although any two conductors separated from each other by an insulating medium possess capacitance, we may optimize the amount of capacitance by situating the conductors in a manner yielding more electric flux for any given amount of applied voltage. Placing the two conductors closer together (thus creating a more intense electric field between them, measured in *volts per inch*) is one way to increase capacitance. Increasing the overlapping area of the conductors (thus providing more area for parallel electric flux lines to form) is another way. Inserting a strongly dielectric (i.e. an exceptionally good insulating) material between the conductors is a third way to increase capacitance.

These three factors may be expressed in a single mathematical formula for capacitance:

$$C = \frac{\epsilon A}{d}$$

Where,

$C$  = Capacitance in Farads

$A$  = Overlapping area of conductors in square meters

$\epsilon$  = Permittivity of the dielectric substance

$d$  = Distance separating the conductors in meters

Capacitance is a non-dissipative quantity. Unlike resistance, a pure capacitance does not dissipate energy in the form of heat; rather, it stores and releases energy from and to the rest of the circuit. We may illustrate the energy-storing behavior of a capacitor by this simple voltage source, switch, and resistor circuit:

Note how the capacitor alternately functions as a source and as a load, depending on what it's connected to. When connected to a source of voltage, the capacitor absorbs (stores) energy in the form of an electric field between its plates. Current flows through the voltage source in the same direction as though it were powering a load (e.g. a resistor). When the capacitor's voltage equals the source voltage, current stops in the circuit. Flipping the switch to the "discharge" position connects the capacitor to a resistor, where it discharges its store of energy, acting as a source to the resistor's load.

Note also how the capacitor maintains the same polarity of voltage during all three steps. Since energy is stored within an *electric field* inside the capacitor, and electric fields are a function of *voltage*, the stored energy manifests itself as a voltage with an unchanging polarity. The Law of Energy Conservation – which states energy cannot spontaneously vanish or appear but must be accounted for – tells us a capacitor's voltage cannot spontaneously vanish, appear, or change polarity. In other words, *voltage is the conserved quantity in a capacitor as it transitions between acting as a source and acting as a load*. Current through a capacitor, however, switches direction depending on whether the capacitor is charging (acting as a load) or discharging (acting as a source).

Capacitance adds when capacitors are connected in parallel. It diminishes when capacitors are connected in series:

$$C_{parallel} = C_1 + C_2 + \cdots C_n \qquad C_{series} = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \cdots + \frac{1}{C_n}}$$

Recall that capacitance stores energy in the form of an electric field, as a function of the voltage applied to it. If we wish to increase capacitance by connecting multiple capacitors to each other, we need to do that in such a way that each capacitor receives the same (total) applied voltage so that each additional amount of capacitance included in the network will contribute a proportional amount of energy storage to the network. We know voltage is guaranteed to be equal only among *parallel*-connected components. If we were to connect multiple capacitors in series with one another, their individual voltages would be some fraction of the total voltage (series voltages always adding to equal the total voltage), thus diminishing the energy stored in each capacitor and similarly diminishing the total capacitance.

Another way to comprehend why capacitance increases in parallel and diminishes in series is to consider a network of capacitors as one equivalent capacitor in terms of aggregate plate area and separation distance. Examining the directions of change to the corresponding variables in the permittivity/area/distance formula for capacitance, we see how parallel-connected capacitances must add while series-connected capacitances must diminish:

The relationship between voltage and current for a capacitor is as follows:

$$I = C \frac{dV}{dt}$$

As such, capacitors oppose changes in voltage over time by passing a current. This behavior makes capacitors useful for stabilizing voltage in DC circuits. One way to think of a capacitor in a DC circuit is as a *temporary voltage source*, always “wanting” to maintain voltage across its terminals as a function of the energy stored within its electric field.

The amount of potential energy ( $E_p$ , in units of joules) stored by a capacitor may be determined by altering the voltage/current/capacitance equation to express power ( $P = IV$ ) and then applying some calculus (recall that power is defined as the time-derivative of work or energy,  $P = \frac{dW}{dt} = \frac{dE}{dt}$ ):

$$I = C \frac{dV}{dt}$$

$$P = IV = CV \frac{dV}{dt}$$

$$\frac{dE_p}{dt} = CV \frac{dV}{dt}$$

$$\frac{dE_p}{dt} dt = CV dV$$

$$\int \frac{dE_p}{dt} dt = \int CV dV$$

$$\int dE_p = C \int V dV$$

$$E_p = \frac{1}{2} CV^2$$

In an AC circuit, the amount of capacitive reactance ( $X_C$ ) offered by a capacitor is inversely proportional to both capacitance and frequency:

$$X_C = \frac{1}{2\pi fC}$$

This means an AC signal finds it “easier” to pass through a capacitor (i.e. less ohms of reactance) at higher frequencies than at lower frequencies.

### 4.13 Inductors

Any conductor possesses a characteristic called *inductance*: the ability to store energy in the form of a magnetic field created by an electric current flowing through that conductor. Inductance is symbolized by the capital letter  $L$  and is measured in the unit of the *Henry* (H).

*Inductors* are devices expressly designed and manufactured to possess inductance. They are typically constructed of a wire coil wound around a ferromagnetic<sup>17</sup> core material. Inductors have current ratings as well as inductance ratings. Due to the effect of *magnetic saturation*, inductance tends to decrease as current approaches the rated maximum value in an iron-core inductor. Here are some schematic symbols for inductors:

An inductor's inductance is related to the magnetic permeability of the core material ( $\mu$ ), the number of turns in the wire coil ( $N$ ), the cross-sectional area of the coil ( $A$ ), and the length of the coil ( $l$ ):

$$L = \frac{\mu N^2 A}{l}$$

---

<sup>17</sup>The term “ferrous” refers to any substance containing the element *iron*. Steel is one such substance, being a combination of iron and carbon.

Inductance is a non-dissipative quantity. Unlike resistance, a pure inductance does not dissipate energy in the form of heat; rather, it stores and releases energy from and to the rest of the circuit. We may illustrate the energy-storing behavior of an ideal<sup>18</sup> inductor by this simple current source, switch, and resistor circuit:

Note how the inductor alternately functions as a source and as a load, depending on what it's connected to. When connected to a source of current, the inductor absorbs (stores) energy in the form of a magnetic field within its core. Voltage is dropped across the current source in the same polarity as though it were powering a load (e.g. a resistor). When the inductor's current equals the rated current of the source, there will no longer be a voltage drop (assuming a perfect inductor with zero internal wire resistance). Flipping the switch to the "discharge" position connects the inductor to a resistor, where it discharges its store of energy, acting as a source to the resistor's load.

Note also how the inductor maintains the same direction of current. Since energy is stored within a *magnetic field* inside the inductor, and magnetic fields are a function of *current*, the stored energy manifests itself as a current with an unchanging direction. The Law of Energy Conservation – which states energy cannot spontaneously vanish or appear but must be accounted for – tells us an inductor's current cannot spontaneously vanish, appear, or change direction. In other words, *current is the conserved quantity in an inductor as it transitions between acting as a source and acting as a load*. Voltage across an inductor, however, switches polarity depending on whether the inductor is charging (acting as a load) or discharging (acting as a source).

<sup>18</sup>Unlike the charge/hold/discharge capacitor circuit, this inductor demonstration circuit would not function quite as well in real life. Real inductors contain substantial amounts of electrical resistance ( $R$ ) in addition to inductance ( $L$ ), which means real inductors have an inherent capacity to dissipate their own store of energy. If a real inductor were placed in a circuit such as this, it would not maintain its store of energy indefinitely in the switch's "neutral" position as a capacitor would. Realistically, the inductor's energy would likely dissipate in a matter of milliseconds following the switch to the "neutral" position.

Inductance adds when inductors are connected in series. It diminishes when inductors are connected in parallel:

$$L_{series} = L_1 + L_2 + \cdots L_n \qquad L_{parallel} = \frac{1}{\frac{1}{L_1} + \frac{1}{L_2} + \cdots + \frac{1}{L_n}}$$

Recall that inductance stores energy in the form of a magnetic electric field, as a function of the electric current flowing through it. If we wish to increase inductance by connecting multiple inductors to each other, we need to do that in such a way that each inductor receives the same (total) current so that each additional amount of inductance included in the network will contribute a proportional amount of energy storage to the network. We know current is guaranteed to be equal only among *series*-connected components. If we were to connect multiple inductors in parallel with one another, their individual currents would be some fraction of the total current (parallel currents always adding to equal the total current), thus diminishing the energy stored in each inductor and similarly diminishing the total inductance.

The relationship between voltage and current for an inductor is as follows:

$$V = L \frac{dI}{dt}$$

As such, inductors oppose changes in current over time by dropping a voltage. This behavior makes inductors useful for stabilizing current in DC circuits. One way to think of an inductor in a DC circuit is as a *temporary current source*, always “wanting” to maintain current through its coil as a function of the energy stored within its magnetic field.

The amount of potential energy ( $E_p$ , in units of joules) stored by an inductor may be determined by altering the voltage/current/inductance equation to express power ( $P = IV$ ) and then applying some calculus (recall that power is defined as the time-derivative of work or energy,  $P = \frac{dW}{dt} = \frac{dE}{dt}$ ):

$$V = L \frac{dI}{dt}$$

$$P = IV = LI \frac{dI}{dt}$$

$$\frac{dE_p}{dt} = LI \frac{dI}{dt}$$

$$\frac{dE_p}{dt} dt = LI dI$$

$$\int \frac{dE_p}{dt} dt = \int LI dI$$

$$\int dE_p = L \int I dI$$

$$E_p = \frac{1}{2} LI^2$$

In an AC circuit, the amount of inductive reactance ( $X_L$ ) offered by an inductor is directly proportional to both inductance and frequency:

$$X_L = 2\pi fL$$

This means an AC signal finds it “harder” to pass through an inductor (i.e. more ohms of reactance) at higher frequencies than at lower frequencies.

## Chapter 5

# AC electricity

While *direct current* (DC) refers to the flow of electrical charge carriers in a continuous direction, *alternating current* (or *AC*) refers to a periodic reversal of charge flow direction<sup>1</sup>. As a mode of transferring electrical power, AC is tremendously useful because it allows us to use *transformers* to easily and efficiently step voltage up or down at will. If an electro-physical sensor senses a physical quantity that oscillates, the electric signal it produces will oscillate (AC) as well. For both these reasons, an instrument technician needs to be aware of how AC circuits work, and how to understand them mathematically.

---

<sup>1</sup>It is also acceptable to refer to electrical voltages and/or currents that vary periodically over time even if their directions never alternate, as AC *superimposed* on DC.

## 5.1 RMS quantities

It is often useful to express the amplitude of an alternating quantity such as voltage or current in terms that are equivalent to direct current (DC). Doing so provides an “apples-to-apples” comparison between AC and DC quantities that makes comparative circuit analysis much easier.

The most popular standard of equivalence is based on *work* and *power*, and we call this the *root-mean-square* value of an AC waveform, or RMS for short. For example, an AC voltage of 120 volts “RMS” means that this AC voltage is capable of delivering the exact same amount of power (in Watts) at an electrical load as a 120 volt DC source powering the exact same load.

The problem is exactly how to calculate this “RMS” value if all we know about the AC waveform is its peak value. If we compare a sine wave and a DC “wave” side by side, it is clear that the sine wave must peak at a greater value than the constant DC level in order to be equivalent in terms of doing the same *work* in the same amount of time:

At first, it might seem like the correct approach would be to use calculus to integrate (determine the area enclosed by) the sine wave over one-half of a cycle: from 0 to  $\pi$  radians. This is close, but not fully correct. The ability of an electrical voltage to dissipate power at a resistor is not directly proportional to the magnitude of that voltage, but rather proportional to the *square* of the magnitude of that voltage! In mathematical terms, resistive power dissipation is predicted by the following equation:

$$P = \frac{V^2}{R}$$

If we double the amount of voltage applied to a resistor, the power increases four-fold. If we triple the voltage, the power goes up by a factor of nine. If we are to calculate the “RMS” equivalent value of a sine wave, we must take this nonlinearity into consideration.

First let us begin with a mathematical equivalence between the DC and AC cases. For DC, the amount of *work* done is equal to the constant power of that circuit multiplied by time. The unit of measurement for power is the *Watt*, which is defined as 1 Joule of work per second. So, multiplying the steady power rate in a DC circuit by the time we keep it powered will result in an answer of joules (total energy dissipated by the resistor):

$$\text{Work} = \left( \frac{V^2}{R} \right) t$$

Showing this equivalence by dimensional analysis:

$$[\text{Joules}] = \left( \frac{[\text{Joules}]}{[\text{s}]} \right) [\text{s}]$$

We cannot calculate the work done by the AC voltage source quite so easily, because the power dissipation varies over time as the instantaneous voltage rises and falls. Work is still the product of power and time, but we cannot simply multiply one by the other because the voltage in this case is a *function* of time ( $V(t)$ ). Instead, we must use integration to calculate the product of power and time, and sum those work quantities into a total work value.

Since we know the voltage provided by the AC source takes the form of a sine wave ( $V(t) = \sin t$  if we assume a sine wave with a peak value of 1 volt), we may write the formula for instantaneous AC power as follows:

$$\text{Power} = \frac{(V(t))^2}{R} = \frac{\sin^2 t}{R}$$

To calculate the work done by this sinusoidal voltage on the resistor, we will integrate this instantaneous power with respect to time, between the intervals of  $t = 0$  and  $t = \pi$  (one half-cycle of the sine wave):

$$\text{Work} = \int_0^\pi \frac{\sin^2 t}{R} dt$$

In order to solve for the amount of DC voltage equivalent (from the perspective of resistive power dissipation) to a one-volt AC sine wave, we will set the DC work and AC work equations equal to each other, making sure the DC side of the equation has  $\pi$  for the amount of time (being the same time interval as the AC side):

$$\left( \frac{V^2}{R} \right) \pi = \int_0^\pi \frac{\sin^2 t}{R} dt$$

Our goal is to solve for  $V$  on the left-hand side of this equation.

First, we know that  $R$  is a constant value, and so we may move it out of the integrand:

$$\left(\frac{V^2}{R}\right)\pi = \frac{1}{R} \int_0^\pi \sin^2 t \, dt$$

Multiplying both sides of the equation by  $R$  eliminates it completely. This should make intuitive sense, as our RMS equivalent value for an AC voltage is defined strictly by the ability to produce the same amount of power as the same value of DC voltage for *any* resistance value. Therefore the actual value of resistance ( $R$ ) should not matter, and it should come as no surprise that it cancels:

$$V^2\pi = \int_0^\pi \sin^2 t \, dt$$

Now, we may simplify the integrand by substituting the half-angle equivalence for the  $\sin^2 t$  function

$$V^2\pi = \int_0^\pi \frac{1 - \cos 2t}{2} \, dt$$

Factoring one-half out of the integrand and moving it outside (because it's a constant):

$$V^2\pi = \frac{1}{2} \int_0^\pi 1 - \cos 2t \, dt$$

We may write this as the difference between two integrals, treating each term in the integrand as its own integration problem:

$$V^2\pi = \frac{1}{2} \left( \int_0^\pi 1 \, dt - \int_0^\pi \cos 2t \, dt \right)$$

The second integral may be solved simply by using substitution, with  $u = 2t$ ,  $du = 2 \, dt$ , and  $dt = \frac{du}{2}$ :

$$V^2\pi = \frac{1}{2} \left( \int_0^\pi 1 \, dt - \int_0^\pi \frac{\cos u}{2} \, du \right)$$

Moving the one-half outside the second integrand:

$$V^2\pi = \frac{1}{2} \left( \int_0^\pi 1 \, dt - \frac{1}{2} \int_0^\pi \cos u \, du \right)$$

Finally we are at a point where we may perform the integrations:

$$V^2\pi = \frac{1}{2} \left( \int_0^\pi 1 \, dt - \frac{1}{2} \int_0^\pi \cos u \, du \right)$$

$$V^2\pi = \frac{1}{2} \left( [t]_0^\pi - \frac{1}{2} [\sin 2t]_0^\pi \right)$$

$$V^2\pi = \frac{1}{2} \left( [\pi - 0] - \frac{1}{2} [\sin 2\pi - \sin 0] \right)$$

$$V^2\pi = \frac{1}{2} \left( [\pi - 0] - \frac{1}{2} [0 - 0] \right)$$

$$V^2\pi = \frac{1}{2}(\pi - 0)$$

$$V^2\pi = \frac{1}{2}\pi$$

We can see that  $\pi$  cancels out of both sides:

$$V^2 = \frac{1}{2}$$

Taking the square root of both sides, we arrive at our final answer for the equivalent DC voltage value:

$$V = \frac{1}{\sqrt{2}}$$

So, for a sinusoidal voltage with a peak value of 1 volt, the DC equivalent or “RMS” voltage value would be  $\frac{1}{\sqrt{2}}$  volts, or approximately 0.707 volts. In other words, a sinusoidal voltage of 1 volt peak will produce just as much power dissipation at a resistor as a steady DC voltage of 0.7071 volts applied to that same resistor. Therefore, this 1 volt peak sine wave may be properly called a 0.7071 volt RMS sine wave, or a 0.7071 volt “DC equivalent” sine wave.

This factor for sinusoidal voltages is quite useful in electrical power system calculations, where the wave-shape of the voltage is nearly always sinusoidal (or very close). In your home, for example, the voltage available at any wall receptacle is 120 volts RMS, which translates to 169.7 volts peak.

Electricians and electronics technicians often memorize the  $\frac{1}{\sqrt{2}}$  conversion factor without realizing it only applies to *sinusoidal* voltage and current waveforms. If we are dealing with a non-sinusoidal wave-shape, the conversion factor between peak and RMS *will* be different! The mathematical procedure for obtaining the conversion factor will be identical, though: integrate the wave-shape’s function (squared) over an interval sufficiently long to capture the essence of the shape, and set that equal to  $V^2$  times that same interval span.

## 5.2 Resistance, Reactance, and Impedance

*Resistance* ( $R$ ) is the dissipative opposition to an electric current, analogous to friction encountered by a moving object. In any example of electrical resistance, the electrical energy is converted into some other form of energy that cannot (or does not) return back to the circuit. Resistance may take the form of an actual resistor, in which case the electrical energy is converted into heat. Resistance may also take the form of an electric motor, an electric light, or an electrochemical cell where the electrical energy is converted into mechanical work, photons, or enables an endothermic chemical reaction, respectively.

*Reactance* ( $X$ ) is the opposition to an electric current resulting from energy storage and release between certain components and the rest of the circuit, analogous to inertia of a moving object. Capacitors and inductors are classic examples of “reactive” electrical components, behaving either as electrical loads or as electrical sources depending on whether the applied electrical signal is increasing or decreasing in intensity at that instant in time. When a purely reactive component is subjected to a sinusoidal signal, it will spend exactly half the time behaving as a load (absorbing energy from the circuit) and half the time behaving as a source (returning energy to the circuit). Thus, a purely reactive component neither contributes nor dissipates any net energy in the circuit, but merely exchanges<sup>2</sup> energy back and forth. Even though the fundamental mechanism of reactance (energy storage and release) is different from the fundamental mechanism of resistance (energy conversion and dissipation), reactance and resistance are both expressed in the same unit of measurement: the ohm ( $\Omega$ ).

*Impedance* ( $Z$ ) is the combined total opposition to an electric current, usually some combination of electrical resistance (energy dissipation) and electrical reactance (energy storage and release). It is also expressed in the unit of the ohm. In order to represent how much of a particular impedance is due to resistance and how much is due to reactance, the value of an impedance may be expressed as a *complex number* with a “real” part (representing resistance) and an “imaginary” part (representing reactance). This concept will be explored in much more detail later in this chapter.

The amount of electrical reactance offered by a capacitor or an inductor depends on the *frequency* of the applied signal. The faster the rate at which an AC signal oscillates back and forth, the more a reactive component tends to react to that signal. The formulae for capacitive reactance ( $X_C$ ) and inductive reactance ( $X_L$ ) are as follows:

$$X_C = \frac{1}{2\pi fC} \qquad X_L = 2\pi fL$$

Just as conductance ( $G$ ) is the reciprocal of resistance ( $1/R$ ), a quantity called *susceptance* ( $B$ ) is the reciprocal of reactance ( $1/X$ ). Susceptance is useful when analyzing parallel-connected reactive components while reactance is useful for analyzing series-connected reactive components, in much the same way that conductance and resistance are useful when analyzing parallel-connected and series-connected resistors, respectively.

Impedance ( $Z$ ) also has a reciprocal counterpart known as *admittance* ( $Y$ ).

---

<sup>2</sup>Charles Proteus Steinmetz, in his book *Theoretical Elements of Electrical Engineering*, refers to the voltage and current values of a reactive component being “wattless” in honor of the fact that they transfer zero net power to or from the circuit (page 41). The voltage and current values of resistive components, by contrast, constitute real power dissipated in the circuit.

### 5.3 Series and parallel circuits

Impedance in a series circuit is the orthogonal sum of resistance and reactance:

$$Z = \sqrt{R^2 + (X_L^2 - X_C^2)}$$

*Equivalent* series and parallel circuits are circuits that have the exact same total impedance as one another, one with series-connected resistance and reactance, and the other with parallel-connected resistance and reactance. The resistance and reactance values of equivalent series and parallel circuits may be expressed in terms of those circuits' total impedance:

If the total impedance of one circuit (either series or parallel) is known, the component values of the equivalent circuit may be found by algebraically manipulating these equations and solving for the desired  $R$  and  $X$  values:

$$Z^2 = R_{series}R_{parallel}$$

$$Z^2 = X_{series}X_{parallel}$$

### 5.4 Transformers

The *transformer* is one of the most important components in all of AC circuitry. Principally used to “step” between different values of AC voltage and current in power systems, transformers find uses in many other types of circuits including electronic amplifiers (for impedance matching) and even sensor circuits (sensing physical position).

### 5.4.1 Basic principles

Before exploring the operation of a transformer, it is useful to review the operation of a simple inductor, which is nothing more than a coil of wire usually wrapped around a ferromagnetic core material:

If we apply an alternating (AC) voltage to this coil, it will generate an alternating magnetic field in the core. Just how much magnetic flux ( $\phi$ ) will develop in the core depends on how much voltage we apply to the coil. The fundamental relationship between voltage and magnetic flux for any conductive coil is given by Faraday's Law of Electromagnetic Induction<sup>3</sup>:

$$V = N \frac{d\phi}{dt}$$

Where,

$V$  = Voltage applied to the coil or induced by the coil (volts)

$N$  = Number of turns of wire

$\frac{d\phi}{dt}$  = Rate of change of magnetic flux (Webers per second)

---

<sup>3</sup>At first it may seem strange to apply Faraday's Law here, because this formula is typically used to describe the amount of voltage *produced* by a coil of wire exposed to a changing magnetic field, not the amount of magnetic field produced by an applied voltage. However, the two are closely related because the inductor must produce a voltage drop in equilibrium with the applied voltage just like any other component, in accordance with Kirchhoff's Voltage Law. In a simple circuit such as this where the voltage source directly connects to the inductor (barring any resistive losses in the connecting wires), the coil's induced voltage drop must exactly equal the source's applied voltage at all points in time, and so Faraday's Law works just as well to describe the source's applied voltage as it does to describe the coil's induced voltage. This is the principle of *self-induction*.

If the applied voltage is sinusoidal (i.e. shaped like a sine wave), then the magnetic flux magnitude will trace a cosine wave over time. We may demonstrate this mathematically by substituting  $\sin \omega t$  (the sine of some frequency  $\omega$  at any particular point in time  $t$ ) for  $V$  in Faraday's equation and integrating:

$$V = N \frac{d\phi}{dt}$$

$$\sin \omega t = N \frac{d\phi}{dt}$$

$$\sin \omega t \, dt = N d\phi$$

$$\int \sin \omega t \, dt = \int N d\phi$$

$$\int \sin \omega t \, dt = N \int d\phi$$

$$-\frac{1}{\omega} \cos \omega t + \phi_0 = N\phi$$

$$\phi = -\frac{1}{N\omega} \cos \omega t + \phi_0$$

Thus, the amount of magnetic flux ( $\phi$ ) in the core at any point in time  $t$  is proportional to the cosine of the frequency-time function  $\omega t$  plus any residual magnetism ( $\phi_0$ ) the core happened to start out with before any voltage was applied to the coil.

The amount of current drawn by this inductor depends on the reluctance of the core's magnetic "circuit" and the number of turns in the coil ( $N$ ). The less reluctance offered by the magnetic path, the less current will be necessary to generate the requisite magnetic field to balance the applied voltage. If we were to take two perfect inductors (i.e. lacking wire resistance) – one with a heavy ferrous core and one with a light ferrous core (or even an air core) – and apply the same AC voltage to them, they would both generate the exact same strength of alternating magnetic field, but the inductor with the lesser core would draw more current from the source in doing so. In other words, the latter inductor would exhibit less reactance (i.e. fewer ohms) to oppose current.

Things get interesting if we wrap a second coil of wire around the same core as the first. For the sake of analysis we will label voltage polarities at one of the peaks of the AC source:

At that moment in time when the top terminal of the source is positive and the bottom terminal is negative, we see that the first coil drops the same voltage (due to self-induction), and that the second coil drops the same voltage as well (due to *mutual* induction). The polarity of both coils' voltages are identical because they are wrapped in the same direction around the core and they both experience the same magnetic flux ( $\phi$ ). When we examine the directions of current through each coil, however, we see they are opposite one another: the left-hand coil acts as a *load* (drawing energy from the AC voltage source) while the right-hand coil acts as a *source* (providing energy to the resistive load).

What we have created here is a true *transformer*: an electromagnetic component transferring energy from electric form to magnetic form and back again to electric form. The AC voltage source is able to energize the resistive load without direct conductive connection between the two, since the magnetic flux serves as the energy “link” between the two circuits.

Transformers are typically drawn as a set of coils sharing a common core. The coil connected to an electrical source is called the *primary*, while the coil connected to an electrical load is called the *secondary*. If the core is ferromagnetic, it is shown as a set of parallel lines between the coils:

*A simple transformer circuit*

### 5.4.2 Loading effects

We may explore transformer behavior by observing the effects of powering one with a constant<sup>4</sup>-voltage AC source and varying the load resistance:

Observe how voltage at both coils is unaffected by load, and similarly how the magnetic flux remains unchanged under different load conditions. The secondary coil acts like a voltage source to the resistive load, reflecting the nature of the primary coil's source behavior. The magnetic flux amplitude is unaffected by secondary loading in order to satisfy Kirchhoff's Voltage Law and Faraday's Law at the primary coil: the coil's voltage drop must be equal and opposite to the source's

<sup>4</sup>In this context, "constant" means an alternating voltage with a consistent peak value, not "constant" in the sense that a DC source is constant at all points in time.

applied voltage, and so the magnetic flux must alternate at the same rates and reach the same peaks so long as the primary source voltage does the same.

Continuing our exploration of transformer behavior, we will now power one with a constant<sup>5</sup>-current AC source and vary the load resistance:

Observe how current now is the unaffected quantity, while voltage and magnetic flux are load-dependent. The secondary coil now acts like a current source to the resistive load, reflecting the nature of the primary coil's source behavior. As load resistance varies, the secondary coil's voltage varies proportionately, which in turn demands a commensurate change in magnetic flux.

<sup>5</sup>In this context, "constant" means an alternating voltage with a consistent peak value, not "constant" in the sense that a DC source is constant at all points in time.

### 5.4.3 Step ratios

Transformers are principally used to step between different levels of voltage and current. This is achieved by building the transformer with primary and secondary coils having different numbers of turns. Since both coils share the same magnetic flux, the number of turns will be proportionate to how much voltage is developed at each coil. We may prove this mathematically with Faraday's Law, using  $\frac{d\phi}{dt}$  as the quantity shared between primary and secondary coils:

$$V_P = N_P \frac{d\phi}{dt} \qquad V_S = N_S \frac{d\phi}{dt}$$

$$\frac{V_P}{N_P} = \frac{d\phi}{dt} \qquad \frac{V_S}{N_S} = \frac{d\phi}{dt}$$

$$\frac{V_P}{N_P} = \frac{V_S}{N_S}$$

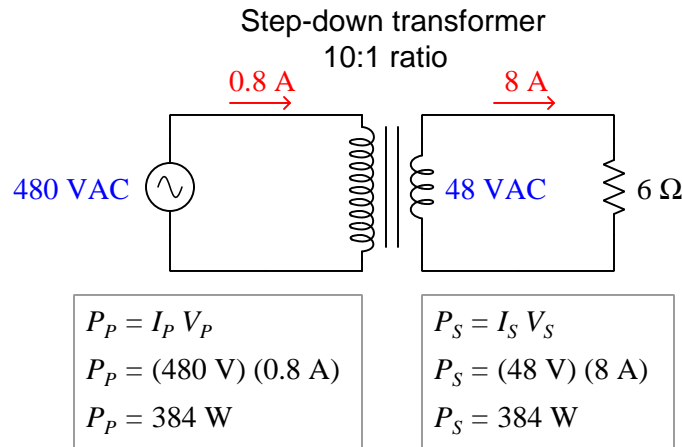

$$\frac{V_P}{V_S} = \frac{N_P}{N_S}$$

That is to say, the ratio of primary to secondary voltage is the same as the ratio of primary to secondary turns. We may exploit this principle to build transformers delivering the same amount of power to two different load resistances from the same power source, the only difference being the number of turns in the secondary coil:

Whichever way a transformer steps voltage from primary to secondary, it must step current the other way.

Here are some quantitative examples, assuming lossless transformers:

Note how primary and secondary powers are always equal to each other for any given transformer arrangement. Real transformers suffer some internal<sup>6</sup> power loss, and as such will exhibit secondary power levels slightly less than primary, but assuming equality provides an easy way to check our voltage and current ratio calculations.

<sup>6</sup>These power losses take the form of *core losses* due to magnetic hysteresis in the ferrous core material, and *winding losses* due to electrical resistance in the wire coils. Core losses may be minimized by reducing magnetic flux density ( $H$ ), which requires a core with a larger cross-section to disperse the flux ( $\phi$ ) over a wider area. Winding losses may be minimized by increasing wire gauge (i.e. thicker wire coils). In either case, these modifications make for a bulkier and more expensive transformer.

### 5.4.4 Transformer impedance

An ideal transformer is completely lossless, conveying electrical power from a connected source (on the primary side) to a connected load (on the secondary side) with 100 percent efficiency. Ideal transformers also pose no limit on the amount of power they may couple from primary to secondary winding – in other words, an ideal transformer imposes no inherent limit to power throughput.

Real transformers, however, are not lossless and in fact do act as current-limiting devices. The mechanisms for this include magnetic hysteresis losses, wire resistance, leakage inductance<sup>7</sup>, etc.

Consider a thought experiment where we short-circuit the secondary winding of an ideal transformer, which is being powered by an AC voltage source of infinite power capacity (i.e. the source has zero impedance). How much current would pass through the shorted secondary circuit?

This question has no realistic answer. If the 480 VAC source has no current limitation (i.e. is capable of supplying infinite current to a shorted load) and the transformer likewise presents no limit at all to current, the shorted secondary circuit would also experience infinite current, at least in principle.

It should be rather obvious that this scenario cannot exist in the real world. Even with a source of infinite current capability, any realistic transformer would act to impede current delivered to a short-circuit on the secondary side. The question of “how much current would pass through the short-circuit” is really a question of how much *impedance* the transformer offers.

<sup>7</sup>Transformers, of course, utilize the principle of electromagnetic induction to generate a voltage at the secondary winding which may power a load. Ideally, 100 percent of the magnetic flux generated by the energized primary winding “links” or “couples” to the secondary winding. However, imperfections in the windings, core material, etc. conspire to prevent every bit of magnetic flux from coupling with the secondary winding, and so any magnetic flux from the primary winding that *doesn't* transfer power to the secondary winding simply absorbs and releases energy like a plain inductor. This is called “leakage” inductance because the flux in question has found a path to “leak” around the secondary winding. Leakage inductance may be modeled in a transformer as a separate series-connected inductance connected to the primary winding. Like any inductance, it presents a reactance equal to  $X_L = 2\pi fL$ , and in a transformer serves to impede primary current.

Let us consider a different thought experiment, this time using a real transformer with a short-circuited secondary winding, powered by a variable AC voltage source:

Imagine gradually increasing the source voltage until the secondary circuit ammeter registers a current equal to the transformer's full-load rating. For an ideal transformer (perfect power coupling), this would happen at some very small amount of voltage applied to the primary winding. Due to the imperfections and losses of real transformers, though, full secondary current will be obtained at a primary voltage equal to some small percentage of the normal (rated) primary voltage. Suppose, for example, our hypothetical transformer with a primary winding rating of 480 VAC outputs full secondary current through a short-circuit at an applied source voltage of only 22 volts. 22 volts is 4.58% of 480 volts, and so we would say this transformer has a measured impedance of 4.58 percent<sup>8</sup>.

Although a short-circuited secondary winding scenario may seem contrived, it actually is quite relevant to real-world conditions. In electrical power systems we are often concerned with the maximum amount of current which will flow during *fault* conditions. If two power conductors directly touch each other, or if a low-resistance arc develops between them through the air, the effect is very nearly a perfect short-circuit. This means transformer impedance will be the dominant factor in limiting fault current: the more impedance a transformer has, the less fault current will manifest during shorted conditions.

One way to apply the impedance percentage value for a power transformer to a fault scenario is to use it as a multiplying factor for secondary current. For example, if a power transformer has a maximum rated secondary current of 180 amps and an impedance rating of 3.3%, the available secondary current into a bolted<sup>9</sup> fault will be:

$$\frac{180 \text{ A}}{3.3\%} = 5454.5 \text{ A}$$

Bolted-fault current calculations are very useful when predicting the amount of energy released in an *arc blast* incident, which is what happens when an electric arc develops between two closely-spaced conductors in a high-power electric power system. The arc behaves as an extremely low-resistance

<sup>8</sup>Although it is possible to express transformer impedance in the more familiar unit of *Ohms* ( $\Omega$ ), percentage is greatly preferred for the simple reason that it applies identically to the primary and secondary sides of the transformer. Expressing transformer impedance in ohms would require a different value depending on whether the primary side or secondary side were being considered.

<sup>9</sup>The rather colorful term “bolted” refers to a short-circuit fault consisting of a large copper bus-bar physically attached to the transformer's secondary terminal using bolts. In other words, a “bolted” fault is as close to a perfect short-circuit as you can get.

connection between the conductors, resulting in very large current values with correspondingly high arc temperatures.

Transformer impedance is also useful for calculating the degree to which the output voltage of a power transformer will “sag” below its ideal value when powering a load. Suppose we had a power transformer with a 5:1 turns ratio, designed to receive 120 VAC at its primary winding and output 24 VAC. Under no-load conditions the transformer’s internal impedance will be of no effect, and the transformer will output 24 VAC exactly. However, when a load is connected to the secondary terminals and current begins to flow to power this load, the transformer’s internal impedance will result in the secondary voltage decreasing by a small amount. For example, if this transformer happens to have an impedance of 5.5%, it means the secondary (output) voltage will sag 5.5% below 24 VAC at full load, assuming the primary voltage is maintained at the standard 120 VAC level. 5.5% of 24 volts is 1.32 volts, and so this transformer’s secondary voltage will “sag” from 24 volts down to 22.68 volts (i.e. 1.32 volts less than 24 volts) as load current increases from zero to its full rated value.

## 5.5 Phasors

*Phasors* are to AC circuit quantities as *polarity* is to DC circuit quantities: a way to express the “directions” of voltage and current waveforms. As such, it is difficult to analyze AC circuits in depth without using this form of mathematical expression. Phasors are based on the concept of *complex numbers*: combinations of “real” and “imaginary” quantities. The purpose of this section is to explore how complex numbers relate to sinusoidal waveforms, and show some of the mathematical symmetry and beauty of this approach.

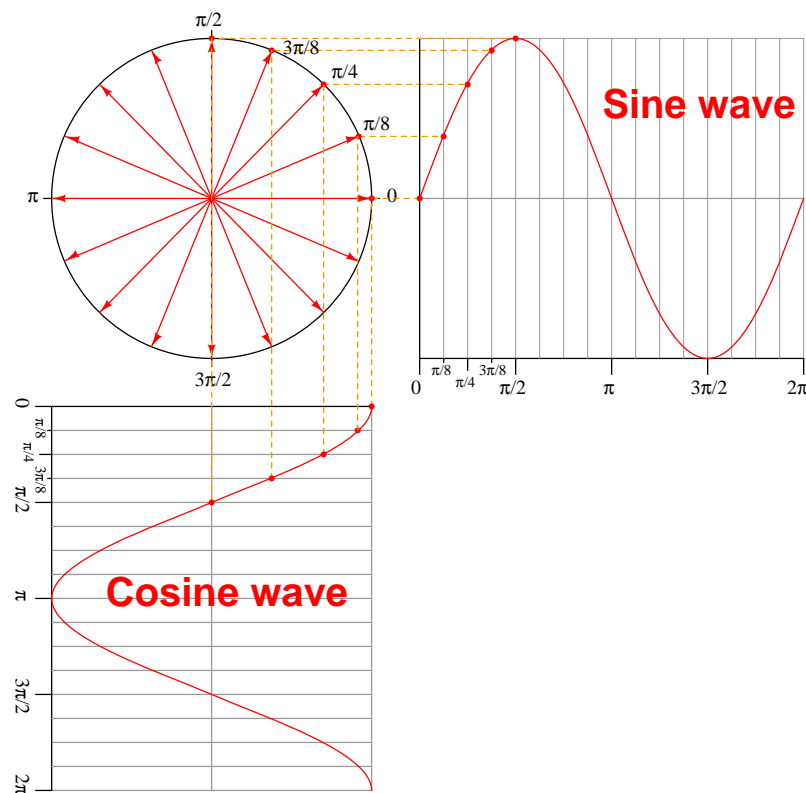

Since waveforms are not limited to alternating current electrical circuits, phasors have applications reaching far beyond the scope of this chapter.

### 5.5.1 Circles, sine waves, and cosine waves

Something every beginning trigonometry student learns (or *should* learn) is how sine and cosine waves may be derived from a circle. First, sketch a circle, then sketch a set of radius vectors from the circle's center to the circle's perimeter at regular angle intervals. Mark each point of intersection between a vector and the circle's perimeter with a dot and label each with the vector angle. Sketch rectangular graphs to the right and below the circle, with regularly-spaced divisions. Label those divisions with the same angles as the vectors and then sketch dashed “projection” lines from each vector tip to the respective divisions on the rectangular graphs, marking each intersection with a dot. Connect the dots with curves to reveal sinusoidal waveshapes.

The following illustration shows the dots and projection lines for the first five vectors (angles 0 through  $\frac{\pi}{2}$  radians<sup>10</sup>) only. As you can see, the circle's vertical projection forms a *sine* wave, while the circle's horizontal projection forms a *cosine* wave:

<sup>10</sup>A full circle contains 360 degrees, which is equal to  $2\pi$  radians. One “radian” is defined as the angle encompassing an arc-segment of a circle's circumference equal in length to its radius, hence the name “radian”. Since the circumference of a circle is  $2\pi$  times as long as its radius, there are  $2\pi$  radians' worth of rotation in a circle. Thus, while the “degree” is an arbitrary unit of angle measurement, the “radian” is a more natural unit of measurement because it is defined by the circle's own radius.

The Swiss mathematician Leonhard Euler (1707-1783) developed a symbolic equivalence between polar (circular) plots, sine waves, and cosine waves by plotting the circle on a *complex plane* where the vertical axis is an “imaginary”<sup>11</sup> number line and the horizontal axis is a “real” number line. *Euler’s Relation* expresses the vertical (imaginary) and horizontal (real) projections of an imaginary exponential function as a complex (real + imaginary) trigonometric function:

$$e^{j\theta} = \cos \theta + j \sin \theta$$

Where,

$e$  = Euler’s number (approximately equal to 2.718281828)

$\theta$  = Angle of vector, in radians

$\cos \theta$  = Horizontal projection of a unit vector (along a real number line) at angle  $\theta$

$j$  = Imaginary “operator” equal to  $\sqrt{-1}$ , represented by  $i$  or  $j$

$j \sin \theta$  = Vertical projection of a unit vector (along an imaginary number line) at angle  $\theta$

To illustrate, we will apply Euler’s relation to a unit<sup>12</sup> vector having an angular displacement of  $\frac{3\pi}{8}$  radians:

<sup>11</sup>The definition of an imaginary number is the square root of a negative quantity.  $\sqrt{-1}$  is the simplest case, and is symbolized by mathematicians as  $i$  and by electrical engineers as  $j$ .

<sup>12</sup>The term “unit vector” simply refers to a vector with a length of 1 (“unity”).

This mathematical translation from circles to sinusoidal waves finds practical application in AC electrical systems, because the rotating vector directly relates to the rotating magnetic field of an AC generator while the sinusoidal function directly relates to the voltage generated by the field's motion. The principle of an AC generator is that a magnet rotates on a shaft past stationary coils of wire. When these wire coils experience the changing magnetic field produced by the rotating magnet, a sinusoidal voltage is induced:

If we mark the shaft of this simple two-pole generator such that an angle of zero is defined as the position where the stator coils develop maximum positive voltage ( $V_0$ ), the AC voltage waveform will follow the cosine function as shown above. If we were to add another set of stationary (“stator”) coils to the generator’s frame perpendicular to this set, that second set of coils would generate an AC voltage following the *sine* function. As it is, there is no second set of stator coils, and so this sine-function voltage is purely an imaginary quantity whereas the cosine-function voltage is the only “real” electricity output by the generator.

The canonical form of Euler’s Relation assumes a circle with a radius of 1. In order to realistically represent the output voltage of a generator, we may include a multiplying coefficient in Euler’s Relation representing the function’s peak value:

$$Ae^{j\theta} = A \cos \theta + jA \sin \theta$$

In the case of the generator shown above, the  $A$  coefficient is the peak<sup>13</sup> voltage ( $V_0$ ) output by the stator coils at the precise moment in time when the shaft angle is zero. In other words, the exponential term ( $e^{j\theta}$ ) tells us which way the vector points while the coefficient ( $A$ ) tells us how long the vector is.

<sup>13</sup>Although  $A$  truly should represent a waveform’s peak value, and  $\theta$  should be expressed in units of radians to be mathematically correct, it is more common in electrical engineering to express  $A$  in RMS (root-mean-square) units and  $\theta$  in degrees. For example, a 120 volt RMS sine wave voltage at a phase angle of 30 degrees will be written by an engineer as  $120e^{j30}$  even though the true phase angle of this voltage is  $\frac{\pi}{6}$  radians and the actual peak value is 169.7 volts.

In electrical studies it is commonplace to use various “shorthand” notations for vectors. An instantaneous quantity (e.g. voltage or current at some moment in time) described simply in terms of real and imaginary values is called *rectangular form*, for example  $0.3827 + j0.9239$  volts. An instantaneous quantity described simply in terms of vector angle and length is called *polar form*, for example 1 volt  $\angle 67.5^\circ$ . Euler’s Relation is the mathematical link connecting rectangular and polar forms.

	<b>Polar</b>	<b>Rectangular</b>
<b>Shorthand notation</b>	$A\angle\theta$	$x + jy$
<b>Full notation</b>	$Ae^{j\theta}$	$A\cos\theta + jA\sin\theta$

All of these vectors described by the imaginary exponential function  $e^{j\theta}$  are of a special kind – vectors inhabiting a space defined by one real axis and one imaginary axis (the so-called *complex plane*). In order to avoid confusing this special quantity with real vectors used to represent quantities in actual space where every axis is real, we use the term *phasor* instead. From this point on in the book, I will use the term “phasor” to describe complex quantities as represented in Euler’s Relation, and “vector” to describe any other quantity possessing both a magnitude and a direction.

Euler's Relation may also be used to describe the behavior of the rotating generator shaft and its corresponding AC voltage output as a function of *time*. Instead of specifying a shaft position (angle  $\theta$ ) we now specify a point in time ( $t$ ) and an angular velocity (rotational speed) represented by the lower-case Greek letter "omega" ( $\omega$ ). Since angular velocity is customarily given in units of radians per second, and time is customarily specified in seconds, the product of those two will be an angle in radians ( $\omega t = \theta$ ). Substituting  $\omega t$  for  $\theta$  in Euler's Relation gives us a function describing the state of the generator's output voltage in terms of time:

$$Ae^{j\omega t} = A \cos \omega t + jA \sin \omega t$$

Where,

$A$  = Peak amplitude of generator voltage, in volts

$e$  = Euler's number (approximately equal to 2.718281828)

$\omega$  = Angular velocity, in radians per second

$t$  = Time, in seconds

$\cos \omega t$  = Horizontal projection of phasor (along a real number line) at time  $t$

$j$  = Imaginary "operator" equal to  $\sqrt{-1}$ , represented by  $i$  or  $j$

$j \sin \omega t$  = Vertical projection of phasor (along an imaginary number line) at time  $t$

With just a little bit of imagination we may visualize both the exponential and complex sides of Euler's Relation in physical form. The exponential ( $e^{j\omega t}$ ) is a phasor rotating counter-clockwise about a central point over time. The complex ( $\cos \omega t + j \sin \omega t$ ) is a pair of cosine and sine waves oscillating along an axis of time. Both of these manifestations may be joined into one visual image if you imagine a corkscrew where the centerline of the corkscrew is the time axis, and the evolution of this function over time follows the curve of the corkscrew down its length. Viewed from one end (looking along the centerline axis), the path appears to be a circle, just as a rotating phasor traces a circle with its tip. Viewed perpendicular to that axis, the path appears to trace a sinusoid, just as the sine or cosine function goes up and down as it progresses from left to right on a rectangular graph. A compression-type coil spring serves just as well as a corkscrew for a visual aid: viewed from the end the spring looks like a circle, but viewed from the side it looks like a sine wave.

To view a flip-book animation of this three-dimensional visualization, turn to Appendix [A.3](#) beginning on page [2865](#).

### 5.5.2 Phasor expressions of phase shifts

As previously discussed, Euler's Relation provides a mathematical tool to express AC circuit quantities such as voltage, which change over time and therefore are more challenging to represent than the static quantities found in DC circuits. At its core, Euler's Relation expresses the mathematical equivalence between an imaginary exponential function ( $e$  raised to some imaginary power) and a complex number (the sum of a real number and an imaginary number):

$$e^{j\theta} = \cos \theta + j \sin \theta$$

If we wish to represent AC quantities having magnitudes other than 1, we may modify Euler's Relation to include a multiplying coefficient specifying the function's peak value:

$$Ae^{j\theta} = A(\cos \theta + j \sin \theta) = A \cos \theta + jA \sin \theta$$

Phasor notation proves extremely useful to compare or combine AC quantities at the same frequency that are out-of-phase with each other. Consider the following example, showing two AC voltage waveforms of equal magnitude (5 volts peak) that are a constant 60 degrees ( $\frac{\pi}{3}$  radians) out of step with each other:

Recalling that the assumed direction of rotation for phasors is counter-clockwise, we see here that phasor  $B$  leads phasor  $A$  (i.e. phasor  $B$  is further counter-clockwise than phasor  $A$ ). This is

also evident from the rectangular graph<sup>14</sup>, where we see sinusoid *A* lags behind sinusoid *B* by  $\frac{\pi}{3}$  radians. If we were to connect a dual-channel oscilloscope to these two voltage sources, we would see the same phase shift on its display.

Suppose we wished to calculate the amount of voltage *between* points B and A, sensing the *difference* in potential between these two AC voltage sources. Phasor notation makes this calculation rather easy to do, since all it entails is calculating the distance between the two phasor tips. We will designate this new measurement  $V_{BA}$  representing the potential at point B with reference to point A<sup>15</sup>:

Simply sketching a new phasor stretching between the tips of phasors B and A yields a graphical solution for  $V_{BA}$ . The length of phasor  $V_{BA}$  represents the magnitude of that voltage, while its angle from horizontal represents the phase shift of that voltage (compared to phasor A at  $0^\circ$ ).

<sup>14</sup>The fact that this graph shows the vertical (imaginary) projections of both phasors rather than the horizontal (real) projections is irrelevant to phase shift. Either way, the voltage waveform of source B will still lead the voltage waveform of source A by  $60^\circ$ .

<sup>15</sup>One way to think of this is to imagine an AC voltage-measuring instrument having red and black test leads just like a regular voltmeter. To measure  $V_{BA}$  you would connect the red test lead to the first point (B) and the black test lead to the second point (A).

If we wished to plot the sine wave represented by this new phasor, all we would have to do is move the  $V_{BA}$  phasor until its tail rested at the center of the circular graph (being careful to preserve its angle), then project its tip to the rectangular graph and plot the resulting wave through the new phasor's complete rotation:

We see clearly now how phasor  $V_{BA}$  is phase-shifted  $120^\circ$  ahead of (leading) phasor A, and  $60^\circ$  ahead of (leading) phasor B, possessing the same magnitude as both A and B. We may express each of these voltages in polar form:

$$V_A = 5 \text{ volts } \angle 0^\circ$$

$$V_B = 5 \text{ volts } \angle 60^\circ$$

$$V_{BA} = 5 \text{ volts } \angle 120^\circ$$

We may mathematically derive this result by subtracting  $V_A$  from  $V_B$  to arrive at  $V_{BA}$ :

$$V_{BA} = V_B - V_A$$

$$(5 \text{ volts } \angle 60^\circ) - (5 \text{ volts } \angle 0^\circ) = 5 \text{ volts } \angle 120^\circ$$

When using phasors to describe differential voltages (i.e. voltages between two non-grounded points), it is important to specify which point is the reference. Suppose, for example, we took this same two-source system where each source has a peak voltage of 5 volts with reference to ground, but we connected our voltage-measuring instrument backwards from before such that the black (reference) lead touches point B and the red (measurement) lead touches point A (sensing  $V_{AB}$  instead of  $V_{BA}$ ). Our new phasor  $V_{AB}$  must then be sketched with its tail (reference) at point B and its tip (measurement) at point A:

The dashed-line phasor is the same angle as the solid-line phasor reaching from point B to point A, just moved so that its tail rests at the circle's center in order to plot its vertical projection on the rectangular graph to the right of the circle. As you can see, the new phasor  $V_{AB}$  is  $180^\circ$  shifted from the old phasor  $V_{BA}$ . This makes sense, as a reversal of the test leads on our voltage-sensing instrument must reverse the polarity of that voltage at every point in time.

We may mathematically derive this result by subtracting  $V_B$  from  $V_A$  to arrive at  $V_{AB}$ :

$$V_{AB} = V_A - V_B$$

$$(5 \text{ volts } \angle 0^\circ) - (5 \text{ volts } \angle 60^\circ) = 5 \text{ volts } \angle -60^\circ$$

Thus, the new phasor  $V_{AB}$  actually *lags* behind both  $V_A$  (by 60 degrees) and  $V_B$  (by 120 degrees). If the voltage-sensing instrument is nothing more than a voltmeter, there will be no difference in its reading of  $V_{BA}$  versus  $V_{AB}$ : in both cases it will simply register 5 volts AC peak. However, if the voltage-sensing instrument is an oscilloscope with its sweep triggered by one of the other voltage signals, this difference in phase will be clearly evident.

It is important to remind ourselves that voltage and current phasors, like the AC waveforms they represent, are actually in constant motion. Just as the generator shaft in an actual AC power system spins, the phasor representing that generator's voltage and the phasor representing that generator's current must also spin. The only way a phasor possessing a *fixed* angle makes any sense in the context of an AC circuit is if that phasor's angle represents a relative shift compared to some other phasor at the same frequency<sup>16</sup>. Here, we see Euler's Relation written in fixed-angle and rotating-angle forms:

<b>Fixed-angle phasor</b>	$Ae^{j\theta} = A \cos \theta + jA \sin \theta$
<b>Rotating phasor</b>	$Ae^{j\omega t} = A \cos \omega t + jA \sin \omega t$

This concept can be very confusing, representing voltage and current phasors as possessing fixed angles when in reality they are continuously spinning at the system's frequency. In order to make better sense of this idea, we will explore an analysis of the same two-source AC system using a special instrument designed just for the purpose.

---

<sup>16</sup>The necessity of a shared frequency is easily understood if one considers a case of two sine waves at different frequencies: their respective phasors would spin at different speeds. Given two phasors spinning at different speeds, the angle separating those two phasors would be constantly changing. It is only when two phasors spin around at precisely the same speed that we can sensibly talk about there being a fixed angular displacement between them. Fortunately this is the usual case in AC circuit analysis, where all voltages and currents share the same frequency.

Imagine building a small synchronous electric motor with an arrow-shaped magnetic rotor. We will wind the stator coils and magnetize the rotor such that the arrow points toward the  $0^\circ$  mark whenever the red lead is positive and the black lead is negative (connected to a DC test source). When connected to an AC source, this “phasometer” will spin in sync<sup>17</sup> with the AC generator powering the circuit, the rotating arrow keeping pace with the generator’s shaft<sup>18</sup>. The intent of this arrow is to serve as a mechanical analogue of an electrical phasor, pointing in the same direction as the phasor points for any sinusoidal voltage or current signal connected to the phasometer:

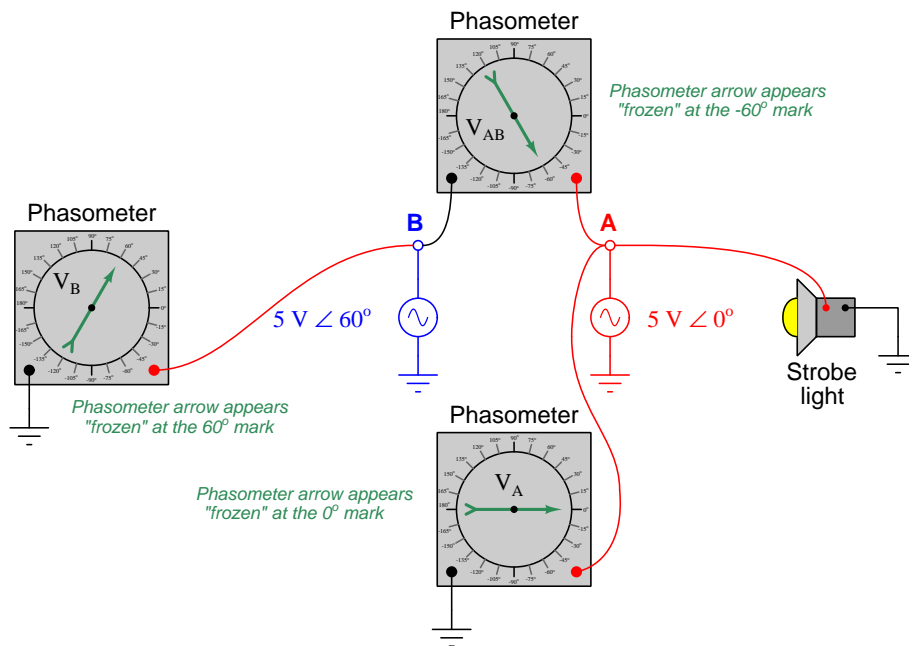

For a system frequency of 60 Hz as is standard for AC power systems in North America, the rotational speed of our phasometer’s rotor will be 3600 revolutions per minute – too fast for the rotating arrow to be anything but a blur of motion to an unaided human eye. Therefore, we will need to add one more component to the phasometer to make it practical: a *strobe light* connected to an AC voltage in the system to act as a synchronizing pulse. This strobe light will emit a flash of light just once per cycle of the AC waveform, and always at the same point in time (angle) within every cycle. Just as a strobe light (also called a “stroboscope”) makes a moving machine part<sup>19</sup> appear to “freeze” in time, this strobe light will visually “freeze” the arrow so we will be able to read its position with our eyes.

<sup>17</sup>An important detail is that our phasometer must always spin counter-clockwise in order to maintain proper phasor convention. We can ensure this will happen by including a pair of *shading coils* (small copper rings wrapped around one corner of each magnetic pole) in the stator structure. For a more detailed discussion of shading coils, refer to the section on AC induction motors (10.4.1) starting on page 726.

<sup>18</sup>This, of course, assumes the generator powering the system is also a two-pole machine like the phasometer. If the generator has more poles, the shaft speed will not match the phasometer’s rotor speed even though the phasometer will still faithfully represent the generator’s *cosine wave* rotation.

<sup>19</sup>Automobile mechanics may be familiar with a tool called a *timing light*, consisting of a strobe light connected to the engine in such a way that the light flashes every time the #1 cylinder spark plug fires. By viewing the marks etched into the engine’s crankshaft with this strobe light, the mechanic is able to check the ignition timing of the engine.

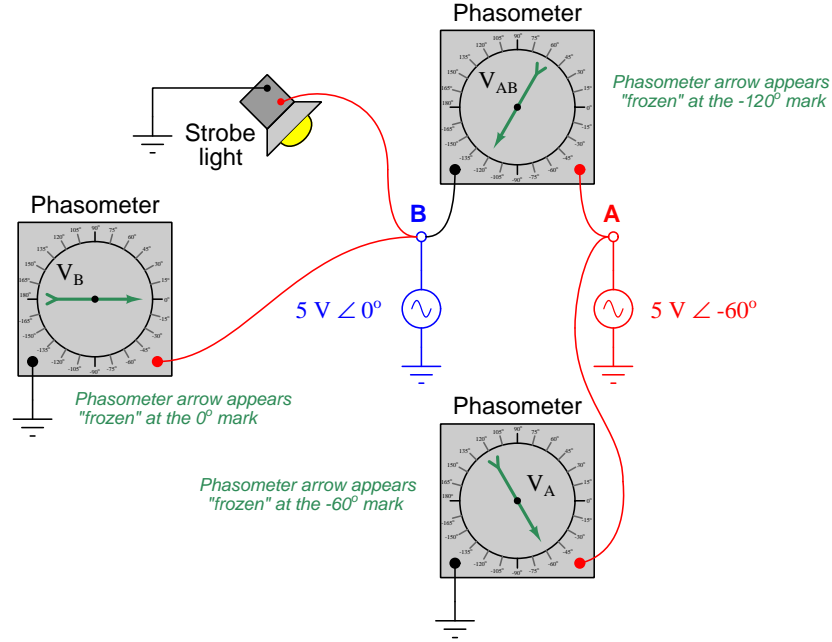

Returning to our two-source AC system, we may perform a “thought experiment” to see what multiple phasometers would register if connected to various points in the system, using a single strobe light connected to source A (pulsing briefly every time its sensed voltage reaches the positive peak). Imagine this one strobe light is bright enough to clearly illuminate the faces of all phasometers simultaneously, visually “freezing” their arrows at the exact same point in every cycle:

The phasometer connected to source A must register  $0^\circ$  because the strobe light flashes whenever source A hits its positive peak (at  $0^\circ$  on its cosine waveform), and the positive peak of a waveform is the precise point at which the phasometer arrow is designed to orient itself toward the  $0^\circ$  mark. The phasometer connected to source B will register  $60^\circ$  because that source is 60 degrees ahead of (leading) source A, having passed its positive peak already and now headed downward toward zero volts at the point in time when the strobe flashes. The upper phasometer registers  $-60^\circ$  at that same time because the voltage it senses at point A with respect to point B is lagging behind source A by that much, the  $V_{AB}$  cosine wave heading toward its positive peak.

If we were to substitute a constant illumination source for the strobe light, we would see all three phasometers' arrows spinning counter-clockwise, revealing the true dynamic nature of the voltage phasors over time. Remember that these phasors are all *continuously moving* quantities, because the voltages they represent are sinusoidal functions of time. Only when we use a strobe light keyed to source A's positive peak do we see fixed-angle readings of  $V_A = 0^\circ$ ,  $V_B = 60^\circ$ , and  $V_{AB} = -60^\circ$ .

You may wonder what might happen if we keep the three phasometers connected to the same points, but change the strobe light's reference point. The answer to this question is that the new reference source voltage will now be our zero-degree definition, with every phasor's angle changing to match this new reference. We may see this effect here, using the same two sources and three phasometers, but moving the strobe light from source A to source B:

Having the strobe light keyed to source B makes it flash 60 degrees earlier than it did when it was keyed to source A, which in turn “freezes” the arrows on the faces of all three phasometers  $-60^\circ$  from where they used to be when source A was the time-reference. The following table compares the phasometer readings with both strobe light reference points:

Strobe reference	$V_A$	$V_B$	$V_{AB}$
Source A	$0^\circ$	$60^\circ$	$-60^\circ$
Source B	$-60^\circ$	$0^\circ$	$-120^\circ$

It is even possible to imagine connecting the strobe light to a special electronic timing circuit pulsing the light at 60 Hz (the AC system's frequency), synchronized to an atomic clock so as to keep ultra-accurate time. Such an arrangement would permit phasor angle measurements based on an absolute time reference (i.e. the atomic clock) rather than a relative time reference (i.e. one of the AC voltage sources). So long as the two AC sources maintained the same frequency and phase shift, the three phasometers would still be displaced  $60^\circ$  from each other, although it would only be by blind luck that any of them would point toward  $0^\circ$  (i.e. that any one voltage would happen to be precisely in-phase with the electronic timer circuit's 60 Hz pulse).

Interestingly, this technique of measuring AC power system phasors against an absolute time reference is a real practice and not just a textbook thought experiment. The electrical power industry refers to this as a *synchrophasor* measurement. Special instruments called *Phasor Measurement Units* or *PMUs* connect to various points within the power system to acquire real-time voltage and current measurements, each PMU also connected to a GPS (Global Positioning System) radio receiver to obtain an absolute time reference with sub-microsecond uncertainty. Each PMU uses the ultra-precise time signal from the GPS receiver to synchronize a “standard” cosine wave at the power system frequency such that this reference waveform is at its positive peak ( $0^\circ$ ) at the top of every second in time.

Synchrophasor technology makes it possible to perform simultaneous comparisons of phasor angles throughout a power system, which is useful for such tasks as analyzing frequency stability in a power grid or detecting “islanding” conditions where tripped circuit breakers segment a power grid and allow distributed generators to begin drifting out of sync with each other.

### 5.5.3 Phasor expressions of impedance

The ultimate purpose of phasors is to simplify AC circuit analysis, so this is what we will explore now. Consider the problem of defining electrical opposition to current in an AC circuit. In DC (direct-current) circuits, resistance ( $R$ ) is defined by Ohm's Law as being the ratio between voltage ( $V$ ) and current ( $I$ ):

$$R = \frac{V}{I}$$

There are some electrical components, though, which do not obey Ohm's Law. *Capacitors* and *inductors* are two outstanding examples. The fundamental reason why these two components do not follow Ohm's Law is because they do not dissipate energy like resistances do. Rather than dissipate energy (in the form of heat and/or light), capacitors and inductors *store* and *release* energy from and to the circuit in which they are connected. The contrast between resistors and these components is remarkably similar to the contrast between *friction* and *inertia* in mechanical systems. Whether pushing a flat-bottom box across a floor or pushing a heavy wheeled cart across a floor, work is required to get the object moving. However, the flat-bottom box will immediately stop when you stop pushing it due to the energy loss inherent to friction, while the wheeled cart will continue to coast because it has kinetic energy stored in it. When a resistor disconnected from an electrical source, both voltage and current immediately cease. Capacitors and inductors, however, may store a "charge" of energy when disconnected from a source (capacitors retaining voltage and inductors retaining current).

The relationships between voltage and current for capacitors ( $C$ ) and inductors ( $L$ ) are as follows:

$$I = C \frac{dV}{dt} \qquad V = L \frac{dI}{dt}$$

Expressed verbally, capacitors pass electric current proportional to how quickly the voltage across them *changes* over time. Conversely, inductors produce a voltage drop proportional to how quickly current through them *changes* over time. The symmetry here is beautiful: capacitors, which store energy in an electric field that is proportional to the applied voltage, oppose changes in voltage. Inductors, which store energy in a magnetic field that is proportional to applied current, oppose changes in current. The manner in which a capacitor or an inductor reacts to changes imposed upon it is a direct consequence of the *Law of Energy Conservation*: since energy can neither appear from nothing nor simply vanish, an *exchange* of energy must take place in order to alter the amount of energy stored within a capacitor or an inductor. The rate at which a capacitor's voltage may change is directly related to the rate at which electric charge (current) enters or exits the capacitor. The rate at which an inductor's current may change is directly related to the amount of electromotive force (voltage) impressed across the inductor.

When either type of component is placed in an AC circuit and subjected to oscillating signals, it will pass a finite amount of alternating current. Even though the mechanism of a capacitor's or inductor's opposition to current (called *reactance*) is fundamentally different from that of a resistor (called *resistance*), just like inertia differs in its fundamental nature from friction, it is still convenient to express the amount of electrical opposition in a common unit of measurement: the *ohm* ( $\Omega$ ). To do this, we will have to figure out a way to take the above equations and manipulate them to express each component's behavior as a ratio of  $\frac{V}{I}$ .

Let's start with capacitors. Suppose we impress a 1 volt peak AC voltage across a capacitor, representing that voltage as the exponential  $e^{j\omega t}$  where  $\omega$  is the angular velocity (frequency) of the signal and  $t$  is time:

We will begin by writing the current/voltage relationship for a capacitor, along with the imaginary exponential function for the impressed voltage:

$$I = C \frac{dV}{dt} \quad V = e^{j\omega t}$$

Substituting  $e^{j\omega t}$  for  $V$  in the capacitor formula, we see we must apply the calculus function of *differentiation* to the time-based voltage function:

$$I = C \frac{d}{dt} (e^{j\omega t})$$

Fortunately for us, differentiation is a very simple<sup>20</sup> process with exponential functions:

$$I = j\omega C e^{j\omega t}$$

Remember that our goal here is to solve for the ratio of voltage over current for a capacitor. So far all we have is a function for current ( $I$ ) in terms of time ( $t$ ). If we take this function for current and divide that into our original function for voltage, however, we see that ratio simplify quite nicely:

$$\begin{aligned} \frac{V}{I} &= \frac{e^{j\omega t}}{j\omega C e^{j\omega t}} \\ \frac{V}{I} &= \frac{1}{j\omega C} = -j \frac{1}{\omega C} \end{aligned}$$

Note<sup>21</sup> how the exponential term completely drops out of the equation, leaving us with a clean ratio strictly in terms of capacitance ( $C$ ), angular velocity ( $\omega$ ), and of course  $j$ .

<sup>20</sup>Recall from calculus that the derivative of the function  $e^x$  with respect to  $x$  is simply  $e^x$ . That is, the value of an exponential function's slope is equal to the value of the original exponential function! If the exponent contains any constants multiplied by the independent variable, those constants become multiplying coefficients after differentiation. Thus, the derivative of  $e^{kx}$  with respect to  $x$  is simply  $ke^{kx}$ . Likewise, the derivative of  $e^{j\omega t}$  with respect to  $t$  is  $j\omega e^{j\omega t}$ .

<sup>21</sup>Note also one of the interesting properties of the imaginary operator:  $\frac{1}{j} = -j$ . The proof of this is quite simple:  $\frac{1}{j} = \frac{j}{j^2} = \frac{j}{-1} = -j$ .

Next, we will apply this same analysis to inductors. Recall that voltage across an inductor and current through an inductor are related as follows:

$$V = L \frac{dI}{dt}$$

If we describe the AC current<sup>22</sup> through an inductor using the familiar imaginary exponential expression  $I = e^{j\omega t}$  (representing a 1 amp peak AC current at frequency  $\omega$ ), we may substitute this expression for current into the inductor's characteristic equation to solve for the inductor's voltage as a function of time:

$$V = L \frac{dI}{dt} \quad I = e^{j\omega t}$$

$$V = L \frac{d}{dt} (e^{j\omega t})$$

$$V = j\omega L e^{j\omega t}$$

Now that we have the inductor's voltage expressed as a time-based function, we may include the original current function and calculate the ratio of  $V$  over  $I$ :

$$\frac{V}{I} = \frac{j\omega L e^{j\omega t}}{e^{j\omega t}}$$

$$\frac{V}{I} = j\omega L$$

In summary, we may express the impedance (voltage-to-current ratio) of capacitors and inductors by the following equations:

$$Z_L = j\omega L \quad Z_C = \frac{1}{j\omega C} \text{ or } -j\frac{1}{\omega C}$$

Most students familiar with electronics from an algebraic perspective (rather than calculus) find the expressions  $X_L = 2\pi fL$  and  $X_C = \frac{1}{2\pi fC}$  easier to grasp. Just remember that angular velocity ( $\omega$ ) is really “shorthand” notation for  $2\pi f$ , so these familiar expressions may be alternatively written as  $X_L = \omega L$  and  $X_C = \frac{1}{\omega C}$ .

---

<sup>22</sup>Note that we begin this analysis with an exponential expression of the *current* waveform rather than the *voltage* waveform as we did at the beginning of the capacitor analysis. It is possible to begin with voltage as a function of time and use calculus to determine current through the inductor, but unfortunately that would necessitate *integration* rather than *differentiation*. Differentiation is a simpler process, which is why this approach was chosen. If  $e^{j\omega t} = L \frac{dI}{dt}$  then  $e^{j\omega t} dt = L dI$ . Integrating both sides of the equation yields  $\int e^{j\omega t} dt = L \int dI$ . Solving for  $I$  yields  $\frac{e^{j\omega t}}{j\omega L}$  plus a constant of integration representing a DC component of current that may or may not be zero depending on where the impressed voltage sinusoid begins in time. Solving for  $Z = V/I$  finally gives the result we're looking for:  $j\omega L$ . Ugly, no?

Furthermore, recall that reactance ( $X$ ) is a *scalar quantity*, having magnitude but no direction. Impedance ( $Z$ ), on the other hand, possesses both magnitude *and* direction (phase), which is why the imaginary operator  $j$  must appear in the impedance expressions to make them complete. The impedance offered by pure inductors and capacitors alike are nothing more than their reactance values ( $X$ ) scaled along the imaginary ( $j$ ) axis (phase-shifted  $90^\circ$ ).

These different representations of opposition to electrical current are shown here for components exhibiting 50 ohms, resistances ( $R$ ) and reactances ( $X$ ) shown as scalar quantities near the component symbols, and impedances ( $Z$ ) as phasor quantities on the complex plane:

### 5.5.4 Phasor arithmetic

Another detail of phasor math that is both beautiful and practical is the famous expression of Euler's Relation, the one all math teachers love because it directly relates several fundamental constants in one elegant equation (remember that  $i$  and  $j$  mean the same thing, just different notational conventions for different disciplines):

$$e^{i\pi} = -1$$

This equation is actually a special case of Euler's Relation, relating imaginary exponents of  $e$  to sine and cosine functions:

$$e^{i\theta} = \cos \theta + i \sin \theta$$

What this equation says is really quite amazing: if we raise  $e$  to an imaginary exponent of some angle ( $\theta$ ), it is equivalent to the real cosine of that same angle plus the imaginary sine of that same angle. Thus, Euler's Relation expresses an equivalence between exponential ( $e^x$ ) and trigonometric ( $\sin x$ ,  $\cos x$ ) functions. Specifically, the angle  $\theta$  describes which way a phasor points on a complex plane, the real and imaginary coordinates of a unit phasor's<sup>23</sup> tip being equal to the cosine and sine values for that angle, respectively.

If we set the angle  $\theta$  to a value equal to  $\pi$ , we see the general form of Euler's relation transform into  $e^{i\pi} = -1$ :

$$e^{i\theta} = \cos \theta + i \sin \theta$$

$$e^{i\pi} = \cos \pi + i \sin \pi$$

$$e^{i\pi} = -1 + i0$$

$$e^{i\pi} = -1$$

---

<sup>23</sup>A "unit" phasor is one having a length of 1.

After seeing this, the natural question to ask is what happens when we set  $\theta$  equal to other, common angles such as  $0$ ,  $\frac{\pi}{2}$ , or  $\frac{3\pi}{2}$  (also known as  $-\frac{\pi}{2}$ )? The following examples explore these angles:

Angle ( $\theta$ )	Exponential	Trigonometric	Rectangular	Polar
$0 \text{ radians} = 0^\circ$	$e^{i0}$	$\cos 0 + i \sin 0$	$1 + i0 = 1$	$1 \angle 0^\circ$
$\pi/2 \text{ radians} = 90^\circ$	$e^{i\pi/2}$	$\cos 90^\circ + i \sin 90^\circ$	$0 + i1 = i$	$1 \angle 90^\circ$
$\pi \text{ radians} = 180^\circ$	$e^{i\pi}$	$\cos 180^\circ + i \sin 180^\circ$	$-1 + i0 = -1$	$1 \angle 180^\circ$
$-\pi/2 \text{ radians} = -90^\circ$	$e^{i-\pi/2}$	$\cos -90^\circ + i \sin -90^\circ$	$0 - i1 = -i$	$1 \angle -90^\circ$

We may show all the equivalences on the complex plane, as unit phasors:

As we saw previously, the amount of opposition to electrical current offered by reactive components (i.e. inductors and capacitors) – a quantity known as *impedance* – may be expressed as functions of  $j$  and  $\omega$ :

$$Z_L = j\omega L$$

$$Z_C = -j \frac{1}{\omega C}$$

Knowing that  $j$  is equal to  $e^{j\pi/2}$  and that  $-j = e^{-j\pi/2}$ , we may re-write the above expressions for inductive and capacitive impedance as functions of an angle:

$$Z_L = \omega L e^{j\pi/2}$$

$$Z_C = \frac{1}{\omega C} e^{-j\pi/2}$$

Using polar notation as a “shorthand” for the exponential term, the impedances for inductors and capacitors are seen to have fixed angles<sup>24</sup>:

$$Z_L = \omega L e^{j\pi/2} = \omega L \angle \frac{\pi}{2} \text{ radians} = \omega L \angle 90^\circ$$

$$Z_C = \frac{1}{\omega C} e^{-j\pi/2} = \frac{1}{\omega C} \angle -\frac{\pi}{2} \text{ radians} = \frac{1}{\omega C} \angle -90^\circ$$

Beginning electronics students will likely find the following expressions of inductive and capacitive impedance more familiar,  $2\pi f$  being synonymous with  $\omega$ :

$$Z_L = (2\pi f L) \angle 90^\circ$$

$$Z_C = \left( \frac{1}{2\pi f C} \right) \angle -90^\circ$$

---

<sup>24</sup>The fact that these impedance phasor quantities have fixed angles in AC circuits where the voltage and current phasors are in constant motion is not a contradiction. Since impedance represents the relationship *between* voltage and current for a component ( $Z = V/I$ ), this fixed angle represents a relative phase shift between voltage and current. In other words, the fixed angle of an impedance phasor tells us the voltage and current waveforms will always remain that much out of step with each other despite the fact that the voltage and current phasors themselves are continuously rotating at the system frequency ( $\omega$ ).

The beauty of complex numbers in AC circuits is that they make AC circuit analysis equivalent to DC circuit analysis. If we represent every voltage and every current and every impedance quantity in an AC circuit as a complex number, all the same<sup>25</sup> laws and rules we know from DC circuit analysis will apply to the AC circuit. This means we need to be able to add, subtract, multiply, and divide complex numbers in order to apply Ohm's Law and Kirchhoff's Laws to AC circuits.

The basic rules of phasor arithmetic are listed here, with phasors having magnitudes of  $A$  and  $B$ , and angles of  $M$  and  $N$ , respectively:

$$Ae^{jM} + Be^{jN} = (A \cos M + B \cos N) + j(A \sin M + B \sin N)$$

$$Ae^{jM} - Be^{jN} = (A \cos M - B \cos N) + j(A \sin M - B \sin N)$$

$$Ae^{jM} \times Be^{jN} = AB e^{j(M+N)}$$

$$Ae^{jM} \div Be^{jN} = \frac{A}{B} [e^{j(M-N)}]$$

Addition and subtraction lend themselves readily to the *rectangular* form of phasor expression, where the real (cosine) and imaginary (sine) terms simply add or subtract. Multiplication and division lend themselves readily to the *polar* form of phasor expression, where magnitudes multiply or divide and angles add or subtract.

To summarize:

- Voltages and currents in AC circuits may be mathematically represented as *phasors*, which are imaginary exponential functions ( $e$  raised to imaginary powers)
- Phasors are typically written in either rectangular form (real + imaginary) or polar form (magnitude @ angle)
- Ohm's Law and Kirchhoff's Laws still apply in AC circuits as long as all quantities are in phasor notation
- Addition is best done in rectangular form: *add the real parts, and add the imaginary parts*
- Subtraction is best done in rectangular form: *subtract the real parts, and subtract the imaginary parts*
- Multiplication is best done in polar form: *multiply the magnitudes, and add the angles*
- Division is best done in polar form: *divide the magnitudes, and subtract the angles*

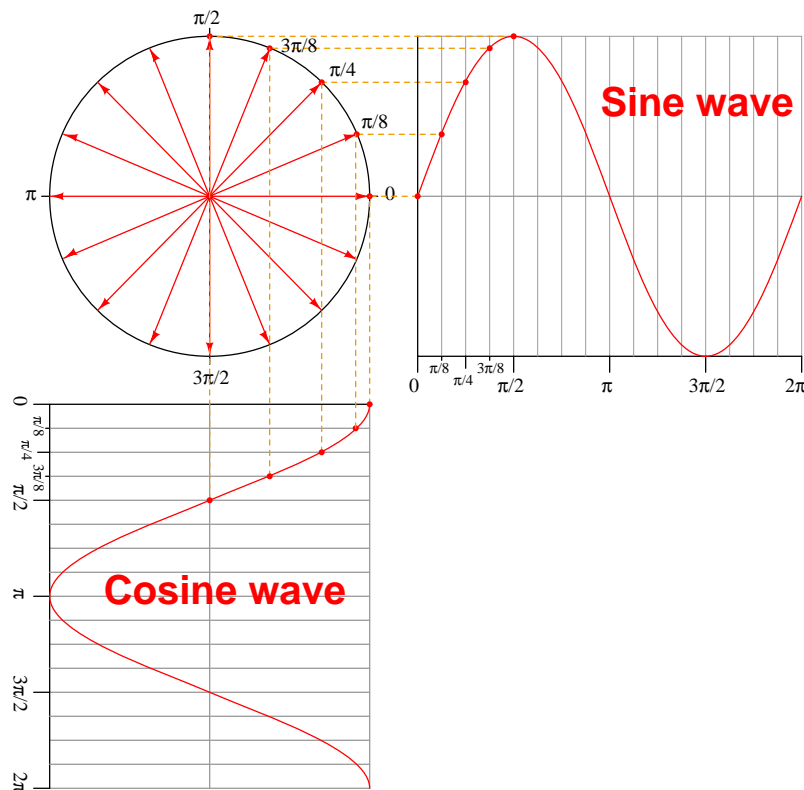

It should be noted that many electronic calculators possess the ability to perform all these arithmetic functions in complex-number form. If you have access to such a calculator, it will *greatly* simplify any AC circuit analysis performed with complex numbers!

---

<sup>25</sup>With one notable exception: Joule's Law ( $P = IV$ ,  $P = V^2/Z$ ,  $P = I^2Z$ ) for calculating power does not apply in AC circuits because *power* is not a phasor quantity like voltage and current.

### 5.5.5 Phasors and circuit measurements

A *phasor* is a special form of vector (a quantity possessing both magnitude and direction) lying in a complex plane. Phasors relate circular motion to simple harmonic (sinusoidal) motion as shown in the following diagram. In AC electrical circuits, this is the relationship between an electromechanical generator's shaft angle<sup>26</sup> and the sinusoidal voltage it outputs:

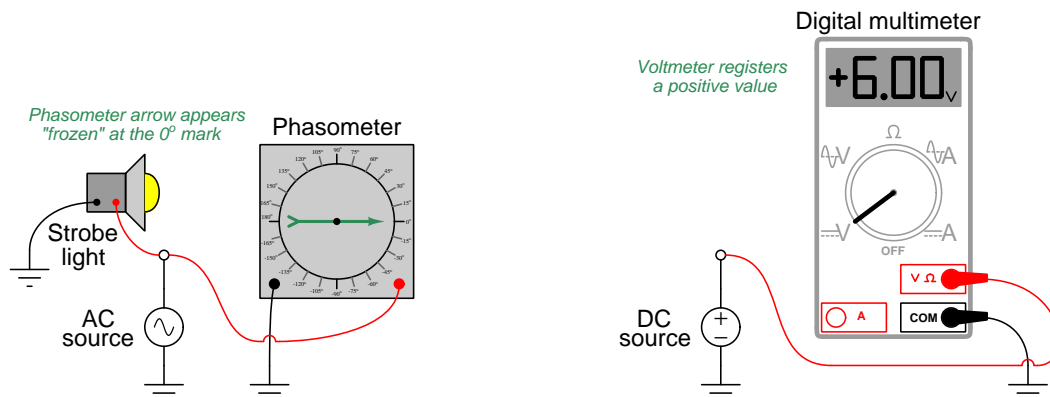

In any operating AC electrical circuit the phasors, just like the sinusoidal waveforms, never rest: they are in continuous motion. When we speak of a phasor as having a fixed angle, what we really mean is that the phasor is either leading or lagging with respect to some other “reference” phasor in the system, not that the phasor itself is stationary. We explored this concept previously, where we used an invented instrument called a “phasometer” to represent the direction of a measured phasor in real time, and then used a strobe light connected to some point in the same system to visually “freeze” the phasometer arrows so we could see which direction each arrow was pointed at the moment in time when our chosen reference waveform reached its positive peak value (i.e.  $0^\circ$  on a cosine wave). The fixed angle represented by each “strobed” phasometer arrow therefore represented the amount of *relative phase shift* between each respective phasor and the reference phasor.

<sup>26</sup> Assuming a two-pole generator, where each period of the sinusoidal waveform corresponds exactly to one revolution of the generator shaft.

*Phasor angles* are to AC quantities what *arithmetic signs* are to DC quantities. If a phasometer registers an angle of 180 degrees, it means the red lead is fully negative and the black lead is fully positive at the moment in time when the strobe light flashes. If a DC voltmeter registers a negative voltage, it means the red lead is negative and the black lead is positive at the time of the measurement:

Reversing each instrument's test lead connections to the circuit will reverse its indication: flipping red and black leads on the phasometer will cause its indication to be 0° instead of 180°; flipping red and black leads on the DC voltmeter will cause it to register a positive voltage instead of a negative voltage:

From these demonstrations we can see that the indication given by a measuring instrument depends as much on how that instrument connects to the circuit as it does on the circuit quantity itself. Likewise, a voltage or current value obtained in the course of analyzing a circuit depends as much on how we label the assumed polarity (or direction) of that quantity on the diagram as it does on the quantity itself.

To illustrate the importance of signs, assumed directions, and phasor angles in circuit analysis, we will consider two multi-source circuits: one DC and one AC. In each case we will explore how Kirchhoff's Current Law relates to currents at a similar node in each circuit, relating the current arrow directions to signs and phasor angles.

First, the DC circuit:

With each 1 k $\Omega$  resistor powered by its own 5 volt DC source, the current through each of these resistors will be 5 milliamps in accordance with Ohm's Law ( $I = \frac{V}{R}$ ). The direction of each current is easily predicted by examining the polarity of each source (with current represented in conventional flow notation *exiting* the positive terminal and *entering* the negative terminal of each source) and/or by examining the polarity of the voltage drop across each resistor (with conventional-flow current *entering* the positive terminal and *exiting* the negative terminal of each load). At the node below the two resistors, these two currents join together to form a larger (10 milliamp) current headed toward ground. Kirchhoff's Current Law declares that the sum of all currents entering a node must equal the sum of all currents exiting that node. Here we see this is true: 5 milliamps in plus 5 milliamps in equals 10 milliamps out.

The voltage polarities and current directions in this DC circuit are all clear and unambiguous because the quantities are *constant* over time. Each power supply acts as an energy source and each resistor acts as an energy load, all the time. Our application of Kirchhoff's Current Law at the node is so obvious it hardly requires explanation: the flow of charge carriers (current) in and out must be in equilibrium.

With AC, however, we know things will not be so simple. AC circuit quantities are not constant over time as they are in DC circuits. Reactive (energy-storing) components such as inductors and capacitors play alternating roles as sources and loads, complicating their analysis. The good news in all of this is that phasor representations of voltage and current allow us to apply all the same fundamental principles we are accustomed to using for DC circuits (e.g. Ohm's Law, Kirchhoff's Voltage Law, Kirchhoff's Current Law, network theorems, etc.). In order to use these principles to calculate AC quantities, though, we must be careful in how we label them in the circuit.

Here, we will modify the circuit to include two AC power sources (phase-shifted by  $60^\circ$ ), and replace one of the  $1\text{ k}\Omega$  resistors with a capacitor exhibiting  $1\text{ k}\Omega$  of reactance at the system frequency. As in the DC circuit, each of the two loads sees the full 5 volts of its respective source. Unlike the DC circuit, we must represent each of the voltage and impedance quantities in complex (phasor) form in order to apply Ohm's Law to calculate load currents.

One more thing we will do to this circuit before beginning any phasor arithmetic is to label each voltage and each current as we did in the DC circuit. Placing  $+$  and  $-$  symbols at the terminals of AC voltage sources, and drawing conventional-flow notation arrows showing *alternating current* through loads at first may seem absurd, since we know this is an AC circuit and so by definition these quantities lack fixed polarities and directions. However, these symbols will become very important to us because they serve to define what  $0^\circ$  means for each of the respective phasors. In other words, these polarities and arrows merely show us which way the voltages and currents are oriented *when each of those phasors is at its positive peak* – i.e. *when each phasor angle comes around to its own  $0^\circ$  mark*. As such, the polarities and arrows we draw do *not necessarily* represent simultaneous conditions. We will rely on the calculated phasor angles to tell us how far these quantities will actually be phase-shifted from each other at any given point in time:

First, calculating current through the resistor<sup>27</sup>, recalling that the impedance of a resistor has a  $0$  degree phase angle (i.e. no phase shift between voltage and current):

$$I_R = \frac{V_R}{Z_R} = \frac{5\text{ V} \angle 0^\circ}{1\text{ k}\Omega \angle 0^\circ} = 5\text{ mA} \angle 0^\circ$$

Next, calculating current through the capacitor<sup>28</sup>, recalling that the impedance for a capacitor has a  $-90$  degree phase angle because voltage across a capacitor lags  $90$  degrees behind current through a capacitor:

$$I_C = \frac{V_C}{Z_C} = \frac{5\text{ V} \angle 60^\circ}{1\text{ k}\Omega \angle -90^\circ} = 5\text{ mA} \angle 150^\circ$$

<sup>27</sup>When dividing two phasors in polar form, the arithmetic is as follows: divide the numerator's magnitude by the denominator's magnitude, then subtract the denominator's angle from the numerator's angle. The result in this case is 5 milliamps (5 volts divided by 1000 ohms) at an angle of 0 degrees (0 minus 0).

<sup>28</sup>The same arithmetic applies to this quotient as well: the current's magnitude is 5 volts divided by 1000 ohms, while the current's phase angle is 60 degrees minus a negative 90 degrees (150 degrees).

From the arrows sketched at the node we can see the total current headed toward ground must be equal to the sum of the two currents headed into the node, just as with the DC circuit. The difference here is that we must perform the addition using phasor quantities instead of scalar quantities in order to account for phase shift between the two currents:

$$I_{total} = I_R + I_C$$

$$I_{total} = 5 \text{ mA} \angle 0^\circ + 5 \text{ mA} \angle 150^\circ$$

Representing these current phasors in rectangular mode so we may sum their real and imaginary parts:

$$I_{total} = (5 + j0 \text{ mA}) + (-4.33 + j2.5 \text{ mA})$$

$$I_{total} = 0.67 + j2.5 \text{ mA}$$

Converting the rectangular form into polar form:

$$I_{total} = 2.59 \text{ mA} \angle 75^\circ$$

This result is highly non-intuitive. When we look at the circuit and see two 5 milliamp currents entering a node, we naturally expect a sum total of 10 milliamps to exit that node. However, that will only be true if those 5 mA quantities are *simultaneous*: i.e. if the two currents are 5 mA in magnitude *at the same point in time*. Since we happen to know these two currents are phase-shifted from each other by 150 degrees (nearly opposed to each other), they never reach their full strength at the same point in time, and so their sum is considerably less than 10 milliamps:

We may make more sense of this result by adding current-sensing phasometers to the circuit, their red and black test leads connected in such a way as to match the arrows' directions (current entering the red lead and exiting the black lead, treating the phasometer as a proper electrical *load*) as though these were DC ammeters being connected into a DC circuit:

A very common and practical example of using “DC notation” to represent AC voltages and currents is in *three-phase* circuits where each power supply consists of three AC voltage sources phase-shifted 120 degrees from each other. Here, we see a “wye” connected generator supplying power to a “wye” connected load. Each of the three generator stator windings outputs 277 volts, with the entirety of that voltage dropped across each of the load resistances:

Note the directions of the three currents (red arrows) in relation to the node at the center of the generator’s “wye” winding configuration, and also in relation to the node at the center of the resistive load’s “wye” configuration. At first this seems to be a direct violation of Kirchhoff’s Current Law: how is it possible to have three currents *all exiting a node with none entering* or to have three currents *all entering a node with none exiting*? Indeed, this would be impossible if the currents were *simultaneously* moving in those directions, but what we must remember is that each of the current arrows simply shows which way each current will be moving *when its respective phasor comes around to the 0° mark*. In other words, the arrows simply define what zero degrees means for each current. Similarly, the voltage polarities would suggest to anyone familiar with Kirchhoff’s Voltage Law in DC circuits that the voltage existing between any two of the power conductors between generator and load should be 0 volts, reading the series-opposed sum of two 277 volt sources. However, once again we must remind ourselves that the + and – symbols do not actually represent polarities at the same point in time, but rather serve to define the orientation of each voltage when its phasor happens to point toward 0°.

If we were to connect three current-sensing phasometers to measure the phase angle of each line current in this system (keying the strobe light to the voltage of the  $0^\circ$  generator winding), we would see the true phase relationships relative to that time reference. The directions of the current arrows and the orientation of the  $+$  and  $-$  polarity marks serve as references for how we shall connect the phasometers to the circuit ( $+$  on red,  $-$  on black; current entering red, exiting black):

We may use the three arrows at the load's center node to set up a Kirchhoff's Current Law equation (i.e. the sum of all currents at a node must equal zero), and confirm that the out-of-phase currents all "entering" that node do indeed amount to a sum of zero:

$$I_{node} = 2.77 \text{ A} \angle 0^\circ + 2.77 \text{ A} \angle 120^\circ + 2.77 \text{ A} \angle 240^\circ$$

Converting polar expressions into rectangular so we may see how they add together:

$$I_{node} = (2.77 + j0 \text{ A}) + (-1.385 + j2.399 \text{ A}) + (-1.385 - j2.399 \text{ A})$$

Combining all the real terms and combining all the imaginary terms:

$$I_{node} = (2.77 - 1.385 - 1.385) + j(0 + 2.399 - 2.399) \text{ A}$$

$$I_{node} = 0 + j0 \text{ A}$$

Looking closer at these results, we may determine which way the three currents were actually flowing at the time of the strobe's flash (when the upper-right generator winding is at its peak positive voltage). The first phasor has a real value of +2.77 amps at that instant in time, which represents 2.77 amps of actual current flowing in the actual direction of our sketched current arrow. The second and third phasors each have real values of -1.385 amps at that same instant in time, representing 1.385 amps each flowing *against* the direction of our sketched arrows (i.e. leaving that node). Thus, we can see that the "snapshot" view of currents at the time of the strobe's flash makes complete sense: one current of 2.77 amps entering the node and two currents of 1.385 amps each exiting the node. Viewed at any instant in time, the principles of DC circuits hold true. It is only when we sketch polarity marks and draw arrows representing voltages and currents *reaching their positive peak values at different times* that the annotations seem to violate basic principles of circuit analysis.

## 5.6 The $s$ variable

A powerful mathematical concept useful for analyzing practically any physical system – electrical circuits included – is something called the  $s$  variable. The  $s$  variable is closely related to Euler's Relation and phasor expressions of waveforms, which is why a discussion of it is included here.

### 5.6.1 Meaning of the $s$ variable

As we saw previously, Euler's Relation allows us to express rotating phasors as imaginary exponents of  $e$ . For example,  $Ae^{j\theta}$  represents a phasor of length  $A$  at an angle of  $\theta$  radians.  $Ae^{j\omega t}$  represents a phasor of length  $A$  rotating at a velocity of  $\omega$  radians per second at a particular instant in time  $t$ . This happens to be an incredibly useful mathematical “trick” for representing sinusoidal waves in physical systems. For example, if we wished to mathematically express a sinusoidal AC voltage as a function of time with a peak voltage value of 10 volts and a frequency of 60 hertz (377 radians per second, since  $\omega = 2\pi f$ ), we could do so like this:

$$V(t) = 10e^{j377t}$$

Exponential functions aren't just useful for expressing sinusoidal waves, however. They also work well for expressing rates of *growth* and *decay*, as is the case with RC and L/R time-delay circuits where exponential functions describe the charging and discharging of capacitors and inductors. Here, the exponent is a real number rather than an imaginary number: the expression  $e^{-t/\tau}$  approaching zero as time ( $t$ ) increases. The Greek letter “tau” ( $\tau$ ) represents the *time constant* of the circuit, which for capacitive circuits is the product of  $R$  and  $C$ , and for inductive circuits is the quotient of  $L$  and  $R$ . For example, if we wished to mathematically express the decaying voltage across a 33  $\mu\text{F}$  capacitor initially charged to 10 volts as it dissipates its stored energy through a 27  $\text{k}\Omega$  resistor (the circuit having a time constant of 0.891 seconds, since  $\tau = RC$ ), we could do so like this:

$$V(t) = 10e^{-(t/0.891)}$$

The sign of the exponential term here is very important: in this example we see it is a negative number. This tells us the function *decays* (approaches zero) over time, since larger positive values of  $t$  result in larger negative values of  $t/\tau$  (recall from algebra that a negative exponent is the equivalent of reciprocating the expression, so that  $e^{-x} = \frac{1}{e^x}$ ). If the exponent were a real positive number, it would represent some quantity *growing* exponentially over time. If the exponent were zero, it would represent a *constant* quantity. We expect a discharging resistor-capacitor circuit to exhibit decaying voltage and current values, and so the negative exponent sign shown here makes sense.

If imaginary exponents of  $e$  represent phasors, and real exponents of  $e$  represent growth or decay, then a *complex* exponent of  $e$  (having both real and imaginary parts) must represent a phasor that grows or decays in magnitude over time. Engineers use the lower-case Greek letter “omega” ( $\omega$ ) along with the imaginary operator  $j$  to represent the imaginary portion, and the lower-case Greek letter “sigma”<sup>29</sup> ( $\sigma$ ) to represent the real portion. For example, if we wished to mathematically express a sine wave AC voltage with a frequency of 60 hertz (377 radians per second) and an amplitude beginning at 10 volts but decaying with a time constant ( $\tau$ ) of 25 milliseconds ( $\sigma = 1/\tau = 40$  time constants per second), we could do so like this:

$$V(t) = 10e^{-40t + j377t}$$

We may factor time from the exponential terms in this expression, since  $t$  appears both in the real and imaginary parts:

$$V(t) = 10e^{(-40 + j377)t}$$

---

<sup>29</sup> $\sigma$  is equal to the reciprocal of the signal's time constant  $\tau$ . In other words,  $\sigma = 1/\tau$ .

With  $t$  factored out, the remaining terms  $-40 + j377$  completely describe the sinusoidal wave's characteristics. The wave's decay rate is described by the real term ( $\sigma = -40$  time constants per second), while the wave's phase is described by the imaginary term ( $j\omega = 377$  radians per second). Engineers use a single variable  $s$  to represent the complex quantity  $\sigma + j\omega$ , such that any growing or decaying sinusoid may be expressed very succinctly as follows:

$$Ae^{st} = Ae^{(\sigma+j\omega)t} = Ae^{\sigma t}e^{j\omega t}$$

Where,

$A$  = Initial amplitude of the sinusoid (e.g. volts, amps) at time  $t = 0$  (arbitrary units)

$s$  = Complex growth/decay rate and frequency ( $\text{sec}^{-1}$ )

$\sigma = \frac{1}{\tau}$  = Real growth/decay rate (time constants per second, or  $\text{sec}^{-1}$ )

$j\omega$  = Imaginary frequency (radians per second, or  $\text{sec}^{-1}$ )

$t$  = Time (seconds)

Separating the expression  $Ae^{\sigma t}e^{j\omega t}$  into three parts –  $A$ ,  $e^{\sigma t}$ , and  $e^{j\omega t}$  – we get a complete description of a rotating phasor:

$A$  = Initial amplitude of the phasor ( $t = 0$ )

$e^{\sigma t}$  = How much the phasor's magnitude has grown ( $\sigma > 0$ ) or decayed ( $\sigma < 0$ ) at time  $t$

$e^{j\omega t}$  = Unit phasor (length = 1) at time  $t$

If we set  $\omega$  at some constant value and experiment with different values of  $\sigma$ , we can see the effect  $\sigma$  has on the shape of the wave over time:

If we set  $\sigma$  at zero and experiment with different values<sup>30</sup> of  $\omega$ , we can see the effect  $\omega$  has on the shape of the wave over time:

As we will soon see, characterizing a sinusoidal response using the complex variable  $s$  allows us to mathematically describe a great many things. Not only may we describe voltage waveforms using  $s$  as shown in these simple examples, but we may also describe the response of entire physical systems including electrical circuits, machines, feedback control systems, and even chemical reactions. In fact, it is possible to map the essential characteristics of *any* linear system in terms of how exponentially growing, decaying, or steady sinusoidal waves affect it, and that mapping takes the form of mathematical functions of  $s$ .

When engineers or technicians speak of a *resonant* system, they mean a circuit containing inductive and capacitive elements tending to sustain oscillations of a particular frequency ( $\omega$ ). A lossless resonant system (e.g. a superconducting tank circuit, a frictionless pendulum) may be expressed by setting the real portion of  $s$  equal to zero ( $\sigma = 0$ ; no growth or decay) and

<sup>30</sup>One value of  $\omega$  not shown in this three-panel graphic comparison is a *negative* frequency. This is actually not as profound as it may seem at first. All a negative value of  $\omega$  will do is ensure that the phasor will rotate in the opposite direction (clockwise, instead of counter-clockwise as phasor rotation is conventionally defined). The real portion of the sinusoid will be identical, tracing the same cosine-wave plot over time. Only the imaginary portion of the sinusoid will be different, as  $j \sin -\theta = -j \sin \theta$ .

letting the imaginary portion represent the resonant frequency ( $j\omega = j2\pi f$ ). Real-life resonant systems inevitably dissipate some energy, and so a real resonant system's expression will have both an imaginary portion to describe resonant frequency and a negative real portion to describe the oscillation's rate of decay over time.

Systems exhibiting a positive  $\sigma$  value are especially interesting because they represent *instability*: unrestrained oscillatory growth over time. A feedback control loop with excessive gain programmed into the loop controller is a simple example of a system where  $\sigma > 1$ . This situation, of course, is highly undesirable for any control system where the goal is to maintain the process variable at a steady setpoint.

### 5.6.2 Impedance expressed using the $s$ variable

Previously, we saw how the impedance of inductors and capacitors could be calculated using  $j\omega$  to represent the frequency of the applied signal. Doing so greatly simplified the mathematics by eliminating the need to manipulate trigonometric functions such as sine and cosine. Here, we will discover that  $s$  works just as nicely for the same task, with the added benefit of showing how inductors and capacitors react to exponentially growing or decaying signals.

First, let's begin with capacitors. We know that voltage across a capacitor and current "through" a capacitor are related as follows:

$$I = C \frac{dV}{dt}$$

Next, we substitute an expression<sup>31</sup> for voltage in terms of  $s$  and then use calculus to differentiate it with respect to time:

$$I = C \frac{d}{dt} (e^{st})$$

$$I = sC e^{st}$$

The ratio of  $\frac{V}{I}$  (the definition of impedance) will then be:

$$Z_C = \frac{V}{I} = \frac{e^{st}}{sC e^{st}}$$

$$Z_C = \frac{1}{sC}$$

Instead of the common scalar expression for capacitive impedance ( $Z_C = \frac{1}{2\pi fC}$ ) which only tells us the magnitude of the impedance (in ohms) but not the phase shift, we have a complex expression for capacitive impedance ( $Z_C = \frac{1}{sC}$ ) describing magnitude, phase shift, and its reaction to the growth or decay of the signal.

---

<sup>31</sup>The expression used here to represent voltage is simply  $e^{st}$ . I could have used a more complete expression such as  $Ae^{st}$  (where  $A$  is the initial amplitude of the signal), but as it so happens this amplitude is irrelevant because there will be an " $A$ " term in both the numerator and denominator of the impedance quotient. Therefore,  $A$  cancels out and is of no consequence.

Likewise, we may do the same for inductors. Recall that voltage across an inductor and current through an inductor are related as follows:

$$V = L \frac{dI}{dt}$$

Substituting an expression for current in terms of  $s$  and using calculus to differentiate it with respect to time:

$$V = L \frac{d}{dt} (e^{st})$$

$$V = sLe^{st}$$

The ratio of  $\frac{V}{I}$  (the definition of impedance) will then be:

$$Z_L = \frac{V}{I} = \frac{sLe^{st}}{e^{st}}$$

$$Z_L = sL$$

As with capacitors, we now have a complex expression for inductive impedance describing magnitude, phase shift, and its reaction to signal growth or decay ( $Z_L = sL$ ) instead of merely having a scalar expression for inductive impedance ( $Z_L = 2\pi fL$ ).

Resistors directly oppose current by dropping voltage, with no regard to rates of change. Therefore, there are no derivatives in the relationship between voltage across a resistor and current through a resistor:

$$V = IR$$

If we substitute  $e^{st}$  for current into this formula, we will see that voltage must equal  $Re^{st}$ . Solving for the ratio of voltage over current to define impedance:

$$Z_R = \frac{V}{I} = \frac{Re^{st}}{e^{st}}$$

$$Z_R = R$$

Not surprisingly, all traces of  $s$  cancel out for a pure resistor: its impedance is exactly equal to its DC resistance.

In summary:

Inductive impedance ( $Z_L$ )	Capacitive impedance ( $Z_C$ )	Resistive impedance ( $Z_R$ )
$sL$	$1/sC$	$R$

Now let's explore these definitions of impedance using real numerical values. First, let's consider a  $22\ \mu\text{F}$  capacitor exposed to a steady AC signal with a frequency of 500 Hz. Since the signal in this case is steady (neither growing nor decaying in magnitude), the value of  $\sigma$  will be equal to zero.  $\omega$  is equal to  $2\pi f$ , and so a frequency of 500 Hz is equal to 3141.6 radians per second. Calculating impedance is as simple as substituting these values for  $s$  and computing  $1/sC$ :

$$Z_C = \frac{1}{sC} = \frac{1}{(\sigma + j\omega)C}$$

$$Z_C = \frac{1}{(0 + j3141.6\ \text{sec}^{-1})(22 \times 10^{-6}\ \text{F})}$$

$$Z_C = \frac{1}{j0.0691}$$

$$Z_C = \frac{-j}{0.0691}$$

$$Z_C = 0 - j14.469\ \Omega \quad (\text{rectangular notation})$$

$$Z_C = 14.469\ \Omega \angle -90^\circ \quad (\text{polar notation})$$

Thus, the impedance of this capacitor will be 14.469 ohms at a phase angle of  $-90^\circ$ . The purely imaginary nature of this impedance (its orthogonal phase shift between voltage and current) tells us there is no net power dissipated by the capacitor. Rather, the capacitor spends its time alternately absorbing and releasing energy to and from the circuit.

Next, we will consider the case of a 150 mH inductor exposed to an exponentially rising DC signal with a time constant ( $\tau$ ) of 5 seconds. 5 seconds per time constant ( $\tau$ ) is equal to 0.2 time constants per second ( $\sigma$ ). Since the signal in this case is DC and not AC, the value of  $\omega$  will be equal to zero. Calculating impedance, once again, is as simple as substituting these values for  $s$  and computing  $sL$ :

$$Z_L = sL = (\sigma + j\omega)L$$

$$Z_L = (0.2 + j0 \text{ sec}^{-1})(150 \times 10^{-3} \text{ H})$$

$$Z_L = 0.03 + j0 \Omega \quad (\text{rectangular notation})$$

$$Z_L = 0.03 \Omega \angle 0^\circ \quad (\text{polar notation})$$

Thus, the impedance of this inductor will be 0.03 ohms at a phase angle of  $0^\circ$ . The purely real nature of this impedance (i.e. no phase shift between voltage and current) tells us energy will be continually absorbed by the inductor, and for this reason it will be seen by the rest of the circuit as though it were a resistor dissipating energy for however long the signal continues to exponentially grow.

A phase shift of 0 degrees for a reactive component such as an inductor may come as a surprise to students accustomed to thinking of inductive impedances *always* having 90 degree phase shifts! However, the application of the complex variable  $s$  to impedance mathematically demonstrates we can indeed have conditions of no phase shift given just the right circumstances. This makes conceptual sense as well if we consider how inductors store energy: if the current through an inductor increases exponentially over time, never reversing direction, it means the inductor's magnetic field will always be growing and therefore absorbing more energy from the rest of the circuit.

We see something even more interesting happen when we subject a reactive component to a *decaying* DC signal. Take for example a 33,000  $\mu\text{F}$  capacitor exposed to a decaying DC signal with a time constant of 65 milliseconds. 65 milliseconds per time constant ( $\tau$ ) is equal to 15.38 time constants per second ( $\sigma$ ). Once again  $\omega$  will be zero because this is a non-oscillating signal. Calculating capacitive impedance:

$$Z_C = \frac{1}{sC} = \frac{1}{(\sigma + j\omega)C}$$

$$Z_C = \frac{1}{(-15.38 + j0 \text{ sec}^{-1})(33000 \times 10^{-6} \text{ F})}$$

$$Z_C = \frac{1}{-0.508}$$

$$Z_C = -1.970 + j0 \Omega \quad (\text{rectangular notation})$$

$$Z_C = 1.970 \Omega \angle 180^\circ \quad (\text{polar notation})$$

A *negative* real impedance figure represents a phase shift of  $180^\circ$  between voltage and current. Once again, this may surprise students of electronics who are accustomed to thinking of capacitive impedances *always* having phase shifts of  $-90$  degrees. What a  $180$  degree phase shift means is the direction of current with respect to voltage polarity has the capacitor functioning as an energy *source* rather than as a *load*. If we consider what happens to a capacitor when it discharges, the  $180$  degree phase shift makes sense: current flowing in this direction depletes the capacitor's plates of stored charge, which means the electric field within the capacitor weakens over time as it releases that energy to the rest of the circuit.

## 5.7 Transfer function analysis

An extremely important topic in engineering is that of *transfer functions*. Simply defined, a transfer function is the ratio of output to input for any physical system, usually with both the output and input being mathematical functions of  $s$ . In other words, we express both the output of a system and the corresponding input of that system in terms of exponentially growing/decaying sinusoidal waves and then solve for the ratio of those two expressions.

Unfortunately, the teaching of transfer functions and their relation to real-world phenomena is often obfuscated by a heavy emphasis on mathematics. The intent of this section is to introduce this concept in a way that is very “gentle” and continually referenced to real-world applications. If I can do anything to help lift the veil of mystery surrounding concepts such as transfer functions, the  $s$  variable, and pole-zero plots, then technicians as well as engineers will be able to appreciate the power of this analytical technique and be able to exchange more ideas in the same “language”.

A simple example of a transfer function is the *gain* of an electronic amplifier. As all students of electronics learn, “gain” is the ratio of output signal to input signal for a circuit. Beginning students learn to represent circuit gains as scalar values (e.g. “The amplifier has a voltage gain of 24”), first as plain ratios and later as decibel figures (e.g. “The amplifier has a voltage gain of 27.6 dB”). One limitation of this approach is that it oversimplifies the situation when the gain of the circuit in question varies with the frequency and/or the growth/decay rate of the signal, which is quite often the case. If we take the engineering approach of expressing output and input signals as functions of  $s$ , we obtain a more complete picture of that circuit’s behavior over a wide range of conditions.

Another simple example of a transfer function is what we have just seen in this book: the *impedance* of a reactive electrical component such as a capacitor or an inductor. Here, the ratio in question is between voltage and current. If we consider current through the component to be the “input” signal and voltage across the component to be the “output” signal – both expressed in terms of  $s$  – then impedance  $Z(s) = \frac{V(s)}{I(s)}$  is the transfer function for that component. This raises an important point about transfer functions: what we define as the “input” and the “output” of the system is quite arbitrary, so long as there is an actual relationship between the two signals.

If we write generalized output/input transfer functions of  $s$  for an AC circuit, we may mathematically analyze that transfer function to gain insight into the behavior and characteristics of that circuit. Features of transfer functions of interest to us include:

- **Zeros:** any value(s) of  $s$  resulting in a zero value for the transfer function (i.e. zero gain)
- **Poles:** any value(s) of  $s$  resulting in an infinite value for the transfer function (i.e. maximum gain)

An AC circuit’s *zeros* tell us where the circuit is unresponsive to input stimuli. An AC circuit’s *poles* tell us where the circuit is able to generate an output signal with no input stimulus (i.e. its natural or *un-driven* mode(s) of response).

In order to clearly understand the concept of transfer functions, practical examples are very helpful. Here we will explore some very simple AC circuits in order to grasp what transfer functions are and how they benefit system analysis.

### 5.7.1 Example: LR low-pass filter circuit

First, let's begin with a simple low-pass filter circuit comprised of an inductor and a resistor connected in series:

The impedance of each component as a function of  $s$  is shown in the diagram: the inductor's impedance is  $sL$  while the resistor's impedance is simply  $R$ . It should be clear to any student of electronics that these two components will function as a *voltage divider*, with the output voltage being some fraction of the input voltage. Knowing this, we may write a transfer function for this circuit based on the voltage divider formula, which tells us the ratio of output voltage to input voltage is the same as the ratio of output impedance to total impedance:

$$\text{Transfer function} = \frac{V_{out}(s)}{V_{in}(s)} = \frac{R}{R + sL} = \frac{R}{R + (\sigma + j\omega)L}$$

This transfer function allows us to calculate the “gain” of the system for any given value of  $s$ , which brings us to the next step of our analysis. At this point we will ask ourselves three questions<sup>32</sup>:

1. How does this system respond when  $s = 0$ ?
2. What value(s) of  $s$  make the transfer function approach a value of zero?
3. What value(s) of  $s$  make the transfer function approach a value of infinity?

The first of these questions refers to a condition where we apply a steady DC signal to the input of the system. If  $s = 0$  then both  $\sigma$  and  $\omega$  must each be equal to zero. A value of zero for  $\sigma$  means the signal is neither growing nor decaying over time, but remains at some unchanging value. A value of zero for  $\omega$  means the signal is not oscillating. These two conditions can only refer to a steady DC signal applied to the circuit. Substituting zero for  $s$  we get:

$$\frac{R}{R + 0L}$$

$$\frac{R}{R} = 1$$

<sup>32</sup>What we are really doing here is applying a problem-solving technique I like to call *limiting cases*. This is where we simplify the analysis of some system by considering scenarios where the mathematical quantities are easy to compute.

Therefore the transfer function of this circuit is unity (1) under DC conditions. This is precisely what we would expect given an inductor connected in series with a resistor, with output voltage taken across the resistor. If there is no change in the applied signal, then the inductor's magnetic field will be unchanging as well, which means it will drop zero voltage (assuming a pure inductor with no wire resistance) leaving the entire input voltage dropped across the resistor.

The second question refers to a condition where the output signal of this circuit is zero. Any values of  $s$  resulting in zero output from the system are called the *zeros* of the transfer function. Examining the transfer function for this particular low-pass LR filter circuit, we see that this can only be true if  $s$  becomes infinitely large, because  $s$  is located in the denominator of the fraction:

$$\frac{R}{R \pm \infty L} = 0$$

This is consistent with the behavior of a low-pass filter: as frequency ( $\omega$ ) increases, the filter's output signal diminishes. The transfer function doesn't just tell us how this circuit will respond to change in frequency, however – it also tells us how the circuit will respond to growing or decaying signals too. Here, we see that infinitely large  $\sigma$  values also result in zero output: the inductor, which tends to oppose any current exhibiting a high rate of change, doesn't allow much voltage to develop across the resistor if the input signal is growing or decaying very rapidly.

The third question refers to a condition where either the transfer function's numerator approaches infinity or its denominator approaches zero. Any values of  $s$  having this result are called the *poles* of the transfer function. Since the numerator in this particular case is a constant ( $R$ ), only a denominator value of zero could cause the transfer function to reach infinity:

$$\frac{R}{R + sL} = \infty \text{ only if } R + sL = 0$$

If the necessary condition for a “pole” is that  $R + sL = 0$ , then we may solve for  $s$  as follows:

$$R + sL = 0$$

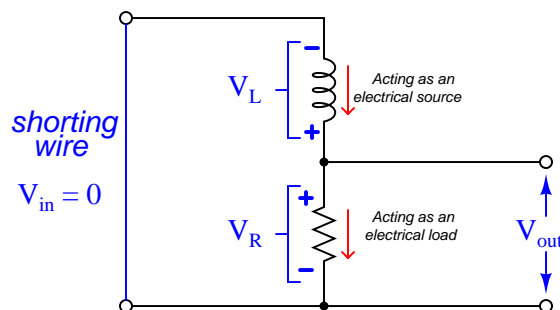

$$sL = -R$$

$$s = -\frac{R}{L}$$

Thus, this transfer function for this simple low-pass filter circuit has one pole located at  $s = -R/L$ . Since both  $R$  and  $L$  are real numbers (not imaginary) with positive values, then the value of  $s$  for the pole must be a real number with a negative value. In other words, the solution for  $s$  at this pole is all  $\sigma$  and no  $\omega$ : this refers to an *exponentially decaying DC signal*.

It is important at this point to consider what this “pole” condition means in real life. The notion that a circuit is able to produce an output signal with zero input signal may sound absurd, but it makes sense if the circuit in question has the ability to store and release energy. In this particular circuit, the inductor is the energy-storing component, and it is able to produce a voltage drop across the resistor with zero input voltage in its “discharging” mode.

An illustration helps make this clear. If the “pole” condition is such that  $V_{in}(s) = 0$ , we may show this by short-circuiting the input of our filter circuit to ensure a zero-input condition:

Assuming the inductor has been “charged” with energy previous to the short-circuiting of the input, an output voltage will surely develop across the resistor as the inductor discharges. In other words, the inductor behaves as an electrical *source* while the resistor behaves as an electrical *load*: connected in series they must of course share the same current, but their respective voltages are equal in magnitude and opposing in polarity in accordance with Kirchhoff’s Voltage Law. Furthermore, the value of  $s$  in this “pole” condition tells us exactly how rapidly the output signal will decay: it will do so at a rate  $\sigma = -R/L$ . Recall that the growth/decay term of the  $s$  variable the reciprocal of the system’s time constant ( $\sigma = 1/\tau$ ). Therefore, a  $\sigma$  value of  $R/L$  is equivalent to a time constant of  $L/R$ , which as all beginning students of electronics learn is how we calculate the time constant for a simple inductor-resistor circuit.

Transfer functions are easier to understand when graphically plotted as three-dimensional surfaces: the real and imaginary portions of the  $s$  variable occupying the horizontal axes, and the magnitude of the transfer function fraction displayed as height. Here is a *pole-zero plot* of this low-pass filter circuit's transfer function, with a resistor value of  $R = 5\ \Omega$  and an inductor value of  $L = 10\ \text{H}$ :

This surface plot makes the meaning of the term “pole” quite obvious: the shape of the function looks just like a rubber mat stretched up at one point by a physical pole. Here, the “pole” rises to an infinite<sup>33</sup> height at a value of  $s$  where  $\sigma = -0.5$  time constants per second and  $\omega = 0$  radians per second. The surface is seen to decrease in height at all edges of the plot, as  $\sigma$  and  $\omega$  increase in value.

The “zero” of this transfer function is not as obvious as the pole, since the function’s value does not equal zero unless and until  $s$  becomes infinite, which of course cannot be plotted on any finite domain. Suffice to say that the zero of this transfer function lies in all horizontal directions at an infinite distance away from the plot’s origin (center), explaining why the surface slopes down to zero everywhere with increasing distance from the pole.

<sup>33</sup>Of course, the mathematical plotting software cannot show a pole of truly infinite height, and so the pole has been truncated. This is why it appears to have a “flat” top.

One of the valuable insights provided by a three-dimensional pole-zero plot is the system's response to an input signal of constant magnitude and varying frequency. This is commonly referred to as the *frequency response* of the system, its graphical representation called a *Bode plot*. We may trace the Bode plot for this system by revealing a cross-sectional slice of the three-dimensional surface along the plane where  $\sigma = 0$  (i.e. showing how the system responds to sinusoidal waves of varying frequency that don't grow or decay over time):

Only one-half of the pole-zero surface has been plotted here, in order to better reveal the cross-section along the  $j\omega$  axis. The bold, red curve traces the edge of the transfer function surface as it begins at zero frequency (DC) to increasingly positive values of  $j\omega$ . The red trace is therefore the Bode plot for this low-pass filter, starting at a maximum value of 1 ( $V_{out} = V_{in}$  for a DC input signal) and approaching zero as frequency increases.

As insightful as three-dimensional pole-zero plots are, they are laborious to plot by hand, and even with the aid of a computer may require significant<sup>34</sup> time to set up. For this reason, pole-zero plots have traditionally been drawn in a two-dimensional rather than three-dimensional format, from a “bird’s eye” view looking down at the  $s$  plane. Since this view hides any features of height, poles and zeros are instead located on the  $s$  plane by  $\times$  and  $\circ$  symbols, respectively. An example of a traditional pole-zero plot for our low-pass filter appears here:

Admittedly, this type of pole-zero plot is a lot less interesting to look at than a three-dimensional surface plotted by computer, but nevertheless contains useful information about the system. The single pole lying on the real ( $\sigma$ ) axis tells us the system will not self-oscillate (i.e.  $\omega = 0$  at the pole), and that it is inherently stable: when subjected to a pulse, its natural tendency is to decay to a stable value over time (i.e.  $\sigma < 0$ ).

It should be noted that transfer functions and pole-zero plots apply to much more than just filter circuits. In fact, *any* physical system having the same “low-pass” characteristic as this filter circuit is describable by the same transfer function and the same pole-zero plots. Electric circuits just happen to be convenient applications because their individual component characteristics are so easy to represent as functions of  $s$ . However, if we are able to characterize the components of a different physical system in the same terms<sup>35</sup>, the same mathematical tools apply.

<sup>34</sup>My first pole-zero plot using the `ePiX` C++ mathematical visualization library took several hours to get it just right. Subsequent plots went a lot faster, of course, but they still require substantial amounts of time to adjust for a useful and aesthetically pleasing appearance.

<sup>35</sup>A powerful mathematical technique known as a *Laplace Transform* does this very thing: translate any differential equation describing a physical system into functions of  $s$ , which may then be analyzed in terms of transfer functions and pole-zero plots.

### 5.7.2 Example: RC high-pass filter circuit

For our next exploratory example we will consider another simple filter circuit, this time comprised of a capacitor and a resistor, with the output signal taken across the resistor. As before, we may derive a transfer function by expressing  $V_{out}/V_{in}$  as a ratio of the resistor's impedance to the total series resistor-capacitor impedance (treating this as a voltage divider circuit):

$$\text{Transfer function} = \frac{V_{out}(s)}{V_{in}(s)} = \frac{R}{R + \frac{1}{sC}}$$

After writing this initial transfer function based on component impedances, we will algebraically manipulate it to eliminate compound fractions. This will aid our analysis of the circuit's DC response, zeros, and poles:

$$\begin{aligned} & \frac{R}{R + \frac{1}{sC}} \\ & \frac{R}{\frac{sRC}{sC} + \frac{1}{sC}} \\ & \frac{R}{\frac{1+sRC}{sC}} \\ & \frac{sRC}{1+sRC} \end{aligned}$$

This transfer function allows us to calculate the “gain” of the system for any given value of  $s$ , which brings us to the next step of our analysis. Once again we will ask ourselves three questions about the transfer function:

1. How does this system respond when  $s = 0$ ?
2. What value(s) of  $s$  make the transfer function approach a value of zero?
3. What value(s) of  $s$  make the transfer function approach a value of infinity?

In answer to the first question, we see that the transfer function is equal to zero when  $s = 0$ :

$$\frac{0RC}{1 + 0RC}$$

$$\frac{0}{1 + 0} = \frac{0}{1} = 0$$

Of course, a value of 0 for  $s$  means exposure to a steady DC signal: one that neither grows nor decays over time, nor oscillates. Therefore, this resistor-capacitor circuit will output zero voltage when exposed to a purely DC input signal. This makes conceptual sense when we examine the circuit itself: a DC input signal voltage means the capacitor will not experience any change in voltage over time, which means it will not pass any current along to the resistor. With no current through the resistor, there will be no output voltage. Thus, the capacitor “blocks” the DC input signal, preventing it from reaching the output. This behavior is exactly what we would expect from such a circuit, which any student of electronics should immediately recognize as being a simple *high-pass* filter: DC is a condition of zero frequency, which should be completely blocked by any filter circuit with a high-pass characteristic.

The answer to our first question is also the answer to the second question: “what value of  $s$  makes the transfer function equal to zero?” Here we see that it is only at a value of  $s = 0$  that the entire transfer function’s value will be zero. Any other values for  $s$  – even infinite – yield non-zero results. In contrast to the last circuit (the resistor-inductor low-pass filter) this circuit exhibits a singular “zero” point in its transfer function: one specific location on the pole-zero plot where the function’s value diminishes to nothing.

When we consider the third question (“What value(s) of  $s$  make the transfer function approach a value of infinity?”) we proceed the same as before: by finding value(s) of  $s$  which will make the denominator of the transfer function fraction equal to zero. If we set the denominator portion equal to zero and solve for  $s$ , we will obtain the *pole* for the circuit:

$$1 + sRC = 0$$

$$sRC = -1$$

$$s = -\frac{1}{RC}$$

We know that both  $R$  and  $C$  are real numbers, not imaginary. This tells us that  $s$  will likewise be a real number at the pole. That is to say,  $s$  will be comprised of all  $\sigma$  and no  $\omega$ . The fact that the value of  $\sigma$  is negative tells us the pole represents a condition of *exponential decay*, just the same as in the case of the resistor-inductor low-pass filter. As before, this means the circuit will produce an output voltage signal with no<sup>36</sup> input voltage signal when the rate of signal decay is  $\sigma = -1/RC$ .

Recall that the rate of decay in the  $s$  variable ( $\sigma$ ) is nothing more than the reciprocal of the system’s time constant ( $\tau$ ). Thus, a rate of decay equal to  $1/RC$  equates to a time constant  $\tau = RC$ ,

---

<sup>36</sup>As before, this counter-intuitive condition is possible only because the capacitor in this circuit has the ability to store energy. If the capacitor is charged by some previous input signal event and then allowed to discharge through the resistor, it becomes possible for this circuit to develop an output voltage even with short-circuited input terminals.

which as all electronics students know is how we calculate the time constant for any simple resistor-capacitor circuit.

Using a computer to plot a three-dimensional representation of this transfer function, we clearly see both the pole and the zero as singularities. Here I have assumed a  $10\ \Omega$  resistor and a  $0.2\ \text{F}$  capacitor to place the pole at the same location as with the low-pass filter circuit  $s = -0.5 + j0$ , for an equitable comparison:

Here we see both the pole at  $s = -0.5 + j0$  and the zero at  $s = 0 + j0$  quite clearly: the pole is a singular point of infinite height while the zero is a singular point of zero height. The three-dimensional surface of the transfer function looks like a rubber sheet that has been stretched to an infinite height at the pole and stretched to ground level at the zero.

As in the last example, we may re-plot the transfer function in a way that shows a cross-sectional view at  $\sigma = 0$  in order to reveal the frequency response of this high-pass filter circuit:

Once again the bold, red curve traces the edge of the transfer function surface as it begins at zero frequency (DC) to increasingly positive values of  $j\omega$ . The red trace is therefore the Bode plot for this high-pass filter, starting at a minimum value of 0 ( $V_{out} = 0$  for a DC input signal) and approaching unity (1) as frequency increases. Naturally, this is the type of response we would expect to see exhibited by a high-pass filter circuit.

A more traditional two-dimensional pole-zero plot for this circuit locates the pole with a “ $\times$ ” symbol and the zero with a “ $\circ$ ” symbol:

### 5.7.3 Example: LC “tank” circuit

Next, we will explore the transfer function for a *tank circuit*, comprised of a capacitor and an inductor. We will assume the use of pure reactances here with no electrical resistance or other energy losses of any kind, just to analyze an ideal case. The output voltage in this particular circuit will be taken across the inductor:

Writing the transfer function for this tank circuit is (once again) a matter of expressing the ratio between the output component's impedance versus the total circuit impedance:

$$\text{Transfer function} = \frac{V_{out}(s)}{V_{in}(s)} = \frac{sL}{sL + \frac{1}{sC}}$$

Algebraically manipulating this function to eliminate compound fractions:

$$\begin{aligned} & \frac{sL}{sL + \frac{1}{sC}} \\ & \frac{sL}{\frac{sLsC}{sC} + \frac{1}{sC}} \\ & \frac{sL}{\frac{s^2LC}{sC} + \frac{1}{sC}} \\ & \frac{sL}{\frac{s^2LC+1}{sC}} \\ & \frac{sLsC}{s^2LC + 1} \\ & \frac{s^2LC}{s^2LC + 1} \end{aligned}$$

Note how this transfer function contains  $s^2$  terms rather than  $s$  terms. This makes it a *second-order function*, which will yield very different results on the pole-zero plot than what we saw with either the resistor-inductor or resistor-capacitor filter circuits.

Asking ourselves the same three questions again:

1. How does this system respond when  $s = 0$ ?
2. What value(s) of  $s$  make the transfer function approach a value of zero?
3. What value(s) of  $s$  make the transfer function approach a value of infinity?

In answer to the first question, we see that the transfer function is equal to zero when  $s = 0$ :

$$\frac{s^2 LC}{s^2 LC + 1}$$

$$\frac{0}{0 + 1} = \frac{0}{1} = 0$$

As with the RC low-pass filter, its response at DC also happens to be a “zero” for the transfer function. With a DC input signal, the output signal of this circuit will be zero volts.

In order to find poles for this transfer function, we must solve for values of  $s$  that will make the denominator term of the transfer function equal to zero:

$$s^2 LC + 1 = 0$$

$$s^2 LC = -1$$

$$s^2 = -\frac{1}{LC}$$

$$s = \sqrt{-\frac{1}{LC}}$$

$$s = \pm j\sqrt{\frac{1}{LC}}$$

Given the fact that both  $L$  and  $C$  are real, positive numbers, and therefore solving for  $s$  requires we take the square root of a negative real number, we see that the value of  $s$  must be imaginary. We also see here that there are *two* poles in this transfer function: one at  $s = 0 + j\sqrt{\frac{1}{LC}}$  and another at  $s = 0 - j\sqrt{\frac{1}{LC}}$ .

Using a computer to plot a three-dimensional representation of this transfer function, we clearly see a single zero at  $s = 0$  and two poles symmetrically positioned along the  $j\omega$  axis. Here I have assumed a 0.2 F capacitor and a 5 H inductor for component values:

The two<sup>37</sup> poles located on the  $j\omega$  axis (one at  $s = 0 + j1$  and the other at  $s = 0 - j1$ ) tell us the circuit is able to generate an oscillating output signal ( $\omega = 1$  radian per second frequency) at constant magnitude ( $\sigma = 0$ ) with no input signal. This is only possible because we have assumed a perfect capacitor and a perfect inductor with no energy losses whatsoever. If we charge up either or both of these components and then immediately short-circuit the input of the circuit to ensure  $V_{in} = 0$ , it will oscillate at its resonant frequency forever.

<sup>37</sup>The *two* solutions for  $\omega$  (one at +1 radian per second and the other at -1 radian per second) merely indicate the circuit is able to oscillate “forward” as well as “backward”. In other words, it is able to oscillate sinusoidally where the positive peak occurs at time  $t = 0$  (+1 rad/sec) as well as oscillate sinusoidally where the negative peak occurs at time  $t = 0$  (-1 rad/sec). We will find that solutions for  $s$  in general are symmetrical about the real axis, meaning if there is any solution for  $s$  requiring an imaginary number value, there will be *two* of them: one with a *positive* imaginary value and the other with a *negative* imaginary value.

Earlier we noted that the poles in this circuit were  $s = 0 + j\sqrt{\frac{1}{LC}}$  and  $s = 0 - j\sqrt{\frac{1}{LC}}$ . In other words, its resonant frequency is  $\omega = \sqrt{\frac{1}{LC}}$ . Recalling that the definition for  $\omega$  is radians of phasor rotation per second, and that there are  $2\pi$  radians in one complete revolution (cycle), we can derive the familiar resonant frequency formula for a simple LC circuit:

$$\omega = \sqrt{\frac{1}{LC}}$$

. . . substituting  $2\pi f$  for  $\omega$  . . .

$$2\pi f = \sqrt{\frac{1}{LC}}$$

$$f = \frac{1}{2\pi\sqrt{LC}}$$

Taking a cross-section of this surface plot at  $\sigma = 0$  to obtain a frequency response (Bode plot) of the LC tank circuit, we see the output of this circuit begin at zero when the frequency ( $\omega$ ) is zero, then the output peaks at the resonant frequency ( $\omega = 1$  rad/sec), then the output approaches unity (1) as frequency increases past resonance:

A more traditional two-dimensional pole-zero plot for this circuit locates shows the zero and the two poles using “o” and “x” symbols:

### 5.7.4 Example: RLC band-pass filter circuit

For our next example circuit, we will add a resistor in series with the inductor and capacitor to explore its effects on the transfer function. Taking our output voltage across the resistor, we should expect to see *band-pass* filtering behavior from this circuit, with maximum voltage developing across the resistor at one frequency where the inductor's and capacitor's impedances cancel:

As usual, the transfer function for this circuit is the ratio between the output component's impedance ( $R$ ) and the total series impedance, functioning as a voltage divider:

$$\text{Transfer function} = \frac{V_{out}(s)}{V_{in}(s)} = \frac{R}{R + sL + \frac{1}{sC}}$$

Algebraically manipulating this function to eliminate compound fractions:

$$\begin{aligned} & \frac{R}{R + sL + \frac{1}{sC}} \\ & \frac{R}{\frac{sRC}{sC} + \frac{s^2LC}{sC} + \frac{1}{sC}} \\ & \frac{R}{\frac{sRC + s^2LC + 1}{sC}} \\ & \frac{sRC}{sRC + s^2LC + 1} \end{aligned}$$

As with the pure tank circuit analyzed previously, we can see that this LC circuit exhibits a *second-order* transfer function because it contains an  $s^2$  term. Running through our three questions again:

1. How does this system respond when  $s = 0$ ?
2. What value(s) of  $s$  make the transfer function approach a value of zero?
3. What value(s) of  $s$  make the transfer function approach a value of infinity?

The answers to the first two questions are one and the same: the numerator of the transfer function will be zero when  $s = 0$ , this being the single *zero* of the function. Recalling that a condition of  $s = 0$  represents a DC input signal (no growth or decay over time, and no oscillation), this makes perfect sense: the presence of the DC-blocking series capacitor in this circuit ensures the output voltage under steady-state conditions must be zero.

In answering the third question to identify any poles for this circuit, we encounter a more complicated mathematical problem than seen with previous example circuits. The denominator of the transfer function's fraction is a *second-degree polynomial* in the variable  $s$ . As you may recall from your study of algebra, any solution resulting in a polynomial having an over-all value of zero is called a *root* of that polynomial expression. Since this particular expression is found in the denominator of the transfer function where we know zero values mark poles of the system, and solutions for  $s$  resulting are roots of the polynomial, then roots of the expression  $sRC + s^2LC + 1$  must mark the locations of the poles on the  $s$  plane.

A very useful algebraic tool for finding roots of a second-degree polynomial expression is the *quadratic formula*:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Where,

$ax^2 + bx + c$  is a polynomial expression

$x$  is the independent variable of that polynomial expression

$a$  is the coefficient of the second-degree ( $x^2$ ) term

$b$  is the coefficient of the first-degree ( $x$ ) term

$c$  is the coefficient of the zero-degree (constant) term

Reviewing the denominator of our transfer function again, we see that  $s$  is the independent variable, and so  $LC$  must be the “ $a$ ” coefficient,  $RC$  must be the “ $b$ ” coefficient, and 1 must be the “ $c$ ” coefficient. Substituting these variables into the quadratic formula will give us a formula for computing the poles of this resistor-inductor-capacitor circuit:

$$s = \frac{-RC \pm \sqrt{(RC)^2 - 4LC}}{2LC}$$

Perhaps the most interesting part of this formula is what lies beneath the radicand (square-root) symbol:  $(RC)^2 - 4LC$ . This portion of the quadratic formula is called the *discriminant*, and its value determines both the number of roots as well as their real or imaginary<sup>38</sup> character. If the discriminant is equal to zero, there will be a single real root for our polynomial and therefore only one pole for our circuit. If the discriminant is greater than zero (i.e. a positive value), then there will be two real roots and therefore two poles lying on the  $\sigma$  axis (i.e. no imaginary  $j\omega$  parts). If the discriminant is less than zero (i.e. a negative value), then there will be two complex roots for our polynomial and therefore two complex poles having both real and imaginary parts.

Let us consider for a moment what the sign of the discriminant means in practical terms. A pole that is purely real means a value for  $s$  that is all  $\sigma$  and no  $\omega$ : representing a condition of growth

---

<sup>38</sup>The only way to obtain a purely imaginary root for this polynomial is for the “ $b$ ” coefficient to be equal to zero. For our example circuit, it means either  $R$  or  $C$  would have to be zero, which is impossible if both of those components are present and functioning. Thus, our RLC filter circuit will have either *real* poles or *complex* poles.

or decay but with no oscillation. This is similar to what we saw with the LR or RC low/high pass filter circuits, where the circuit in a state of discharge could generate an output signal even with its input terminals shorted to ensure no input signal.

If we have a positive value for the discriminant which yields *two* real poles, it means two different possible values for  $\sigma$  (rate of growth/decay) that could occur with no signal input to the circuit. This behavior is only possible with two energy-storing components in the circuit: a kind of *double time-constant* where different portions of the circuit discharge at different rates. The lack of any imaginary part within  $s$  means the circuit still will not self-oscillate.

If we have a negative value for the discriminant which yields *two* complex poles, it means two different values for  $s$  both having real and imaginary parts. Since the real part ( $\sigma$ ) represents growth/decay while the imaginary part ( $\omega$ ) represents oscillation, complex poles tell us the circuit will be able to self-oscillate but not at a constant magnitude as with an ideal (lossless) tank circuit. In fact, intuition should tell us these complex poles must have negative real values representing decaying oscillations, because it would violate the Law of Energy Conservation for our circuit to self-oscillate with increasing magnitude.

Looking at the discriminant  $(RC)^2 - 4LC$  we see that it is possible to push the circuit into any one of these three modes of operation merely by adjusting the value of  $R$  and leaving both  $L$  and  $C$  unchanged. If we wish to calculate the critical value of  $R$  necessary to produce a single real pole for any given values of  $L$  and  $C$ , we may set the discriminant equal to zero and algebraically solve for  $R$  as follows:

$$(RC)^2 - 4LC = 0$$

$$(RC)^2 = 4LC$$

$$RC = \sqrt{4LC}$$

$$RC = 2\sqrt{L}\sqrt{C}$$

$$R = \frac{2\sqrt{L}\sqrt{C}}{C}$$

$$R = \frac{2\sqrt{L}\sqrt{C}}{\sqrt{C}\sqrt{C}}$$

$$R = \frac{2\sqrt{L}}{\sqrt{C}} = 2\sqrt{\frac{L}{C}}$$

This critical value of  $R$  resulting in one real pole is the minimum amount of resistance necessary to prevent self-oscillation. If the circuit is operating at this point, it is said to be *critically damped*. Larger values of  $R$  will result in multiple real poles, where the circuit is said to be *over-damped*. Smaller values of  $R$  will permit some self-oscillation to occur, and the circuit is said to be *under-damped*.

Sometimes electrical engineers intentionally install resistors into circuits containing both inductance and capacitance for the express purpose of damping oscillations. In such cases, the resistor is called an *anti-resonance* resistor, because its purpose is to combat resonant oscillations that would otherwise occur as the inductive and capacitive elements of the circuit exchange energy back and forth with each other. If the engineer's intent is to install just enough resistance into the circuit to prevent oscillations without creating unnecessary time delays, then the best value of the resistor will be that which causes critical damping.

Recall that the subject of transfer functions, poles, and zeros applies to *any* linear system, not just AC circuits. Mechanical systems, feedback control loops, and many other physical systems may be characterized in the same way using the same mathematical tools. This particular subject of damping is extremely important in applications where oscillations are detrimental. Consider the design of an automobile's suspension system, where the complementary energy-storing phenomena of spring tension and vehicle mass give rise to oscillations following impact with a disturbance in the road surface. It is the job of the shock absorber to act as the "resistor" in this system and dissipate energy in order to minimize oscillations following a bump in the road. An under-sized shock absorber won't do a good enough job dissipating the energy of the disturbance, and so the vehicle's suspension will exhibit complex poles (i.e. there will be some lingering oscillations following a bump). An over-sized shock absorber will be too "stiff" and allow too much of the bump's energy to pass through to the vehicle frame and passengers. A perfectly-sized shock absorber, however, will "critically damp" the system to completely prevent oscillation while presenting the smoothest ride possible.

Likewise, oscillations following a disturbance are undesirable in a feedback control system where the goal is to maintain a process variable as close to setpoint as possible. An under-damped feedback loop will tend to oscillate excessively following a disturbance. An over-damped feedback loop won't oscillate, but it will take an excessive amount of time to converge back on setpoint which is also undesirable because this means more time spent off setpoint. A critically-damped feedback loop is the best-case compromise, where oscillations are eliminated and convergence time is held to a minimum.

In order to fully illustrate the characteristics of this circuit's transfer function, we will do so for three different resistor values: one where  $R$  yields critical damping (one real pole), one where  $R$  makes the circuit over-damped (two real poles), and one where  $R$  makes the circuit under-damped (two complex poles). We will use three-dimensional plotting to show the transfer function response in each case. To be consistent with our former tank circuit example, we will assume the same capacitor value of 0.2 Farads and the same inductor value of 5 Henrys. The resistor value will be modified in each case to create a different damping condition.

First, the critically-damped example, with a resistor value of 10 ohms:

As expected, a single zero appears at  $s = 0$ , and a single<sup>39</sup> pole at  $s = -1 + j0$ . Thus, this circuit has a decay rate of -1 time constants per second ( $\tau = 1$  second) as seen when we use the quadratic formula to solve for  $s$ :

$$s = \frac{-RC \pm \sqrt{(RC)^2 - 4LC}}{2LC}$$

$$s = \frac{-(10)(0.2) \pm \sqrt{[(10)(0.2)]^2 - (4)(5)(0.2)}}{(2)(5)(0.2)}$$

$$s = \frac{-2 \pm \sqrt{0}}{2} = (-1 + j0) \text{ sec}^{-1}$$

Interestingly, only  $L$  and  $R$  determine the decay rate ( $\sigma$ , the real part of  $s$ ) in the critically damped condition. This is clear to see if we set the discriminant to zero in the quadratic formula and look for variables to cancel:

$$s = \frac{-RC \pm \sqrt{0}}{2LC} = -\frac{R}{2L}$$

<sup>39</sup>Or, one might argue there are two *repeated* poles, one at  $s = -1 + j0$  and another at  $s = -1 - j0$ .

Next, we will plot the same transfer function with a larger resistor value (15 ohms) to ensure over-damping:

We clearly see *two* poles<sup>40</sup> centered along the  $\sigma$  axis in this plot, representing the two real roots of the transfer function's denominator. Again, we will use the quadratic formula to solve for these two values of  $s$ :

$$s = \frac{-RC \pm \sqrt{(RC)^2 - 4LC}}{2LC}$$

$$s = \frac{-(15)(0.2) \pm \sqrt{[(15)(0.2)]^2 - (4)(5)(0.2)}}{(2)(5)(0.2)}$$

$$s = \frac{-3 \pm \sqrt{(3)^2 - 4}}{2}$$

$$s = \frac{-3 + \sqrt{5}}{2} = (-0.382 + j0) \text{ sec}^{-1}$$

$$s = \frac{-3 - \sqrt{5}}{2} = (-2.618 + j0) \text{ sec}^{-1}$$

These real poles represent two different decay rates (time constants) for the over-damped circuit: a fast decay rate of  $\sigma = -2.618 \text{ sec}^{-1}$  and a slow decay rate of  $\sigma = -0.382 \text{ sec}^{-1}$ , the slower of these two decay rates dominating the circuit's transient response over long periods of time.

<sup>40</sup>The center of the pole farthest from the plot's origin actually lies outside the plotted area, which is why that pole appears to be vertically sliced. This plot's domain was limited to the same values ( $\pm 2$ ) as previous plots for the sake of visual continuity, the compromise here being an incomplete mapping of one pole.

Next, we will plot the same transfer function with a smaller resistor value (5 ohms) to ensure under-damping:

We clearly see *two* poles once again, but neither of them are located on an axis. These represent two *complex* values for  $s$  describing the circuit's behavior with zero input. The imaginary ( $j\omega$ ) part of  $s$  tells us the circuit has the ability to self-oscillate. The negative, real ( $\sigma$ ) part of  $s$  tells us these oscillations decrease in magnitude over time. Using the quadratic formula to solve for these two poles:

$$s = \frac{-RC \pm \sqrt{(RC)^2 - 4LC}}{2LC}$$

$$s = \frac{-(5)(0.2) \pm \sqrt{[(5)(0.2)]^2 - (4)(5)(0.2)}}{(2)(5)(0.2)}$$

$$s = \frac{-1 \pm \sqrt{(1)^2 - 4}}{2}$$

$$s = \frac{-1 + \sqrt{-3}}{2} = (-0.5 + j0.866) \text{ sec}^{-1}$$

$$s = \frac{-1 - \sqrt{-3}}{2} = (-0.5 - j0.866) \text{ sec}^{-1}$$

The calculated  $\omega$  value of 0.866 radians per second is slower than the 1 radian per second resonant frequency calculated for the pure tank circuit having the same  $L$  and  $C$  values, revealing that the damping resistor skews the “center” frequency of this RLC band-pass filter. The calculated  $\sigma$  value of  $-0.5$  time constants per second (equivalent to a time constant of  $\tau = 2$  seconds) describes the

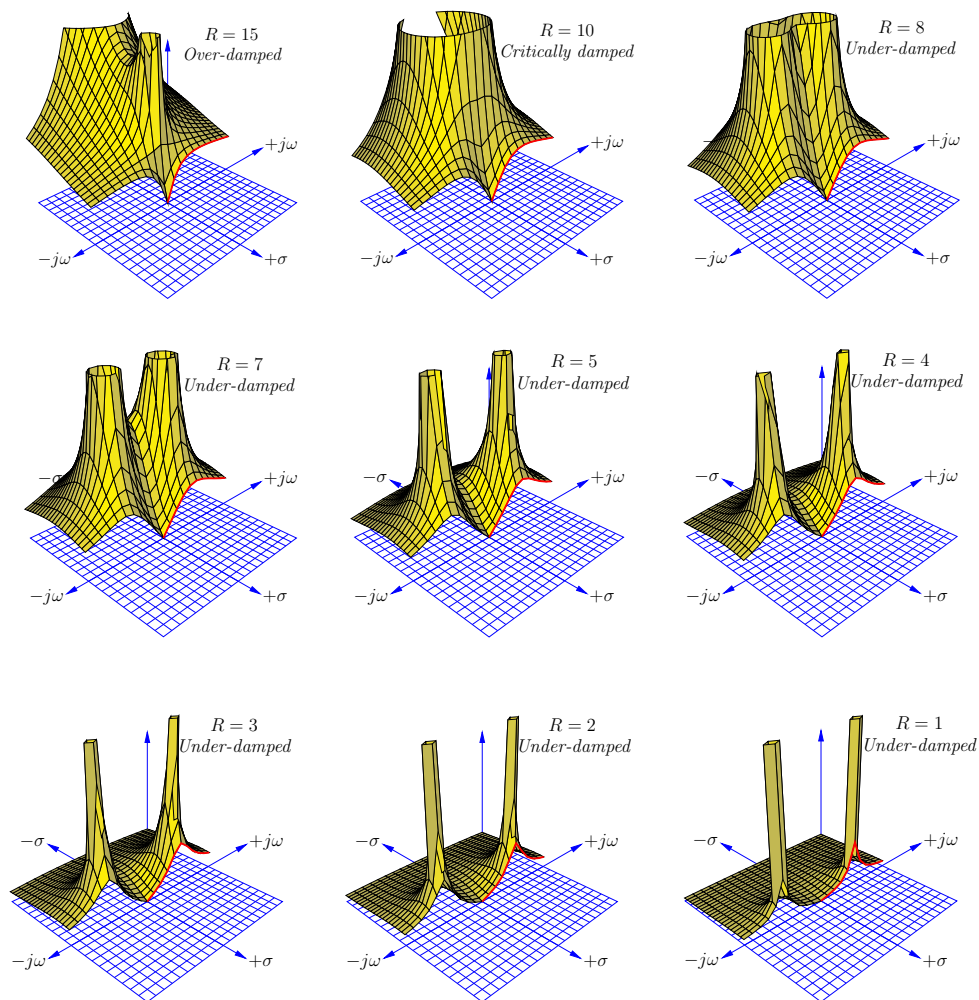

rate at which the sinusoidal oscillations decay in magnitude. Here as well we see the under-damped decay rate ( $\sigma = -0.5 \text{ sec}^{-1}$ ) is slower than the critically damped decay rate ( $\sigma = -1 \text{ sec}^{-1}$ ).

If we compare two-dimensional pole-zero plots for each of the three resistor values in this RLC circuit, we may contrast the over-damped, critically-damped, and under-damped responses:

If we take cross-sectional plots of the transfer function at  $\sigma = 0$  to show the frequency response of this RLC band-pass filter, we see the response become “sharper” (more selective) as the resistor’s value decreases and the poles move closer to the  $j\omega$  axis. Electronic technicians relate this to the *quality factor* or  $Q$  of the band-pass filter circuit, the circuit exhibiting a higher “quality” of band-pass selection as the ratio of reactance to resistance increases:

Although each and every pole in a pole-zero plot has the same (infinite) height, poles grow narrower when moved farther away from each other, and wider when closely spaced. As the resistance in this circuit decreases and the poles move farther away from each other and closer to the  $j\omega$  axis, their widths narrow and the frequency response curve’s peak becomes narrower and steeper.

### 5.7.5 Summary of transfer function analysis

Here is a summary of some of the major concepts important to transfer function analysis:

- The  **$s$  variable** is an expression of growing/decaying sinusoidal waves, comprised of a real part and an imaginary part ( $s = \sigma + j\omega$ ). The real part of  $s$  ( $\sigma$ ) is the growth/decay rate, telling us how rapidly the signal grows or decays over time, with positive values of  $\sigma$  representing growth and negative values of  $\sigma$  representing decay. This growth/decay rate is the reciprocal of *time constant* ( $\sigma = 1/\tau$ ), and is measured in reciprocal units of time (time constants per second, or  $\text{sec}^{-1}$ ). The imaginary part of  $s$  ( $j\omega$ ) represents the *frequency* of the sinusoidal quantity, measured in radians per second ( $\text{sec}^{-1}$ ).
- An important assumption we make when analyzing any system's transfer function(s) is that the system is **linear** (i.e. its output and input magnitudes will be proportional to each other for all conditions) and **time-invariant** (i.e. the essential characteristics of the system do not change with the passage of time). If we wish to analyze a non-linear system using these tools, we must limit ourselves to ranges of operation where the system's response is approximately linear, and then accept small errors between the results of our analysis and the system's real-life response.
- For any linear time-invariant system (an "LTI" system),  $s$  is descriptive throughout the system. In other words, for a certain value of  $s$  describing the input to this system, that same value of  $s$  will also describe the output of that system.
- A **transfer function** is an expression of a systems' *gain*, measured as a ratio of output over input. In engineering, transfer functions are typically mathematical functions of  $s$  (i.e.  $s$  is the independent variable in the formula). When expressed in this way, the transfer function for a system tells us how much gain the system will have for any given value of  $s$ .
- Transfer functions are useful for analyzing the behavior of electric circuits, but they are not limited to this application. Any linear system, whether it be electrical, mechanical, chemical, or otherwise, may be characterized by transfer functions and analyzed using the same mathematical techniques. Thus, transfer functions and the  $s$  variable are general tools, not limited to electric circuit analysis.
- A **zero** is any value of  $s$  that results in the transfer function having a value of zero (i.e. zero gain, or no output for any magnitude of input). This tells us where the system will be least responsive. On a three-dimensional pole-zero plot, each zero appears as a low point where the surface touches the  $s$  plane. On a traditional two-dimensional pole-zero plot, each zero is marked with a circle symbol ( $\circ$ ). We may solve for the zero(s) of a system by solving for value(s) of  $s$  that will make the *numerator* of the transfer function equal to zero, since the numerator of the transfer function represents the *output* term of the system.
- A **pole** is any value of  $s$  that results in the transfer function having an infinite value (i.e. maximum gain, yielding an output without any input). This tells us what the system is capable

of doing when it is not being “driven” by any input stimulus. Poles are typically associated with energy-storing elements in a passive system, because the only way an unpowered system could possibly generate an output with zero input is if there are energy-storing elements within that system discharging themselves to the output. On a three-dimensional pole-zero plot, each pole appears as a vertical spike on the surface reaching to infinity. On a traditional two-dimensional pole-zero plot, each pole is marked with a ( $\times$ ) symbol. We may solve for the pole(s) of a system by solving for value(s) of  $s$  that will make the *denominator* of the transfer function equal to zero, since the denominator of the transfer function represents the *input* term of the system.

- **Second-order** systems are capable of self-oscillation. This is revealed by poles having imaginary values. These oscillations may be completely undamped (i.e.  $s$  is entirely imaginary, with  $\sigma = 0$ ), in which case the system is able to oscillate forever on its own. If energy-dissipating elements are present in a second-order system, the oscillations will be damped (i.e. decay in magnitude over time).
- An **under-damped** system exhibits complex poles, with  $s$  having both imaginary ( $j\omega$ ) frequency values and real ( $\sigma$ ) decay values. This means the system can self-oscillate, but only with decreasing magnitude over time.
- A **critically damped** system is one having just enough dissipative behavior to completely prevent self-oscillation, exhibiting a single pole having only a real ( $\sigma$ ) value and no imaginary ( $j\omega$ ) value.
- An **over-damped** system is one having excessive dissipation, exhibiting multiple real poles. Each of these real poles represents a different decay rate ( $\sigma$ ) or time constant ( $\tau = 1/\sigma$ ) in the system. When these decay rates differ in value substantially from one another, the slowest one will dominate the behavior of the system over long periods of time.

## 5.8 Polyphase AC power

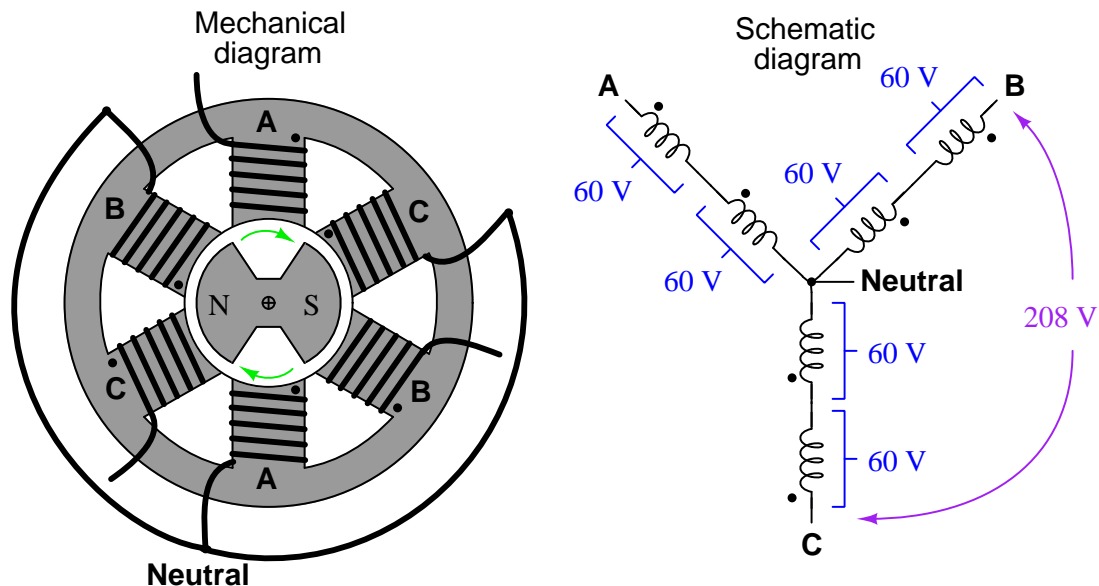

“Polyphase” means “many phases,” describing a form of AC electrical system where multiple sinusoidal voltages exist that are not in step with each other. The most common form of polyphase AC power in industry is *three-phase*, but all polyphase systems share similar traits. A good way to understand three-phase AC systems is to begin with an understanding of simpler, single-phase systems.

A simple *alternator* (AC generator) is nothing more than a magnetized rotor spinning between a pair of electromagnetic poles, the stationary wire coils (“stator windings”) developing AC voltage as the spinning rotor’s magnet passes by:

Note that the stator is comprised of two windings connected in series-aiding fashion, so that their respective AC voltages directly add. If each winding of this machine develops 60 volts, the series pair will develop 120 volts. This machine is properly called a *single-phase* alternator, because all its stator winding voltages are in-phase with each other.

A much more common alternator design uses three sets of stator poles, each one with its own winding pair, to generate three AC voltages phase-shifted from one another by  $120^\circ$ . The reason these three AC voltages are not in-phase with each other is precisely because the three stator poles are not physically aligned with each other, which means the magnetic poles of the spinning rotor will pass by each stator pole pair at different times:

Note that each pair of stator winding voltages directly add, because they are in phase with each other. In the example shown, each individual stator winding develops 60 volts, with each series-aiding pair (each “phase” of the alternator) developing 120 volts. However, the voltage appearing between different stator winding pairs is neither the simple sum ( $120 + 120$ ) nor the simple difference ( $120 - 120$ ) of each phase voltage. Rather, the phase-to-phase voltage is the *trigonometric sum* of two phasor quantities, spaced  $120^\circ$  apart. In the example shown,  $120\angle 0^\circ + 120\angle 120^\circ = 207.85\angle 60^\circ$ , which is approximately 208 volts. This machine is properly called a *three-phase* alternator. More specifically, this alternator is one with a *wye-connected* stator winding set, because the geometric configuration of the stator windings resembles that of the letter “Y”.

The following oscilloscope screenshot shows the output of a three-phase alternator, each channel of the oscilloscope connected across one phase of the alternator (e.g. Channel 1 across “A” and Neutral, Channel 2 across “B” and Neutral, and Channel 3 across “C” and Neutral):

In this oscillograph image we can clearly see a 120 phase shift between successive phase voltage waveforms. From this image we may also discern the *phase sequence* or *phase rotation* of the system: the sequential order in which the three phases reach their respective peak values. Phase sequence is determined by the direction of the alternator shaft's rotation as well as the orientation of the stator phase windings. Surveying the three sine waves from left to right (the forward direction of time) on the oscillograph, we see channel 1 (Yellow) reaches its positive peak 120 degrees before channel 2 (Blue), which reaches its positive peak 120 degrees before channel 3 (Magenta). A common method of describing phase rotation is to list the phase letter labels in their order of sequence over time, in this case the triad *ABC*. It should be noted that a phase sequence of *ABC* is synonymous with *BCA* and also with *CAB*. This is easy to see if we write the letters in sequence for several rotations of the alternator, seeing that all three triads may be found within the longer sequence: *ABCABCABCABC*.

This trigonometric relationship between voltages in this “wye” connected alternator is clearly shown in the following *phasor diagram*. Solid phasors express the phase voltage for each of the three winding pairs in a three-phase alternator, while dashed lines express the line voltage between any two of the three output terminals on the alternator. The direction of each phasor expresses its phase shift in time, as the sine wave voltages produced by each of the three phase windings will be shifted apart from each other by 120 degrees. Here, each phase winding in the alternator happens to produce 120 VAC, resulting in a line voltage equal to the trigonometric sum of the 120 VAC phasors, 208 VAC:

**Voltage phasor diagram for a wye-connected alternator**

A simple way to calculate the side lengths of these non-right triangles is to use the *Law of Sines*, which simply states the ratio between the length of a triangle’s side and the sine of its opposite angle is constant, for *any* triangle:

$$\frac{\sin a}{A} = \frac{\sin b}{B} = \frac{\sin c}{C}$$

Applying this to the solution of the voltage between phases A and B (120 volts each, individually):

$$\frac{\sin 120^\circ}{V_{AB}} = \frac{\sin 30^\circ}{V_A} = \frac{\sin 30^\circ}{V_B}$$

$$\frac{\sin 120^\circ}{V_{AB}} = \frac{\sin 30^\circ}{120 \text{ volts}}$$

$$V_{AB} = (120 \text{ volts}) \left( \frac{\sin 120^\circ}{\sin 30^\circ} \right)$$

$$V_{AB} = 207.84 \text{ volts} \approx 208 \text{ volts}$$

The ratio  $\frac{\sin 120^\circ}{\sin 30^\circ}$  is equal to the square-root of three ( $\sqrt{3}$ ), and this factor frequently appears in three-phase electrical system calculations.

Some three-phase alternators have their phase windings connected differently, in a “delta” configuration rather than a “wye” configuration:

The phasor diagram for voltage in a delta-connected alternator is simpler, because phase voltage is exactly equal to line voltage, with each phase coil directly connected to a pair of line terminals:

**Voltage phasor diagram for a delta-connected alternator**

The following photograph shows the terminal connections on the rear side of a three-phase alternator intended to provide electrical power on a heavy-duty truck or boat. Note the three power terminals at the bottom of the photograph (with yellow-colored wire connectors attached), where the three-phase AC power is output. Also note the two copper “slip rings” I am pointing to with my finger, where DC power is conducted through stationary carbon “brushes,” through the copper rings on the shaft, to a winding on the spinning rotor to control its magnetization. The shaft of this alternator, normally coupled to the crankshaft of the vehicle’s engine by a V-belt, is on the far side of the alternator hidden from view of the camera:

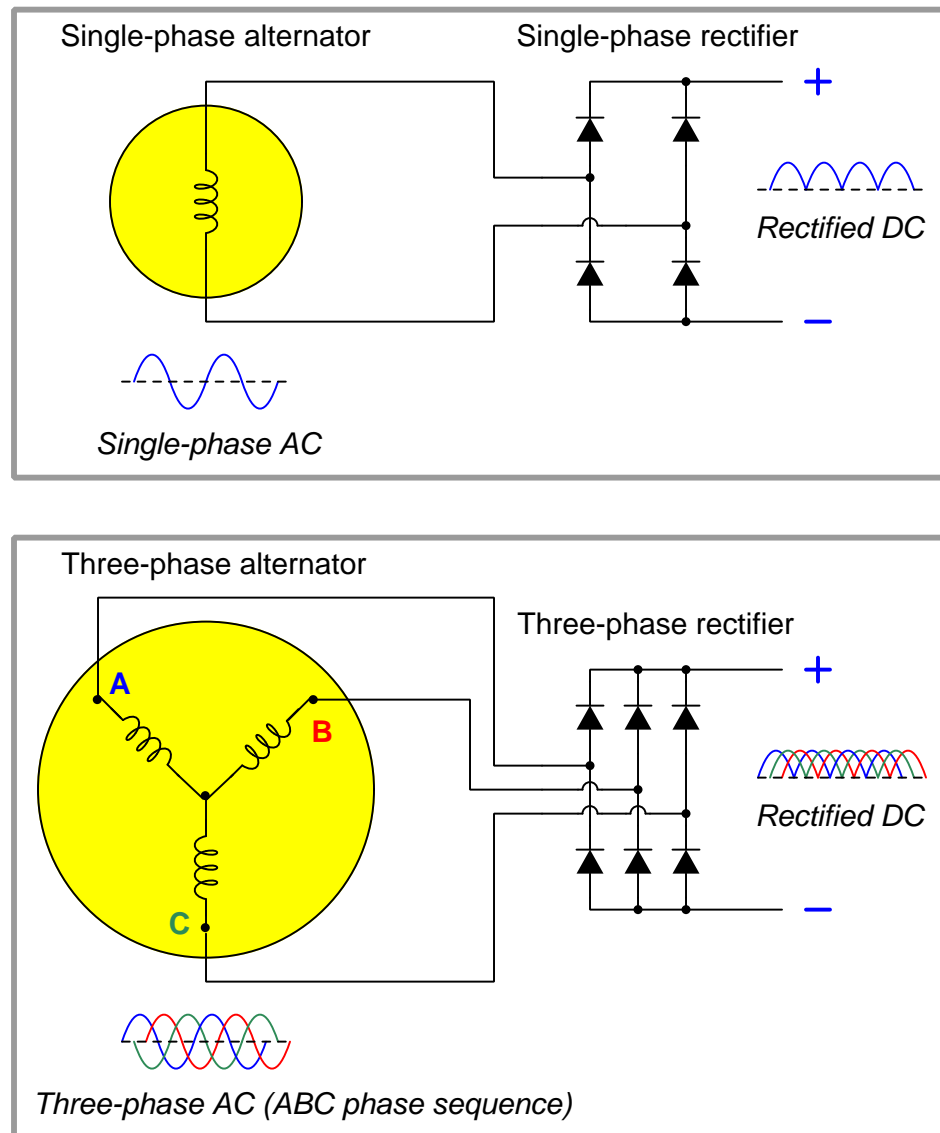

Larger alternator units, such as those found in power plants, do not differ substantially in design from this small unit. Sets of stator windings around the circumference of the machine connected in either a wye or a delta configuration generate three-phase AC power, while a magnetized rotor spins at the center of the machine providing the changing magnetic field necessary to induce voltage in those stator windings. Permanent-magnet rotors are seldom used because they offer no way to control or regulate the machine’s output voltage during operation. Instead, the rotor has a single winding of its own, energized by DC supplied externally by a voltage regulator circuit. If more AC voltage is desired from the alternator, the regulator circuit sends more direct current to the rotor in order to strengthen its magnetic field. If less AC voltage is desired, the regulator sends less current to the rotor’s winding in order to weaken its magnetic field.

One of the advantages of three-phase AC power over single-phase AC power is a more constant delivery of electrical energy to the load over time. With three sets of stator windings at work, the combined effect is not unlike a triple bicycle with the three riders' legs staggered by  $120^\circ$  of rotation, or of a multi-cylinder automobile engine with the pistons staggered apart from each other: at any given time, at least one of the phases will be at or near its peak. Single-phase AC systems, by contrast, *pulsate* to a much greater extent.

In a single-phase AC circuit, energy transfer actually stops completely twice per cycle, when the current waveform passes through zero. This never happens in a polyphase system, because there are always other phases at non-zero current values when any one phase is at its zero-crossing point, owing to the fact that the phases in a polyphase power system are shifted from one another. This fact results in more efficient transfer of energy in AC power systems: a three-phase power system can actually transfer the same amount of power as a comparable single-phase power system using less metal in the power line conductors, despite the fact that a greater number of conductors is necessary (3 versus 2).

Another advantage of three-phase AC power is in applications where the AC is to be rectified into DC. The rectified output of a three-phase alternator is "smoother" than the rectified output of a single-phase alternator, with less ripple voltage to interfere with on-board electronic devices such as radios, because the phase-shifted currents overlap each other. This is why all automotive alternators are three-phase rather than single-phase machines.

A comparison of single-phase rectification versus three-phase rectification shows this clearly:

Not only is the ripple of the rectified DC voltage less in a three-phase system than in a single-phase system, but the frequency of that ripple is three times as great, making it easier to filter<sup>41</sup> out of the DC power.

<sup>41</sup>Low-pass filter circuits are typically used to “smooth” the ripple from the output of a rectifier. The greater the frequency of this ripple voltage, the easier it is to filter from the DC (which has a frequency of zero). All other factors being equal, a low-pass filter attenuates higher-frequency components to a greater extent than lower-frequency components.

### 5.8.1 Delta and Wye configurations

Two basic forms of three-phase sources and loads appearing in industrial power systems are the *delta* ( $\Delta$ ) and the *wye* (or simply *Y*) configurations. A “wye-connected” device has its three elements joined at one common point in the middle as such:

Wye-connected  
motor or generator

Wye-connected  
resistive load

By contrast, a “delta-connected” device has its three elements joined as the sides of a triangle:

Delta-connected  
motor or generator

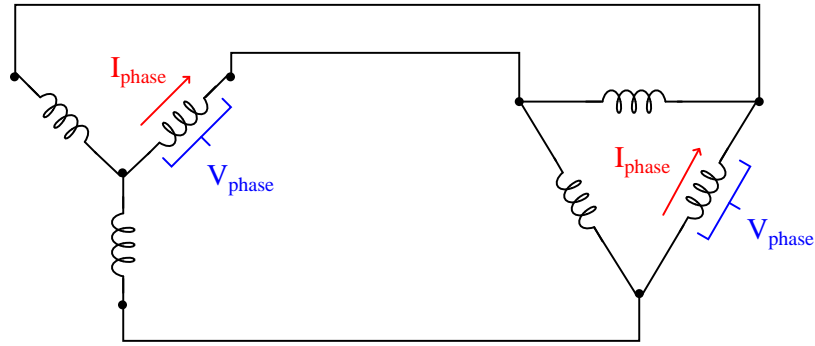

Delta-connected  
resistive load

Each configuration has its own unique advantages and disadvantages in the larger context of a three-phase electrical power system. Either source type may connect to either load type (e.g. delta to wye, delta to delta, wye to delta, wye to wye) so long as the voltage and current ratings of all components are compatible.

The voltage appearing across the terminals of each element in a polyphase device is called the *phase voltage*, and the current through each element in a polyphase device is called the *phase current*:

Voltage appearing between any two of the connecting conductors (power lines) is called the *line voltage* of the polyphase system, and current through any of the connecting conductors (power lines) is called the *line current*:

Line and phase quantities relate to each other differently between delta devices and wye devices. Line voltage for a balanced<sup>42</sup> wye device exceeds phase voltage by a factor of  $\sqrt{3}$ , while line current for a balanced delta device exceeds phase current by the same factor:

System type	Voltage	Current
Wye (Y)	$V_{line} = \sqrt{3} \times V_{phase}$	$I_{line} = I_{phase}$
Delta ( $\Delta$ )	$V_{line} = V_{phase}$	$I_{line} = \sqrt{3} \times I_{phase}$

<sup>42</sup>Here, the term “balanced” refers to a condition where all phase voltages and currents are symmetrically equal. Unbalanced conditions can and do exist in real polyphase power systems, but the degree of imbalance is usually quite small except in cases of component faults.

While it may be tempting to simply memorize these mathematical relationships, it is far better to *understand* why they are so. In a wye-connected device, line current must be equal to phase current because each power line is in series with each (respective) phase element, and we know that series-connected elements must share the same current. Likewise, line voltage must be equal to phase voltage in a delta-connected device because each power line pair connects in parallel fashion to each (respective) phase element, and we know that parallel-connected elements always share the same voltage:

Phase and line voltages are unequal in wye-connected devices, as are phase and line currents in delta-connected devices. In each of these cases, though, we may see once again by visual inspection that these line and phase quantities cannot be equal because the line quantities are the result of *two* joining phase quantities. In a wye network, line voltage is the series (phasor) sum of two phase voltages. In a delta network, line current is the parallel (phasor) sum of two currents summing at a node. If we know the system in question is balanced, however, we may be assured that the multiplying factor between these line and phase quantities will be the square-root of three ( $\sqrt{3}$ ), therefore line voltage is  $\sqrt{3}$  times greater than wye phase voltage, and line current is  $\sqrt{3}$  times greater than delta phase current:

As an example of phase and line voltages in a wye-connected system, we see a great many three-phase industrial power circuits in the United States of the “480/277” volt configuration. These are a wye-connected devices exhibiting having phase voltages of 277 volts (each) and a balanced line voltage of 480 volts.

In the wye-connected system we see how the two phase voltages add in series (indirectly) to form the larger line voltage. In the delta-connected system we see how the larger line current splits up in parallel branches (indirectly) to form two smaller phase currents. The key to understanding these mathematical relationships is to recognize where the rules of series and parallel connections dictate the quantities be identical or different, and then all we need to remember is that if the two are different, the line quantity will be greater by a factor of  $\sqrt{3}$ .

### 5.8.2 Power in three-phase circuits

Suppose we have a 480/277 wye-connected alternator supplying electrical power to a delta-connected load consisting of three 200 ohm resistive heating elements:

To begin our calculation of all electrical quantities in this circuit, we will apply Ohm's Law to the calculation of phase current at the load, since we already know phase voltage (480 volts) and phase resistance (200 ohms) there:

$$I_{phase(load)} = \frac{480 \text{ V}}{200 \Omega} = 2.4 \text{ A}$$

Now that we know phase current at the delta-connected load, we may calculate line current for the whole system by multiplying by the square-root of three:

$$I_{line} = (\sqrt{3})(2.4 \text{ A}) = 4.157 \text{ A}$$

This line current must be the same as the phase current in the wye-connected alternator, since line and phase currents are equal in wye-connected devices by virtue of their series connection. We already know the phase voltage of the alternator (277 volts) because that was given to us, but we could just as well calculate it from the line voltage of 480 volts as such:

$$V_{line} = (\sqrt{3})(V_{phase(source)})$$

$$V_{phase(source)} = \frac{V_{line}}{\sqrt{3}}$$

$$V_{phase(source)} = \frac{480 \text{ V}}{\sqrt{3}} = 277.1 \text{ V} \approx 277 \text{ V}$$

Tabulating all phase voltages and currents in our balanced system with a line voltage of 480 V and a line current of 4.157 A:

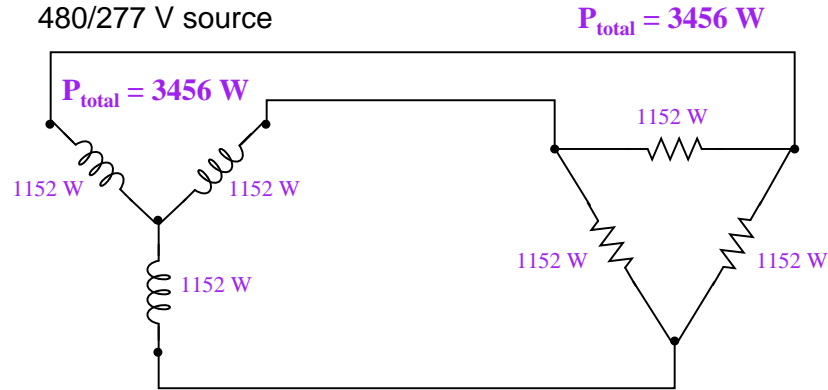

Quantity	Source	Load
$V_{phase}$	277 V	480 V
$I_{phase}$	4.157 A	2.4 A

Power for each of the three source or three load elements in this balanced system is simply the product of phase voltage and phase current ( $P = IV$ ) because voltage and current are in-phase at each of the individual resistors. Expanding our table to include the power for each phase element:

Quantity	Source	Load
$V_{phase}$	277 V	480 V
$I_{phase}$	4.157 A	2.4 A
$P_{phase}$	1152 W	1152 W

Total generated power at the alternator (as well as total dissipated power at the resistive heater) is the simple sum of all three phase elements: 3456 watts in each case. No “square-root-of-three” factor is required in this calculation, because power (work over time) is not a phasor quantity<sup>43</sup>. The Law of Energy Conservation demands that all power be accounted for, and thus three resistors dissipating 1152 watts each must be together dissipating 3456 watts total:

In the interest of convenience, though, it is helpful to have a formula to calculate power in a balanced three-phase system knowing just the line voltage and current rather than phase voltages and currents. You will note how the simple product of line voltage (480 V) and line current (4.157 A) does *not* yield total power (3456 W) in this system. We may develop a proper formula for calculating total power from line voltage and current by beginning with the formula described in calculating total power from the power of each resistor at the delta-connected load:

$$P_{total} = (3)(P_{phase})$$

$$P_{total} = (3)(I_{phase})(V_{phase})$$

<sup>43</sup>You may recall from basic physics that while force and displacement are both vector quantities (having direction as well as magnitude), *work* and *energy* are not. Since power is nothing more than the rate of work over time, and neither work nor time are vector quantities, power is not a vector quantity either. This is closely analogous to voltage, current, and power in polyphase electrical networks, where both voltage and current are phasor quantities (having phase angle “direction” as well as magnitude) but where power merely has magnitude. We call such “directionless” quantities *scalar*. Scalar arithmetic is simple, with quantities adding and subtracting directly rather than trigonometrically.

We may substitute  $I_{line}$  for  $I_{phase}$  and  $V_{line}$  for  $V_{phase}$  in this equation if we properly relate them for the delta<sup>44</sup> connection. While  $V_{line} = V_{phase}$  in a delta configuration,  $I_{phase} = \frac{I_{line}}{\sqrt{3}}$ :

$$P_{total} = (3) \left( \frac{I_{line}}{\sqrt{3}} \right) (V_{line})$$

We may consolidate the two constants in this formula (3 and  $\sqrt{3}$ ) by re-writing the number 3 as the product  $\sqrt{3}\sqrt{3}$ , then canceling one of these with the  $\sqrt{3}$  in the denominator:

$$P_{total} = (\sqrt{3}\sqrt{3}) \left( \frac{I_{line}}{\sqrt{3}} \right) (V_{line})$$

$$P_{total} = (\sqrt{3})(I_{line})(V_{line})$$

As a test, we may check to see that this new formula accurately calculates the total power of our balanced three-phase system:

$$P_{total} = (\sqrt{3})(4.157 \text{ A})(480 \text{ V})$$

$$P_{total} = 3456 \text{ W}$$

---

<sup>44</sup>We end up with the same final result if we substitute line quantities in a wye-connected system, too. Instead of  $V_{line} = V_{phase}$  and  $I_{phase} = \frac{I_{line}}{\sqrt{3}}$  in the delta connection we have  $I_{line} = I_{phase}$  and  $V_{phase} = \frac{V_{line}}{\sqrt{3}}$  in the wye connection. The end-result is still  $P_{total} = (\sqrt{3})(I_{line})(V_{line})$  based on line quantities.

### 5.8.3 Grounded three-phase circuits

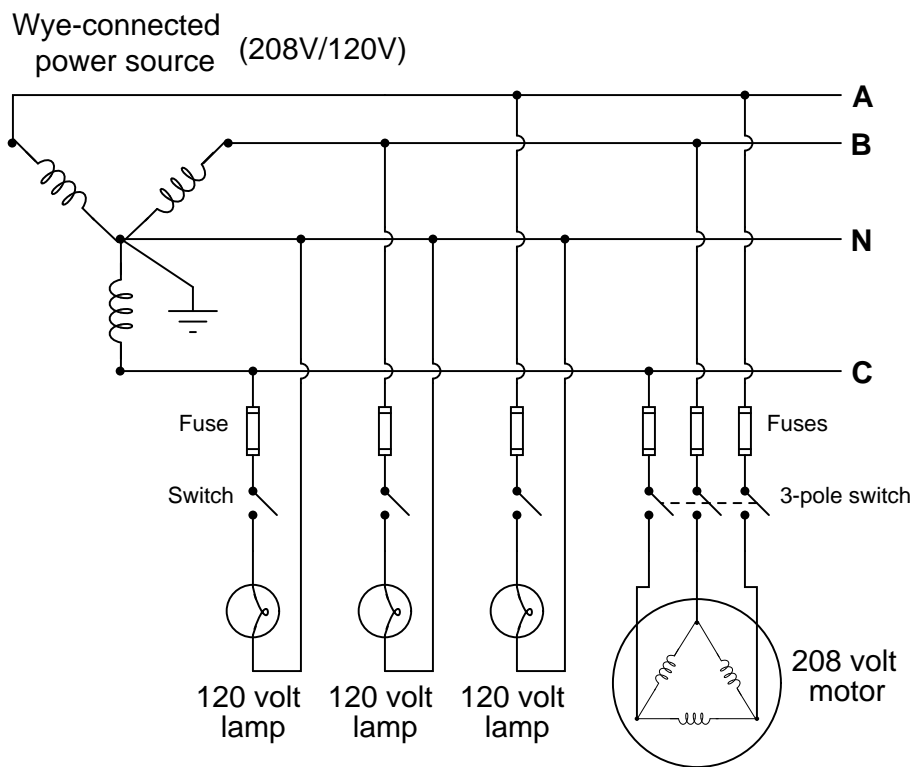

So far all the three-phase configurations shown have been *ungrounded*: that is, none of the terminals or conductors have any direct connection to earth ground. While it is possible (and practical in many cases) to use polyphase power without an explicit earth ground connection, it is not always the safest. Establishing a firm connection to earth limits the voltage which may develop between any non-grounded (“hot”) conductor and earth ground. This is especially important in power systems with overhead lines, where lightning strikes may dramatically elevate common-mode voltages in the system.

In wye-connected systems, the natural point to ground is the center of the “Y”, like this:

The three “hot” terminals of the source are typically labeled “A”, “B”, and “C”, while the grounded point is referred to as the “Neutral” (N). The voltage measured between any two of the “hot” terminals (A to B, B to C, or A to C) will be  $\sqrt{3}$  times more than the voltage measured between any “hot” terminal and the neutral (A to N, B to N, or C to N). Common voltages for 4-wire wye-connected systems include 208/120 and 480/277.

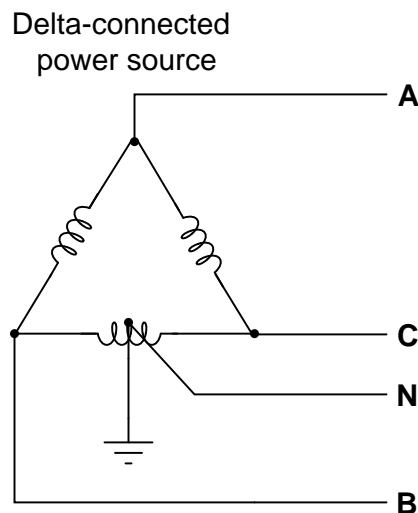

The existence of dual voltage levels in a center-grounded wye system enables the use of loads with different voltage ratings. For example, in a 208/120 wye system, a three-phase motor with windings rated for 208 volts would draw power from the three “hot” conductors directly, while light bulbs rated for 120 volts would connect between any “hot” conductor and the neutral:

A good practice in such systems is to equally spread the 120 volt loads among the three phases, so that (ideally) the phase loading on the source will be nicely balanced when all loads are operating. If the loading is perfectly balanced, in fact, the neutral conductor will carry no current at the point where it connects to the center of the wye.

Note the use of fuses on all the “hot” load conductors, but no fuses on any “neutral” (grounded) conductor. The reason for this is so that in the event of a fuse blowing, only the hot conductor(s) will be disconnected from the load, leaving the neutral conductor connected and thereby maintaining the lowest possible potential at the load relative to earth ground.

In delta-connected systems, there is no “natural” point to connect to earth ground as there is in wye-connected systems. The most common grounding configuration for a delta-connected source is shown here, sometimes called the “high-leg” connection. Here, one of the source’s phase coils is center-tapped to provide a connection point for earth ground:

This configuration yields *three different* voltages available to power loads. If the phase voltage of the delta-connected source is 240 volts, the three available voltages are:

- 240 volts (between A-B, B-C, and A-C)
- 120 volts (between B-N and C-N)
- 208 volts (between A-N)<sup>45</sup>

A disadvantage of this configuration is that the lower-voltage loads cannot be balanced among all three phase coils of the source as they can in wye-connected systems. Any single-phase loads (those connected between any one “hot” conductor and the neutral conductor) inevitably place more burden on the B-C phase coil than the other two phase coils. However, this imbalance is often negligible in industrial settings where three-phase loads are predominant and single-phase loads are few (and low-wattage).

---

<sup>45</sup>A colorful term for this odd voltage is *bastard voltage*.

### 5.8.4 Symmetrical components

Balanced three-phase networks are relatively easy to calculate quantities in, as each line and phase variable is symmetrical. For instance, if we happen to know one of the phase voltages in a balanced Wye-connected power system component is 2400 volts, then we may safely conclude the other two phase voltages are 2400 volts as well. The voltage between any two lines in this same system is guaranteed to be  $\sqrt{3}$  larger than any phase voltage:  $2400\sqrt{3} \approx 4160$  volts.

Calculations become much more complex, however, in *unbalanced* three-phase networks. One of the assumptions we must discard in an unbalanced network is the simple factor of  $\sqrt{3}$  relating phase and line quantities: while  $V_{line} = V_{phase}\sqrt{3}$  in a balanced Wye-connected system, it is not necessarily true in an *unbalanced* Wye-connected system. Compare these phasor diagrams of a balanced versus unbalanced 2400/4160 volt Wye systems, the unbalanced system being representative of a three-phase generator with a fault in one of the phase windings causing that phase voltage to be substantially less than it ought to be:

Balanced Wye-connected system

Unbalanced Wye-connected system  
(phase B voltage  $1/10$  of other phases)

In fact, the existence of faults in three-phase power systems is the primary reason for considering unbalanced systems, since the vast majority of three-phase electrical components are expressly designed to be balanced. If power system engineers and technicians are to analyze faults, they must have some means of quantifying unbalanced system conditions.

A breakthrough in mathematical analysis for unbalanced three-phase electrical circuits came in 1913 from a man named Charles Legeyt Fortescue, who presented his discovery in a paper entitled, “Method of Symmetrical Co-ordinates Applied to the Solution of Polyphase Networks” after doing research on AC induction motors operating under unbalanced conditions. His discovery condenses to the fact that any set of phasors describing conditions of voltage or current in a three-phase network, no matter how unbalanced and asymmetrical they may be, are mathematically equivalent to the sum of three unique phasor sets with different rotations. Thus, it is possible to mathematically decompose an unbalanced phasor triad into a multiple sets of balanced phasor triads, each of those

balanced sets being relatively easy to analyze on its own because the simple rules of symmetrical networks (e.g. the  $\sqrt{3}$  factor between phase and line quantities) still apply.

Fortescue's breakthrough is reminiscent of Jean Baptiste Joseph Fourier's discovery roughly 100 years prior that any periodic waveform, no matter its shape, is mathematically equivalent to a summation of pure sinusoidal waveforms of harmonic frequencies (called a Fourier Series). In both cases, we see there is a mathematical equivalence between one entity that is ugly and asymmetrical, and a set of pure and symmetrical entities that are easier to deal with on mathematical terms.

In Fortescue's model, which is widely known under the title of *symmetrical components*, any set of three phasors describing voltage or current in a three-phase system is equivalent to the summation of three different three-phasor sets:

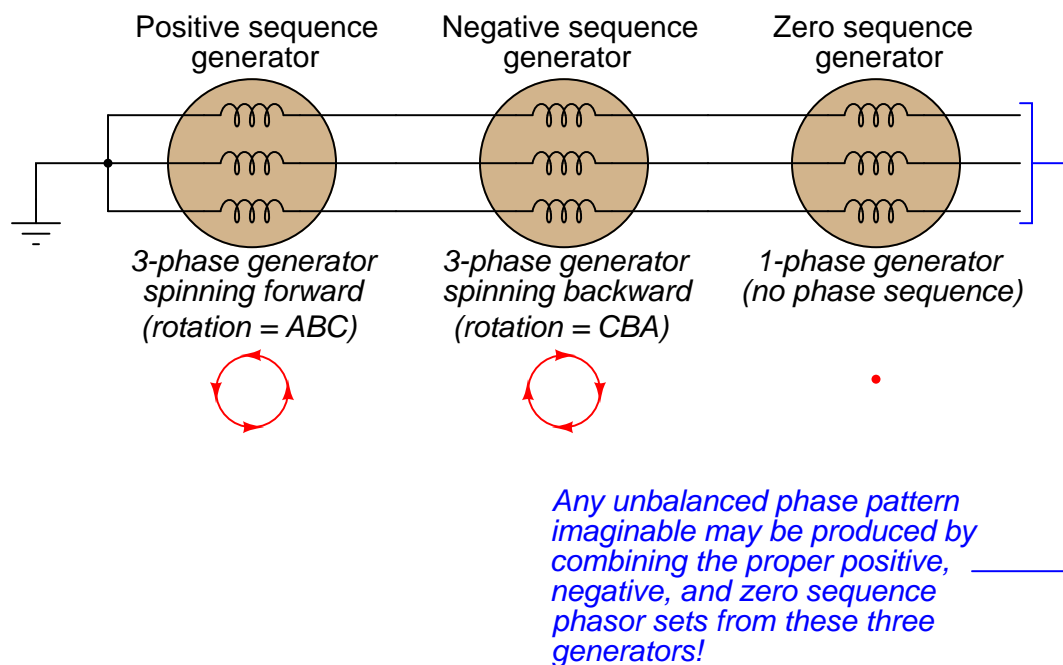

- One set of three phasors rotating in the normal A-B-C direction of the power system, called the *positive sequence*. By convention, this sequence is designated by the number 1.
- One set of three phasors rotating in the reverse direction (A-C-B)<sup>46</sup>, called the *negative sequence*. By convention, this sequence is designated by the number 2.
- One set of three phasors all pointed in the same direction, having no sequence at all, called the *zero sequence*. By convention, this sequence is designated by the number 0.

Fortescue's discovery was that we may synthesize any possible three-phasor set simply by superimposing these positive, negative, and/or zero sequence phasor sets at the appropriate magnitudes and phase shifts. Each positive sequence, negative sequence, and zero sequence set is perfectly balanced, although they must usually differ in magnitude from each other in order for the summation of all three to equal the real-world unbalanced set.

<sup>46</sup>If you are having difficulty seeing the A-B-C or A-C-B rotations of the positive and negative sequences, you may be incorrectly visualizing them. Remember that the phasors (arrows) themselves are rotating about the center point, and you (the observer) are stationary. If you imagine yourself standing where the tip of each "A" phasor now points, then imagine all the phasor arrows rotating counter-clockwise, you will see each phasor tip pass by your vantage point in the correct order.

Another way of stating this is to say that the actual voltages and currents in a three-phase power system, no matter how unbalanced they may be from each other, are really equivalent to multiple sets of voltages and currents existing in the circuit simultaneously, each with its own rotational sequence and perfectly balanced magnitude. Our hypothetical three-phase generator with the faulted phase winding, therefore, is really equivalent to *three* healthy generators with their windings wired together to be series-aiding: one generator spinning in the normal direction, the next generator spinning the wrong direction, and the last generator a single-phase unit with three in-phase windings. The combined sum of these three generators' outputs would create the exact same patterns of voltages and currents as the one faulted-winding generator:

Let us explore this in more detail by means of a concrete example. Taking the faulted-winding generator whose phasor voltage diagram was shown earlier (phase voltages  $V_A$  and  $V_C$  at 2400 volts each, but phase voltage  $V_B$  at only 240 volts), our task is to see how to decompose this unbalanced set of voltage phasors into three balanced sets of phasors (positive-, negative-, and zero-sequence):

Somehow, we must determine the specific pattern of balanced positive-, negative-, and zero-sequence phasor sets that will be equivalent to the unbalanced phasor set describing our faulted generator. Once we determine these symmetrical components, we will then sum them together to demonstrate how the respective phasors do indeed add up to the original (unbalanced) phasor diagram.

Thankfully, symmetrical component analysis provides us with a set of equations for calculating the “A” phasor of each sequence<sup>47</sup>. Please note that each variable in each of the following equations is a *phasor* quantity, possessing both a magnitude and a phase angle. Also note that these equations apply just as well to calculations of *current* as they do to voltage:

$$V_{a1} = \frac{1}{3}(V_a + V_b\angle +120^\circ + V_c\angle +240^\circ) \quad \text{Positive-sequence phasor } A$$

$$V_{a2} = \frac{1}{3}(V_a + V_b\angle +240^\circ + V_c\angle +120^\circ) \quad \text{Negative-sequence phasor } A$$

$$V_{a0} = \frac{1}{3}(V_a + V_b + V_c) \quad \text{Zero-sequence phasor } A$$

The “+120°” and “+240°” references deserve further explanation<sup>48</sup>. What we are saying here is that the calculations involve shifting the angle of the unbalanced system’s phasor by either +120 degrees or +240 degrees when calculating the phasors for the positive and negative sequences. Performing the calculations:

**Given phasors in unbalanced system:**

$$V_a = 2400\angle 0^\circ$$

$$V_b = 240\angle 240^\circ$$

$$V_c = 2400\angle 120^\circ$$

$$V_{a1} = \frac{1}{3}[2400\angle 0^\circ + 240\angle(240^\circ + 120^\circ) + 2400\angle(120^\circ + 240^\circ)] = 1680\angle 0^\circ$$

$$V_{a2} = \frac{1}{3}[2400\angle 0^\circ + 240\angle(240^\circ + 240^\circ) + 2400\angle(120^\circ + 120^\circ)] = 720\angle -60^\circ$$

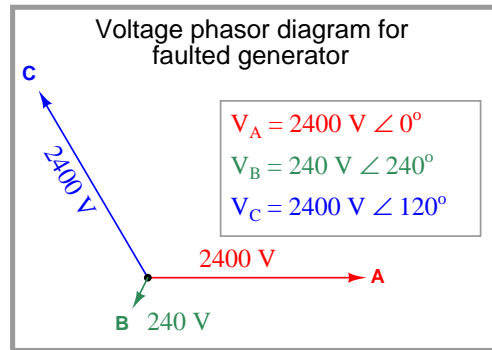

$$V_{a0} = \frac{1}{3}[2400\angle 0^\circ + 240\angle 240^\circ + 2400\angle 120^\circ] = 720\angle 60^\circ$$

Recalling that our faulted generator is mathematically equivalent to three healthy generators with their respective phase windings connected in series, these solutions tell us that the equivalence is one generator spinning the correct direction at 1680 volts per phase, connected to another generator spinning the wrong direction as well as phase-shifted  $-60$  degrees at 720 volts per phase, connected to a single-phase generator phase-shifted  $+60$  degrees at 720 volts per phase. These three healthy generators, each one producing a symmetrical (balanced) set of voltages, will together behave the same as our one 2400 volt phase generator with the faulted “B” winding.

<sup>47</sup>It is good to remember that each of the symmetrical components is perfectly balanced (i.e. the “b” and “c” phasors each have exactly the same magnitude as the “a” phasor in each sequential set), and as such each of the phasors for each symmetrical set will have exactly the same magnitude. It is common to denote the calculated phasors simply as  $V_1$ ,  $V_2$ , and  $V_0$  rather than  $V_{a1}$ ,  $V_{a2}$ , and  $V_{a0}$ , the “a” phasor implied as the representative of each symmetrical component.

<sup>48</sup>A “shorthand” notation commonly seen in symmetrical component analysis is the use of a *unit phasor* called  $a$ , equal to  $1\angle 120^\circ$ . Multiplying any phasor quantity by  $a$  shifts that phasor’s phase angle by +120 degrees while leaving its magnitude unaffected. Multiplying any phasor quantity by  $a^2$  shifts that phasor’s phase angle by +240 degrees while leaving its magnitude unaffected. An example of this “ $a$ ” notation is seen in the following formula for calculating the positive sequence voltage phasor:  $V_{a1} = \frac{1}{3}(V_a + aV_b + a^2V_c)$

Graphically, the decomposition of the original unbalanced phasor diagram into symmetrical components is as follows:

The graphical proof that these three symmetrical component phasor sets do indeed add up to be equivalent to the original (unbalanced) phasor diagram of the faulted generator is as follows:

### Summation of symmetrical phasor sets (+, -, and 0 sequences)

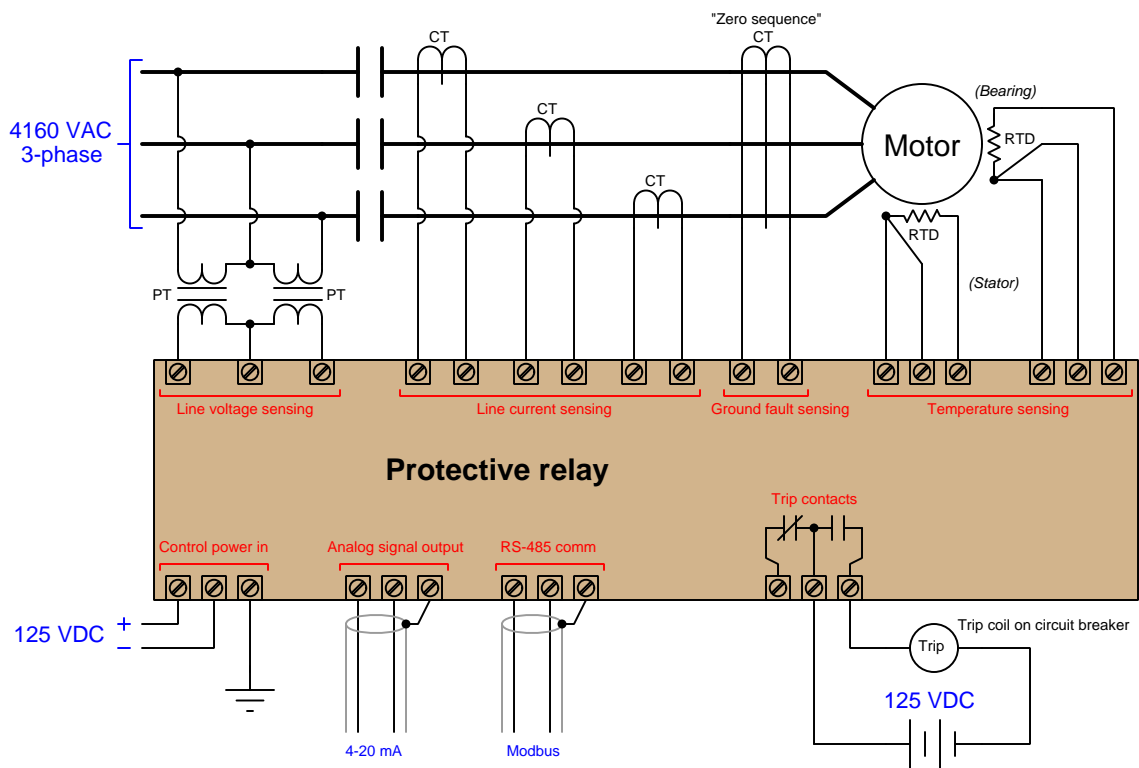

### Phasor diagram for (original) faulted generator

In a perfectly balanced three-phase power system, the only sequence in existence is the positive sequence (1). Any and all measurements of voltage and current, therefore, represent the positive sequence of the system. Since the magnitudes of the negative- and zero-sequence components are zero. If an imbalance occurs for any reason – from unbalanced single-phase loads on a three-phase power system to actual faults (opens, shorts) – negative-sequence and/or zero-sequence components arise.

While negative-sequence quantities cannot be measured directly by any voltmeter or ammeter, zero-sequence components can. In Y-connected systems, zero-sequence current manifests itself as current through the neutral conductor, while zero-sequence voltage manifests itself as voltage between the center of an ungrounded Wye and ground. Zero-sequence current manifests in Delta-connected systems as current *circulating* in the phase elements of the source or load.

The following illustration shows a medium-voltage (4160 volt) electric motor circuit equipped with a *protective relay* to halt the motor in the event its electrical or thermal parameters indicate the potential for damage:

Note the “zero sequence” current transformer (CT) encircling all three lines conducting power to the motor. This large CT magnetically senses the instantaneous sum of currents into and out of the motor, which should be zero under normal operating conditions. If, however, a ground fault develops within the motor, the instantaneous sum of currents will become non-zero, causing the “zero sequence CT” to register some current. If this zero-sequence current becomes large enough,

the protective relay will command the contactor feeding power to the motor to trip (open) in order to protect the motor against further damage.

This exact same principle is used in household “GFCI” (Ground Fault Current Interruptor) receptacles and circuit breakers required by the National Electrical Code to be used in “wet” areas of a residence such as bathrooms: a small current transformer senses the net sum of current through the “hot” and “neutral” conductors. If this net current measurement is anything but zero, the interruptor contacts trip, ceasing the flow of power to the load and thereby protecting the person using that load from injury due to ground-fault current passing through their body:

### Ground-Fault Current Interruptor (GFCI)

*Any current leaking from the load to earth ground is sensed as an imbalance of current by the CT*

## 5.9 Phasor analysis of transformer circuits

Three-phase AC is the dominant mode of electric power generation and distribution in modern societies. Analyzing voltages and currents in these systems can be quite complex, but phasor representation is a tool useful for simplifying that analysis by representing voltage and current quantities in graphical form. This section of the book illustrates the use of phasors as an analytical tool through examples. This section begins with single-phase phasor analysis and progresses to three-phase phasor analysis.

Extensive use of an imaginary instrument I call the “phasometer” helps relate phasor arrow direction to real circuit connections. For a detailed introduction to this instrument, see section 5.5.2 beginning on page 382. Suffice it to say, a “phasometer” is nothing more than a small synchronous AC motor with an arrow-shaped rotor, which when coupled with a strobe light set to flash whenever some reference voltage reaches its positive peak, graphically shows the relative phase of the measured quantity with respect to that reference voltage. In other words, a phasometer/strobe combination shows a “snapshot” view of the waveform’s position at that point in time when the reference wave is at its positive peak. This is precisely how phasors are drawn: arrows with angles displaced from  $0^\circ$  by an amount proportional to the phase shift between that quantity and some reference waveform.

Here is what a triplet of phasometers would indicate if connected to a three-phase power bus, with phase A used as the reference and given an ABC phase sequence (also called “phase rotation”):

In an ABC phase sequence, phase B's voltage lags behind phase A's voltage by  $120^\circ$ , while phase C's voltage leads ahead of phase A's voltage by  $120^\circ$  (or, one could say phase C lags a full  $240^\circ$  behind phase A).

### 5.9.1 Phasors in single-phase transformer circuits

Phasors are to AC circuit quantities as polarity is to DC circuit quantities, and for this reason they are particularly useful in analyzing transformer circuits because transformers by their very nature allow polarities to be mixed and matched.

In the “Basic principles” discussion of the “Transformers” section of this book (subsection 5.4.1 beginning on page 362), we used standard DC polarity marks (+ and −) to denote the polarity of voltage at an instant in time where the sinusoidal waves for each winding reached their peaks. Although it is often important to show the polarity of transformer windings relative to each other, the use of DC notation for this purpose can be misleading. An alternative symbology places a dot, or square, or some other distinguishing mark at one end of each transformer winding to show common polarity at any instant in time. The marked terminal of a transformer winding is called the “polarity” terminal, while the unmarked terminal is called the “nonpolarity” terminal:

#### Transformer polarity symbols

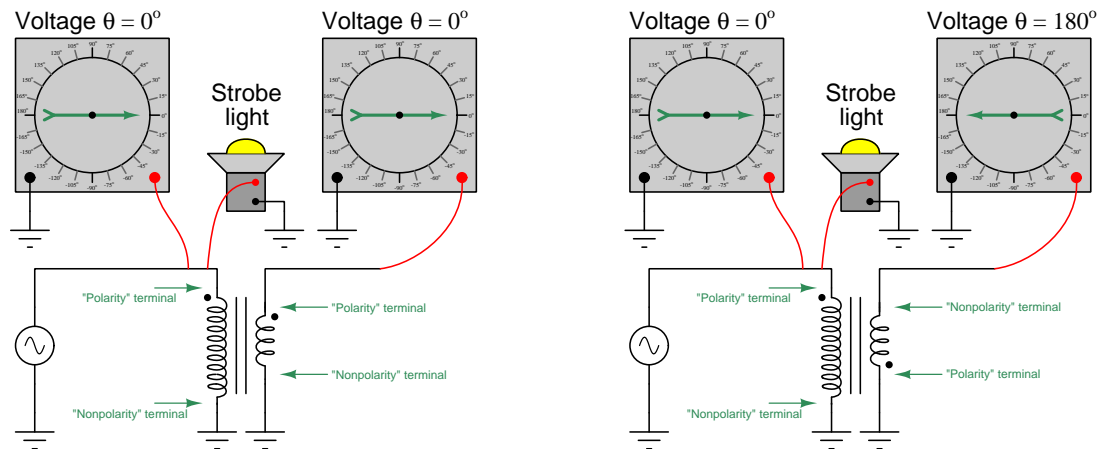

The marks should be interpreted in terms of *voltage polarity*, not current. To illustrate using a “test circuit<sup>49</sup>” feeding a momentary pulse of DC to a transformer:

If the battery polarity were reversed, the “polarity” (dot) terminal of each winding would be *negative* with respect to the “nonpolarity” terminal at the moment in time when the switch is pressed. That is to say, the “polarity” marks merely show which terminals will share the same instantaneous voltage polarity at any given point in time – not which terminal is always positive.

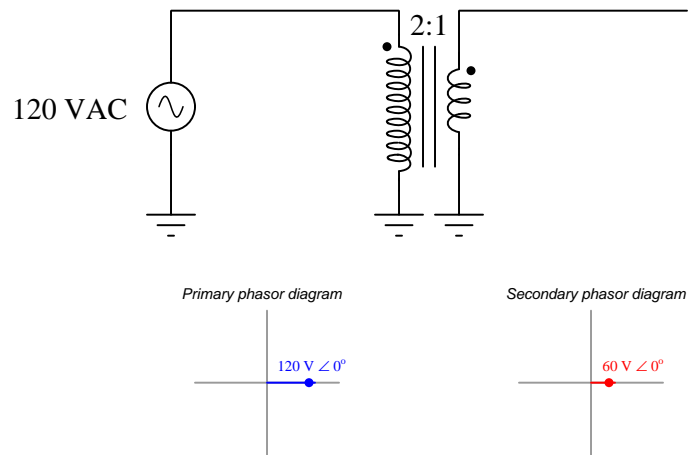

<sup>49</sup>The battery-and-switch test circuit shown here is not just hypothetical, but may actually be used to test the polarity of an unmarked transformer. Simply connect a DC voltmeter to the secondary winding while pressing and releasing the pushbutton switch: the voltmeter’s polarity indicated while the button is pressed will indicate the relative phasing of the two windings. Note that the voltmeter’s polarity will reverse when the pushbutton switch is released and the magnetic field collapses in the transformer coil, so be sure to pay attention to the voltmeter’s indication *only* during the instant the switch closes!

Consider these examples, where the polarity of a transformer's secondary winding is changed to illustrate the effect on AC phase shift from primary to secondary. In the left-hand example, the "polarity" terminal of the transformer's secondary winding exhibits a phase angle of  $0^\circ$  (with respect to ground) at the same point in time when the primary winding's voltage is at  $0^\circ$ : the two winding voltages are in-phase with each other. In the right-hand example, the secondary winding polarity has been reversed, the effect being a  $180^\circ$  phase shift in voltage. A pair of phasometers in each example, both synchronized to the positive peak of the primary voltage, shows the phase relationships clearly:

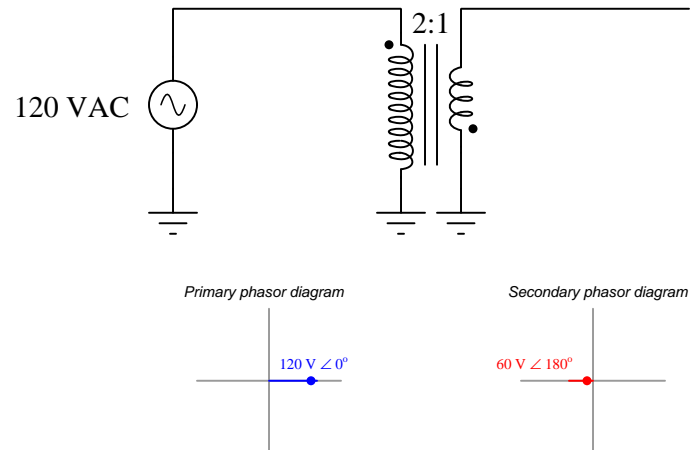

A useful way to analyze phase shifts in transformer circuits is to sketch separate phasor diagrams for the primary and secondary windings, and use the polarity marks on each winding to reference each phasor's position on the diagram. We begin this analysis by first sketching a phasor for any voltage of which the phase angle is given to us. Since transformer windings share common phase shift by virtue of those windings sharing the same magnetic field, the phasor representing the other winding's voltage must possess the same angle. The only distinction is the length of each phasor (representing primary and secondary voltage magnitudes) and its origin (starting point on the diagram).

Applying this analysis to the in-phase transformer circuit example. We will regard the secondary winding's voltage as a phasor that is half the length of the primary winding's voltage given the 2:1 turns ratio, but oriented at the same angle:

The result is a pair of phasors both at  $0^\circ$  angles. Note the placement of dots on each phasor to mark the relationship of the phasor to each winding polarity. The center of the diagram where the real and imaginary axes intersect is the point representing zero potential (ground). The length of each phasor tells us the magnitude of each waveform, in this case 120 volts and 60 volts AC, respectively. The “nonpolarity” end of each phasor line must be located at the origin because the nonpolarity terminal of each transformer winding is connected to ground.

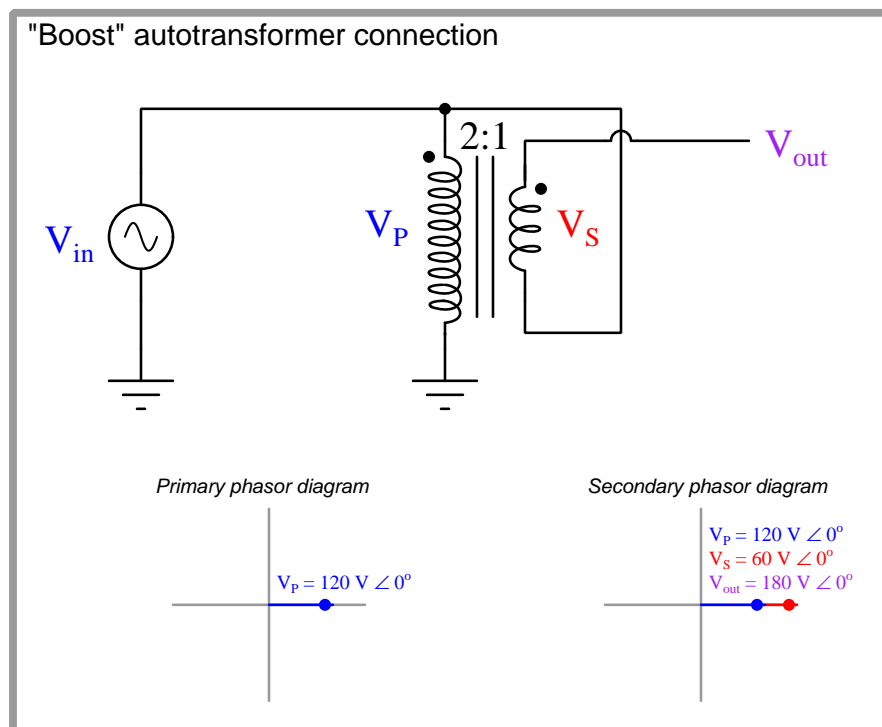

Now consider the same analysis applied to the out-of-phase transformer circuit:

The result of this transformer connection is a pair of horizontal phasors, angled  $180^\circ$  apart from each other. Note how the secondary phasor still has its polarity mark on the right-hand end, but now that end of the phasor is anchored at the diagram's origin because now the “polarity” (dot) terminal of the transformer's secondary winding is connected to ground. Following our rule of keeping primary and secondary phasors at equal angles, the only difference made by grounding the opposite terminal of the secondary winding is the reference point of the secondary phasor. The secondary phasor must remain locked at the same angle as the primary phasor, but its position on the diagram is determined by where the transformer winding connects to ground.

The following analyses illustrate the relationships between phase angles, transformer polarity, circuit connections, and phasor diagrams.

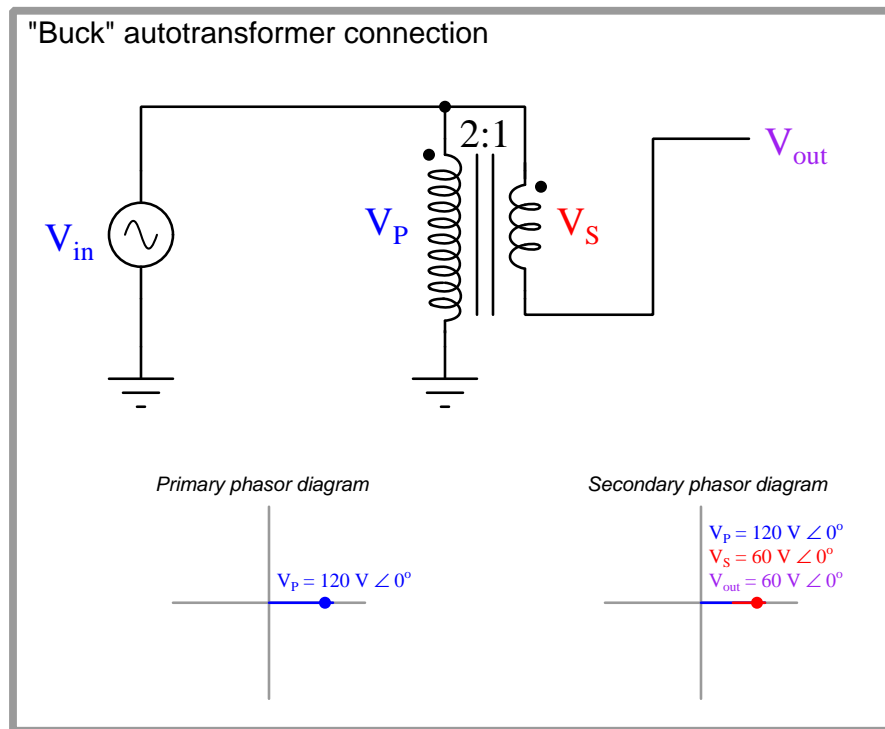

Here we have an “autotransformer<sup>50</sup>” connected to *boost* the primary voltage. The  $V_P$  and  $V_S$  phasors representing voltage across the primary and secondary windings must have common angles (i.e. both horizontal phasors), but the secondary phasor is “stacked” on the end of the primary phasor to create a longer phasor representing the voltage  $V_{out}$  with reference to ground. We can tell the phasors will be stacked polarity-end-to-nonpolarity-end because that is how the two transformer windings are electrically connected to each other:

The result of this “boost” configuration is an output voltage that is the direct sum of the primary and secondary winding voltages: 180 volts with a 2:1 transformer ratio and 120 volt source. If the transformer ratio were 4:1 instead of 2:1, the output would be 150 volts ( $120 \text{ volts} + \frac{120}{4} \text{ volts}$ ).

<sup>50</sup>An *autotransformer* is any transformer configuration where the primary and secondary windings are connected rather than galvanically isolated from each other as is typical.

Here we have another autotransformer, this time connected to *buck* the primary voltage. The  $V_P$  and  $V_S$  phasors still share common angles, but now they are “stacked” differently: polarity-end-to-polarity-end. This is challenging to see on the second phasor diagram because the  $V_P$  and  $V_S$  overlap each other, sharing a common “polarity” (dot) end point:

The result of this “buck” configuration is a  $V_{out}$  that is the *difference* between  $V_P$  and  $V_S$  rather than being the sum of the two as was the case with the “boost” configuration. If the transformer ratio were 4:1 instead of 2:1, the output of this buck autotransformer would be 90 volts (120 volts  $-\frac{120}{4}$  volts).

### 5.9.2 Phasors in three-phase transformer circuits

In the following three-phase transformer circuit, each transformer has been labeled with a number, and each pair of phasors representing primary and secondary winding voltages for each transformer has that same identifying number written next to it for convenient reference. Numbering the phasors makes it clear which phasor(s) belong to which transformer.

As usual, the primary and secondary phasors for each transformer share the same angle, but the secondary phasors are “stacked” polarity-end-to-nonpolarity-end because that is precisely how the secondary windings are electrically connected to each other. Assuming an ABC phase sequence with  $V_A$  being the reference phasor defining  $0^\circ$  phase angle:

## 5.10 Transmission lines

Many years ago, when I was first learning about electricity, I happened to discover a length of coaxial television cable with the rating “50 ohm” printed on the jacket. Having my own ohmmeter, and wanting to know what the “50 ohm” label referred to, I tried measuring the resistance of this cable to see where it would exhibit 50 ohms of resistance. First I tried measuring between the two open-ended wires (the center conductor and the braided shield conductor), where my meter registered infinite resistance (no continuity). This is what I expected a normal cable would read when connected to nothing else. Next I tried connecting my meter from one end of the cable to the other: between both ends of the center conductor my meter registered 0 ohms, and between both ends of the shield conductor my meter also read 0 ohms. In fact, this is all I was ever able to measure with my ohmmeter: either 0 ohms or infinite ohms (open), no matter what I tried. I was confounded – how could this piece of cable possibly be called a “50 ohm” cable if I could not measure 50 ohms anywhere on it?

It was not until years later that I came across a reference in an old book to something called *surge impedance*, describing how lengths of cable responded to short-duration electrical pulses, that I finally understood the “50 ohm” rating of that coaxial cable. What I failed to discover with my ohmmeter – in fact, what I never could have even seen with a plain ohmmeter – is that the cable did indeed act like a 50 ohm resistor, *but only for extremely short periods of time*. This is an aspect of electrical theory I was completely unprepared to comprehend at that time, knowing only how DC circuits functioned. This is the subject we are about to explore now.

In basic DC electrical theory, students learn that open circuits always drop the full applied voltage and cannot have electric currents anywhere in them. Students likewise learn that short

circuits drop negligible voltage while conducting full electrical current. They also learn that the effects of electricity occur instantaneously throughout the circuit: for example, if a functioning circuit suffers an “open” fault, current through that branch of the circuit halts immediately and everywhere. These basic rules of electricity are extremely useful for DC circuit analysis, indeed even essential for troubleshooting DC circuits, but they are not 100% correct. Like many of the scientific principles one initially learns, they are only approximations of reality.

The effects of electricity do *not* propagate instantaneously throughout a circuit, but rather spread at the speed of light (approximately 300,000,000 meters per second). Normally we never see any consequences of this finite speed because everything happens so fast, just as I never saw my ohmmeter register 50 ohms when I tried to test that coaxial cable many years ago. However, when we test a circuit on a time scale of nano-seconds (*billionths* of a second!), we find some very interesting phenomena during the time electricity propagates along the length of a circuit: open circuits can indeed (temporarily) exhibit current, and short circuits can indeed (temporarily) exhibit voltage drops.

When a pulse signal is applied to the beginning of a two-conductor cable, the reactive elements of that cable (i.e. capacitance between the conductors, inductance along the cable length) begin to store energy. This translates to a current drawn by the cable from the source of the pulse, as though the cable were acting as a (momentarily) resistive load. If the cable under test were infinitely long, this charging effect would never end, and the cable would indeed behave exactly like a resistor from the perspective of the signal source. However, real cables (having finite length) do stop “charging” after some time following the application of a voltage signal at one end, the length of that time being a function of the cable’s physical length and the speed of light.

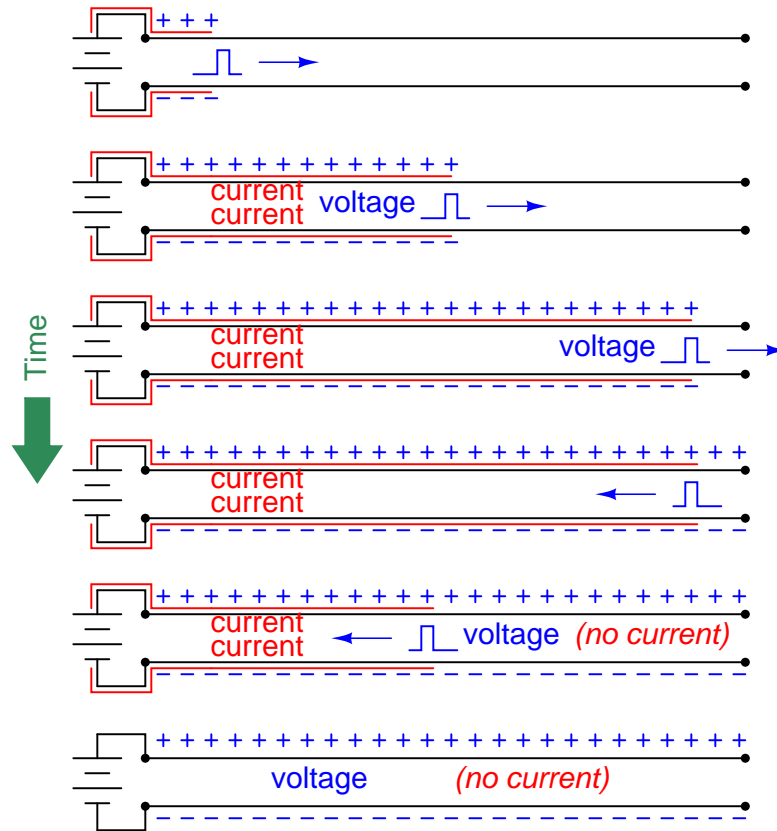

In honor of the cable’s capacity to behave as a temporary load to any impressed signal, we typically refer to it as something more than just a cable. From the perspective of an electrical pulse, measured on a time scale of nanoseconds, we refer to any cable as a *transmission line*. All electrical cables act as transmission lines, but the effects just mentioned are so brief in duration that we only notice them when the cable is exceptionally long and/or the pulse durations are exceptionally short (i.e. high-frequency signals).

During the time when a transmission line is absorbing energy from a power source – whether this is indefinitely for a transmission line of infinite length, or momentarily for a transmission line of finite length – the current it draws will be in direct proportion to the voltage applied by the source. In other words, a transmission line behaves like a resistor, at least for a moment. The amount of “resistance” presented by a transmission line is called its *characteristic impedance*, or *surge impedance*, symbolized in equations as  $Z_0$ . Only after the pulse signal has had time to travel down the length of the transmission line and reflect back to the source does the cable stop acting as a load and begin acting as a plain pair of wires.

A transmission line’s characteristic impedance is a function of its conductor geometry (wire diameter, spacing) and the permittivity of the dielectric separating those conductors. If the line’s design is altered to increase its bulk capacitance and/or decrease its bulk inductance (e.g. decreasing the distance between conductors), the characteristic impedance will decrease. Conversely, if the transmission line is altered such that its bulk capacitance decreases and/or its bulk inductance increases, the characteristic impedance will increase. It should be noted that the length of the transmission line has absolutely no bearing on characteristic impedance. A 10-meter length of RG-58/U coaxial cable will have the exact same characteristic impedance as a 10000 kilometer length of RG-58/U coaxial cable (50 ohms, in both cases). The only difference is the *length of time* the cable will behave like a resistor to an applied voltage.

### 5.10.1 Open-ended transmission lines

The following sequence illustrates the propagation of a voltage pulse forward and back (reflected) on an open-ended transmission line beginning from the time the DC voltage source is first connected to the left-hand end:

The end result is a transmission line exhibiting the full source voltage, but no current. This is exactly what we would expect in an open circuit. However, during the time it took for the pulse to travel down the line's length and back, it drew current from the source equal to the source voltage divided by the cable's characteristic impedance ( $I_{surge} = \frac{V_{source}}{Z_0}$ ). For a brief amount of time, the two-conductor transmission line acted as a *load* to the voltage source rather than an open circuit. Only after the pulse traveled down the full length of the line and back did the line finally act as a plain open circuit.

An experiment performed with a square-wave signal generator and oscilloscope<sup>51</sup> connected to one end of a long wire pair cable (open on the far end) shows the effect of the reflected signal:

The waveform steps up for a brief time, then steps up further to full source voltage. The first step represents the voltage at the source during the time the pulse traveled along the cable's length, when the cable's characteristic impedance acted as a load to the signal generator (making its output voltage "sag" to a value less than its full potential). The next step represents the reflected pulse's return to the signal generator, when the cable's capacitance is fully charged and is no longer drawing current from the signal generator (making its output voltage "rise"). A two-step "fall" appears at the trailing edge of the pulse, when the signal generator reverses polarity and sends an opposing pulse down the cable.

The duration of the first and last "steps" on the waveform represents the time taken by the signal to propagate down the length of the cable *and* return to the source. This oscilloscope's timebase was set to 0.5 microseconds per division for this experiment, indicating a pulse round-trip travel time of approximately 0.2 microseconds. A cable of this type has a *velocity factor* of approximately 0.7, which means electrical impulses travel at only 70% the speed of light through the cable, and so the round-trip distance calculates to be approximately 42 meters which makes the cable 21 meters in length:

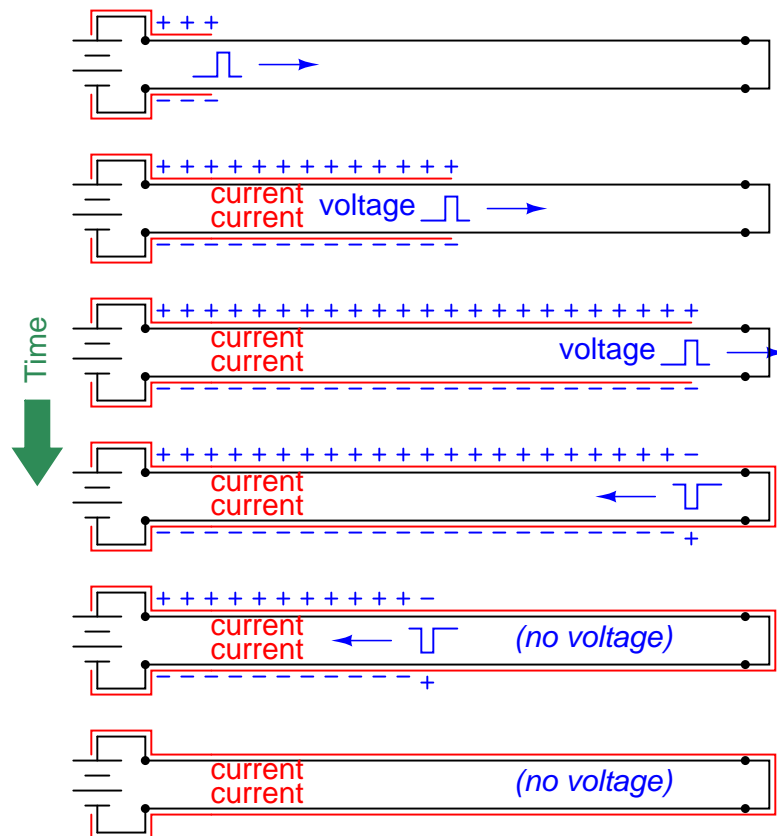

$$\text{Distance} = \text{Velocity} \times \text{Time} = (70\%)(3 \times 10^8 \text{ m/s})(0.2 \mu\text{s}) = 42 \text{ m}$$

$$\text{Cable length} = \frac{1}{2}(\text{Distance traveled by pulse}) = (0.5)(42 \text{ m}) = 21 \text{ m}$$

<sup>51</sup>The signal generator was set to a frequency of approximately 240 kHz with a Thévenin resistance of 118 ohms to closely match the cable's characteristic impedance of 120 ohms. The signal amplitude was just over 6 volts peak-to-peak.

### 5.10.2 Shorted transmission lines

The following sequence illustrates the propagation of a voltage pulse forward and back (reflected) on a shorted-end transmission line beginning from the time the DC voltage source is first connected to the left-hand end:

The end result is a transmission line exhibiting the full current of the source ( $I_{max} = \frac{V_{source}}{R_{wire}}$ ), but no voltage. This is exactly what we would expect in a short circuit. However, during the time it took for the pulse to travel down the line's length and back, it drew current from the source equal to the source voltage divided by the cable's characteristic impedance ( $I_{surge} = \frac{V_{source}}{Z_0}$ ). For a brief amount of time, the two-conductor transmission line acted as a moderate *load* to the voltage source rather than a direct short. Only after the pulse traveled down the full length of the line and back did the line finally act as a plain short-circuit.

An experiment performed with the same signal generator and oscilloscope connected to one end of the same long wire pair cable (shorted on the far end) shows the effect of the reflected signal:

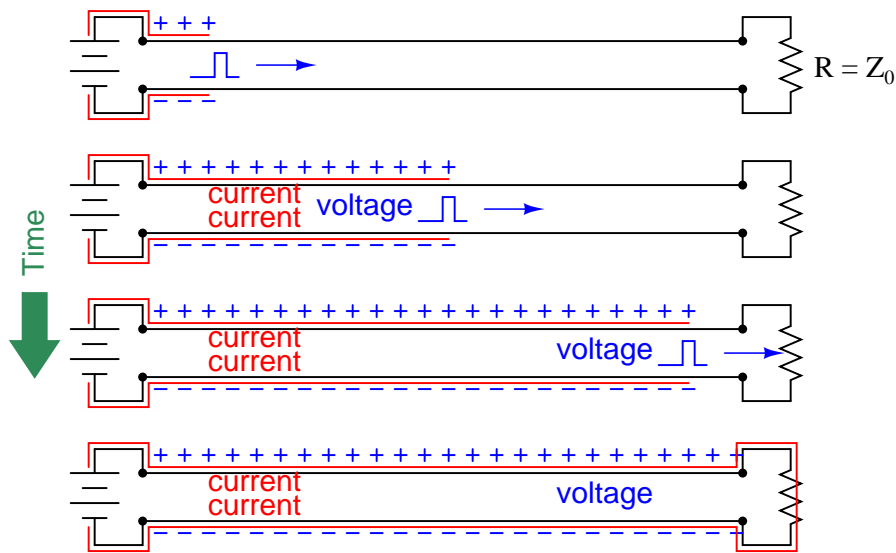

Here, the waveform steps up for a brief time, then steps down toward zero. As before, the first step represents the voltage at the source during the time the pulse traveled along the cable's length, when the cable's characteristic impedance acted as a load to the signal generator (making its output voltage "sag" to a value less than its full potential). The step down represents the (inverted) reflected pulse's return to the signal generator, nearly canceling the incident voltage and causing the signal to fall toward zero. A similar pattern appears at the trailing edge of the pulse, when the signal generator reverses polarity and sends an opposing pulse down the cable.

Note the duration of the pulse on this waveform, compared to the first and last "steps" on the open-circuited waveform. This pulse width represents the time taken by the signal to propagate down the length of the cable *and* return to the source. This oscilloscope's timebase remained at 0.5 microseconds per division for this experiment as well, indicating the same pulse round-trip travel time of approximately 0.2 microseconds. This stands to reason, as the cable length was not altered between tests; only the type of termination (short versus open).

### 5.10.3 Properly terminated transmission lines

Proper “termination” of a transmission line consists of connecting a resistance to the end(s) of the line so that the pulse “sees” the exact same amount of impedance at the end as it did while propagating along the line’s length. The purpose of the termination resistor is to completely dissipate the pulse’s energy in order that none of it will be reflected back to the source.

The following sequence illustrates the propagation of a voltage pulse on a transmission line with proper “termination” (i.e. a resistor matching the line’s surge impedance, connected to the far end) beginning from the time the DC voltage source is first connected to the left-hand end:

From the perspective of the pulse source, this properly terminated transmission line “looks” the same as an unterminated line of infinite length. There is no reflected pulse, and the DC voltage source “sees” an unchanging load resistance the entire time.

An experiment performed with a termination resistor in place shows the near-elimination of reflected pulses:

The pulse looks much more like the square wave it should be, now that the cable has been properly terminated<sup>52</sup>. With the termination resistor in place, a transmission line *always* presents the same impedance to the source, no matter what the signal level or the time of signal application. Another way to think of this is from the perspective of cable length. With the proper size of termination resistor in place, *the cable appears infinitely long* from the perspective of the power source because it never reflects any signals back to the source and it always consumes power from the source.

Data communication cables for digital instruments behave as transmission lines, and must be terminated at both ends to prevent signal reflections. Reflected signals (or “echoes”) may cause errors in received data in a communications network, which is why proper termination can be so important. For point-to-point networks (networks formed by exactly two electronic devices, one at either end of a single cable), the proper termination resistance is often designed into the transmission and receiving circuitry, and so no external resistors need be connected. For “multi-drop” networks where multiple electronic devices tap into the same electrical cable, excessive signal loading would occur if each and every device had its own built-in termination resistance, and so the devices are built with no internal termination, and the installer must place two termination resistors in the network (one at each far end of the cable).

---

<sup>52</sup>The termination shown here is imperfect, as evidenced by the irregular amplitude of the square wave. The cable used for this experiment was a length of twin-lead speaker cable, with a characteristic impedance of approximately 120 ohms. I used a 120 ohm ( $\pm 5\%$ ) resistor to terminate the cable, which apparently was not close enough to eliminate all reflections.

#### 5.10.4 Discontinuities

A transmission line's characteristic impedance will be constant throughout its length so long as its conductor geometry and dielectric properties are consistent throughout its length. Abrupt changes in either of these parameters, however, will create a *discontinuity* in the cable capable of producing signal reflections. This is why transmission lines must never be sharply bent, crimped, pinched, twisted, or otherwise deformed.

The probe for a guided-wave radar (GWR) liquid level transmitter is another example of a transmission line, one where the vapor/liquid interface creates a discontinuity: there will be an abrupt change in characteristic impedance between the transmission line in vapor space versus the transmission line submerged in a liquid due to the differing dielectric permittivities of the two substances. This sudden change in characteristic impedance sends a reflected signal back to the transmitter. The time delay measured between the signal's transmission and the signal's reception by the transmitter represents the vapor space distance, or *ullage*.

For more detail on the theory and function of radar level measurement, see section [20.5.2](#) beginning on page [1473](#).

#### 5.10.5 Velocity factor

The speed at which an electrical signal propagates down a transmission line is never as fast as the speed of light in a vacuum, owing to the permittivity of the line's electrical insulation being greater than that of a vacuum. A value called the *velocity factor* expresses the propagation velocity as a ratio to light, and its value is always less than one:

$$\text{Velocity factor} = \frac{v}{c}$$

Where,

$v$  = Propagation velocity of signal traveling along the transmission line

$c$  = Speed of light in a vacuum ( $\approx 3.0 \times 10^8$  meters per second)

Velocity factor is a function of dielectric constant, but not conductor geometry. A greater permittivity value results in a slower velocity (lesser velocity factor).

### 5.10.6 Cable losses

Ideally, a transmission line is a perfectly loss-less conduit for electrical energy. That is, every watt of signal power entering the transmission line is available at the end where the load is connected. In reality, though, this is never the case. Conductor resistance, as well as losses within the dielectric (insulating) materials of the cable, rob the signal of energy.

For transmission lines, power loss is typically expressed in units of decibels per 100 feet or per 100 meters. A “decibel,” as you may recall, is ten times the logarithm of a power ratio:

$$\text{Gain or Loss in dB} = 10 \log \left( \frac{P}{P_{ref}} \right)$$

Thus, if a transmission line receives 25 milliwatts of signal power at one end, but only conveys 18 milliwatts to the far end, it has suffered a 1.427 dB loss ( $10 \log \frac{0.018}{0.025} = -1.427$  dB) from end to end. Power loss in cables is strongly dependent on frequency: the greater the signal frequency, the more severe the power loss per unit cable length.

## 5.11 Antennas

Capacitors store energy in electric fields, proportional to the square of voltage. Inductors store energy in magnetic fields, proportional to the square of current. If capacitors and inductors are connected together, their complementary energy storage modes create a condition where electrical energy transfers back and forth between the capacitance and the inductance: voltage and current both oscillating sinusoidally. We refer to this cyclic exchange of energy as *resonance*. The simplest resonant circuit possible is the so-called *tank circuit*, comprised of a single inductor connected to a single capacitor:

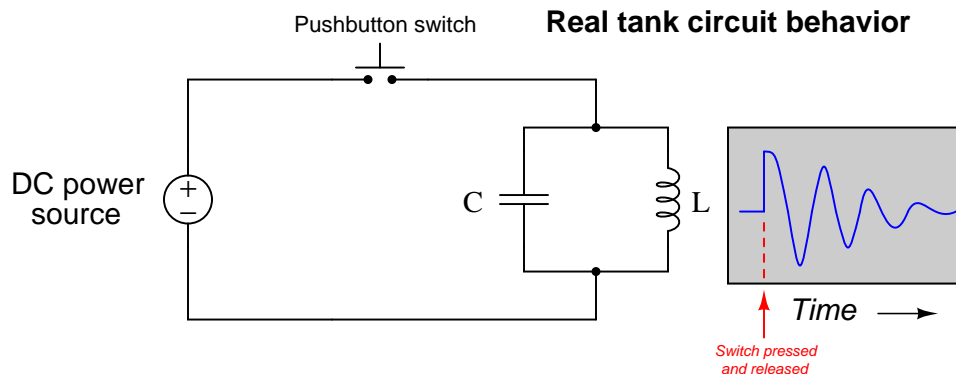

The natural frequency at which a tank circuit oscillates is given by the formula  $f_r = \frac{1}{2\pi\sqrt{LC}}$ , where  $f_r$  is the resonant frequency in Hertz,  $C$  is the capacitance in Farads, and  $L$  is the inductance in Henrys.

A perfect tank circuit – devoid of electrical resistance and any other energy-dissipating characteristics (e.g. capacitor dielectric losses, inductor hysteresis losses) – would continue to oscillate forever once initially stimulated. That is, if initially “charged” with an impulse of DC voltage, the tank circuit would continue to produce AC voltage and current oscillations at its resonant frequency, at constant peak amplitude, forever:

Since real capacitors and inductors are not lossless, real tank circuits exhibit decaying-amplitude oscillations after initial “charging,” until no energy is stored in either the capacitor or the inductor:

Capacitive losses take the form of heat loss in the dielectric substance separating the capacitor plates. The electric field between the capacitor’s plates imparts forces on any polar<sup>53</sup> molecules within that substance, thereby doing “work” on those molecules by forcing them back and forth as the electric field alternates. Though these forces and motions are extremely small, they are nevertheless capable of draining considerable energy from the capacitor, dissipating it in the form of heat.

Inductive losses are similar, but in the form of work done on ferromagnetic molecules in the core material as the magnetic field alternates polarity. Like dielectric heating, magnetic losses also drain energy from the inductor, dissipating it in the form of heat.

Of course, both capacitors and inductors also contain ohmic resistance in the metals used to form the plates and wire coils, respectively. Resistance naturally dissipates energy in the form of heat, constituting another energy-loss mechanism for both capacitors and inductors (albeit much more significant in inductors than in capacitors!).

The combined effect of all these energy-loss mechanisms is that the oscillations of an unpowered tank circuit decay over time, until they cease completely. This is similar in principle to a pendulum gradually coming to a halt after being set in motion with a single push: if not for air resistance and other forms of friction, the pendulum should swing forever! With air friction and mechanical friction in the pendulum’s bearing, though, a pendulum’s oscillations gradually diminish in amplitude until all its energy has been lost – swing by swing – to heat.

<sup>53</sup>A “polar” molecule is one where the constituent atoms are bound together in such a way that there is a definite electrical polarity from one end of the molecule to the other. Water (H<sub>2</sub>O) is an example of a polar molecule: the positively charged hydrogen atoms are bound to the negatively charged oxygen atom in a “V” shape, so the molecule as a whole has a positive side and a negative side which allows the molecule to be influenced by external electric fields. Carbon dioxide (CO<sub>2</sub>) is an example of a non-polar molecule whose constituent atoms lie in a straight line with no apparent electrical poles. Interestingly, microwave ovens exploit the fact of water molecules’ polarization by subjecting food containing water to a strong oscillating electric field (microwave energy in the gigahertz frequency range) which causes the water molecules to rotate as they continuously orient themselves to the changing field polarity. This oscillatory rotation manifests itself as heat within the food.

Capacitance and inductance, however, are not limited to capacitors and inductors: *any* pair of conductors separated by an insulating medium will exhibit capacitance, and *any* electrical conductor will exhibit inductance along its length. Even a two-conductor cable (a *transmission line*) has distributed capacitance and inductance capable of storing energy. If a long, unterminated (no load connected to the far end) cable is “charged” by a pulse of applied DC voltage, it will sustain a series of echoing pulses at a period dependent on the cable’s length and velocity factor:

The ability for a transmission line to support periodic signal “echoes” means it may also resonate when energized by an AC power source, just like a tank circuit. Unlike a tank circuit, however, a transmission line is able to resonate at more than one frequency: a “fundamental” frequency, or any whole-number multiple of that fundamental frequency called a *harmonic frequency*. For example, an unterminated transmission line with a length of 1 kilometer and a velocity factor of 0.7 has a round-trip echo time (period) of 9.53 microseconds, equivalent to a resonant frequency of 104.9 kHz. However, it will resonate equally well at exactly twice this fundamental frequency (209.8 kHz – the *second harmonic* of 104.9 kHz) as well as three times the fundamental frequency (314.8 kHz – the *third harmonic* of 104.9 kHz), etc. A simple LC tank circuit, by contrast, will only resonate at a single frequency.

This “poly-resonant” behavior of transmission lines has an analogue in the world of music. “Wind” instruments such as trombones, flutes, trumpets, saxophones, clarinets, recorders, etc., are really nothing more than tubes with at least one open end. These tubes will acoustically resonate at specific frequencies when “excited” by turbulent air flow at one end. The lowest frequency such a tube will resonate at is its “fundamental” frequency, but increasing the turbulence of the incoming air flow will cause the tone to “jump” to some harmonic of that fundamental frequency. The fundamental frequency of the tube may be altered by changing the length of the tube (e.g. as in a trombone or trumpet) or by opening ports along the tube’s length to alter its effective length (flute, saxophone, clarinet, recorder, etc.).

If we were to alter our transmission line test circuit, splaying the two conductors apart from each other rather than running them alongside one another, it would also form another type of resonant circuit, owing to the distributed capacitance and inductance along the wires' lengths:

This special case of resonant circuit has some very interesting properties. First, its resonant frequency is quite high, because the distributed inductance and capacitance values are extremely small compared to the values of discrete components such as inductors and capacitors. Second, it is a very “lossy” circuit despite having no appreciable electrical resistance to dissipate energy, no solid insulating medium to incur dielectric losses, and no ferromagnetic core to exhibit hysteresis losses. This special form of resonant circuit loses energy not to heat, but rather to *electromagnetic radiation*. In other words, the energy in the electric and magnetic fields leave the circuit and propagate through space in the form of *electro-magnetic waves*, or what we more commonly refer to now as *radio waves*: a series of electric and magnetic fields oscillating as they radiate away from the wires at the speed of light.

Tank circuits and transmission lines do not radiate energy because they are intentionally designed to *contain* their fields: capacitors are designed to fully contain their electric fields, inductors are designed to fully contain their magnetic fields, and the fields within transmission lines are likewise constrained. Our two-wire resonant circuit, by contrast, does just the opposite: its electric and magnetic fields are exposed to open space with no containment whatsoever. What we have built here is not a tank circuit nor a transmission line, but rather an *antenna*<sup>54</sup>: a structure designed to radiate electric and magnetic fields as waves into surrounding space.

<sup>54</sup>An older term used by radio pioneers to describe antennas is *radiator*, which I personally find very descriptive. The word “antenna” does an admirable job describing the physical appearance of the structure – like antennas on an insect – but the word “radiator” actually describes its *function*, which is a far more useful principle for our purposes.

### 5.11.1 Maxwell and Hertz

An interesting historical footnote is that this phenomenon of electromagnetic waves propagating through space was predicted theoretically before it was demonstrated experimentally. A Scottish physicist named James Clerk Maxwell made an astonishing theoretical prediction which he published in 1873, expressed in these four equations:

$$\oint \mathbf{E} \cdot d\mathbf{A} = \frac{Q}{\epsilon_0}$$

$$\oint \mathbf{B} \cdot d\mathbf{A} = 0$$

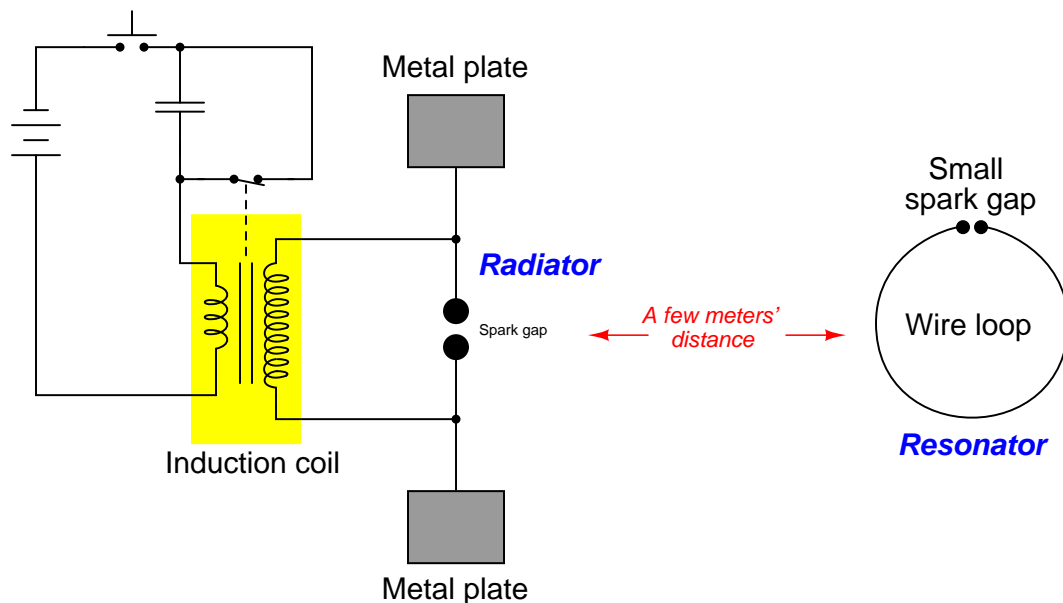

$$\oint \mathbf{E} \cdot d\mathbf{s} = -\frac{d\Phi_B}{dt}$$

$$\oint \mathbf{B} \cdot d\mathbf{s} = \mu_0 I + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}$$

The last two equations hold the most interest to us with respect to electromagnetic waves. The third equation states that an electric field ( $\mathbf{E}$ ) will be produced in open space by a changing magnetic flux ( $\frac{d\Phi_B}{dt}$ ). The fourth equation states that a magnetic field ( $\mathbf{B}$ ) will be produced in open space either by an electric current ( $I$ ) or by a changing electric flux ( $\frac{d\Phi_E}{dt}$ ). Given this complementary relationship, Maxwell reasoned, it was possible for a changing electric field to create a changing magnetic field which would then create another changing electric field, and so on. This cause-and-effect cycle could continue, ad infinitum, with fast-changing electric and magnetic fields radiating off into open space without needing wires to carry or guide them. In other words, the complementary fields would be self-sustaining as they traveled.

The Prussian Academy of Science offered a reward to anyone who could experimentally validate Maxwell's prediction, and this challenge was met by Professor Heinrich Hertz at the Engineering College in Karlsruhe, Germany in 1887, eight years after Maxwell's death. Hertz constructed and tested a pair of devices: a "radiator" to produce the electromagnetic waves, and a "resonator" to receive them.

A simplified diagram showing Hertz's experimental device is shown here:

An “induction coil” (a buzzing device constructed of a self-interrupting relay and step-up transformer winding to generate a continuous pulsing waveform of high voltage) provided an extremely noisy (i.e. frequency-rich) AC signal to the radiator, while a spark gap at the resonator provided indication that the electromagnetic waves were captured and converted into voltage by the resonator wire.

Both the radiator and the resonator are what we would now call *antennas*. The purpose of the transmitting antenna (radiator) is to take high-frequency AC power and radiate that power in the form of electromagnetic waves: self-sustaining electric and magnetic fields propagating out into open space. The purpose of the receiving antenna is to capture those electromagnetic waves and convert them into an AC signal. All antennas – from historical to the most modern – behave in fundamentally the same way: energize them with high-frequency AC power, and they will radiate electromagnetic waves at that frequency; expose them to electromagnetic waves, and they will produce a very small AC signal at the same frequency as the incident radiation.

### 5.11.2 Antenna size

Earlier it was mentioned that antennas are fundamentally *resonant* elements: they “prefer” to electrically oscillate at a fundamental frequency (and at whole-number multiples of that fundamental frequency). An antenna will behave most efficiently – whether transmitting or receiving – when operated in a condition of resonance. The relationship between ideal frequency and antenna length is inverse: the longer the antenna, the lower its fundamental frequency, and vice-versa. This is the same mathematical relationship we see between frequency and wavelength ( $\lambda$ ) for any moving wave:

$$v = \lambda f$$

The prototypical antenna shown earlier – with two wires oriented  $180^\circ$  from each other – operates best at a wavelength twice as long as the total length of wire.

A “half-wave” dipole antenna with a total length of 5 meters<sup>55</sup> will radiate optimally at a frequency of 30 MHz, given that the velocity of electromagnetic waves in open space is approximately  $3 \times 10^8$  meters per second. This same antenna will also effectively resonate at any *harmonic* (integer multiple) of 30 MHz (e.g. 60 MHz, 90 MHz, 120 MHz, etc.) just as a transmission line is able to resonate at a fundamental frequency as well as any harmonic thereof.

<sup>55</sup>In practice, the ideal length of a dipole antenna turns out to be just a bit shorter than theoretical, due to lumped-capacitive effects at the wire ends. Thus, a resonant 30 MHz half-wave dipole antenna should actually be about 4.75 meters in length rather than exactly 5 meters in length.

A popular variation on the theme of the half-wave dipole antenna is the so-called *quarter-wave* or “whip” antenna, which is exactly what you might think it is: one-half of a half-wave antenna. Instead of two wires pointed away from each other, we substitute an earth-ground connection for one of the wires:

Quarter-wave antennas tend to be less effective than half-wave antennas, but are usually much more convenient to construct for real applications.

### 5.11.3 Antenna orientation and directionality

Another factor affecting antenna performance is the orientation of the receiving antenna with respect to the transmitting antenna. Antenna conductors should be *parallel* to each other in order to maximize reception, in order that the electric and magnetic fields emanating from the wires of the transmitting antenna will “link” properly with the wires of the receiving antenna(s). If the goal is optimum communication in any direction (omnidirectionality), dipole and whip antennas should be arranged *vertically* so that all antenna conductors will be parallel to each other regardless of their geographic location.

Omnidirectionality may seem like a universally good trait for any antenna: to be able to transmit and receive electromagnetic waves equally well in any direction. However, there are good reasons for wanting directionality in an antenna. One reason is for greater security: perhaps you have an application where you do *not* wish to broadcast information in all directions, where anyone at all could receive that information. In that case, the best antennas to use would be those that work best in one direction and one direction only, with transmitting and receiving antenna pairs pointed directly at each other.

Another reason for antenna directionality is improved reception. As noted before, the AC signal received at an antenna is very small, typically on the order of *microvolts*. Since electromagnetic radiation tends to “spread” as it travels, becoming weaker with distance from the transmitting antenna, long-range radio communication benefits from increased sensitivity. A transmitting antenna that is directional will focus more of its power in one direction than in others, resulting in less “wasted” power radiated in unwanted directions. Likewise, a receiving antenna that is directional does a better job of “collecting” the electromagnetic energy it receives from that direction (as well as ignoring electromagnetic waves coming from other directions).

A simple yet highly effective antenna design for directional transmission and reception is the *Yagi*, named after its inventor. A Yagi is based on a half-wave dipole element surrounded by one or more wires longer than  $\lambda/2$  to the rear (called “reflectors”) and one or more wires shorter than  $\lambda/2$  to the front (called “directors”). The terms “reflector” and “director” are quite apt, describing their interaction with electromagnetic waves from the perspective of the dipole: reflectors *reflect* the waves, while directors *direct* the waves. The result is an antenna array that is much more directional than a simple dipole:

*"Yagi" antenna operating  
in transmission mode*

*"Yagi" antenna operating  
in reception mode*

An example of a Yagi antenna used as part of a SCADA system is shown in this photograph, the antenna of course being the multi-element array in the upper-right corner:

Another example of a highly directional antenna design is the *parabolic dish*, often used in microwave and satellite communications. This photograph shows two “dish” antennas, one open to the weather (right) and the other covered with a weather-proof diaphragm to keep the antenna elements protected (left):

Some dish antennas use mesh or metal-tube reflectors rather than a solid parabolic reflector, as is the case in this next photograph:

## Chapter 6

# Introduction to industrial instrumentation

Instrumentation is the science of automated measurement and control. Applications of this science abound in modern research, industry, and everyday living. From automobile engine control systems to home thermostats to aircraft autopilots to the manufacture of pharmaceutical drugs, automation surrounds us. This chapter explains some of the fundamental principles of industrial instrumentation.

The first step, naturally, is measurement. If we can't measure something, it is really pointless to try to control it. This "something" usually takes one of the following forms in industry:

- Fluid pressure
- Fluid flow rate
- The temperature of an object
- Fluid volume stored in a vessel
- Chemical concentration
- Machine position, motion, or acceleration
- Physical dimension(s) of an object
- Count (inventory) of objects
- Electrical voltage, current, or resistance

Once we measure the quantity we are interested in, we usually transmit a signal representing this quantity to an indicating or computing device where either human or automated action then takes place. If the controlling action is automated, the computer sends a signal to a final controlling device which then influences the quantity being measured.

This final control device usually takes one of the following forms:

- Control valve (for throttling the flow rate of a fluid)
- Electric motor
- Electric heater

Both the measurement device and the final control device connect to some physical system which we call the *process*. To show this as a general block diagram:

The common home thermostat is an example of a measurement and control system, with the home's internal air temperature being the "process" under control. In this example, the thermostat usually serves two functions: sensing and control, while the home's heater adds heat to the home to increase temperature, and/or the home's air conditioner extracts heat from the home to decrease temperature. The job of this control system is to maintain air temperature at some comfortable level, with the heater or air conditioner taking action to correct temperature if it strays too far from the desired value (called the *setpoint*).

Industrial measurement and control systems have their own unique terms and standards, which is the primary focus of this lesson. Here are some common instrumentation terms and their definitions:

**Process:** The physical system we are attempting to control or measure. *Examples: water filtration system, molten metal casting system, steam boiler, oil refinery unit, power generation unit.*

**Process Variable, or PV:** The specific quantity we are measuring in a process. *Examples: pressure, level, temperature, flow, electrical conductivity, pH, position, speed, vibration.*

**Setpoint**, or **SP**: The value at which we desire the process variable to be maintained at. In other words, the “target” value for the process variable.

**Primary Sensing Element**, or **PSE**: A device directly sensing the process variable and translating that sensed quantity into an analog representation (electrical voltage, current, resistance; mechanical force, motion, etc.). *Examples: thermocouple, thermistor, bourdon tube, microphone, potentiometer, electrochemical cell, accelerometer.*

**Transducer**: A device converting one standardized instrumentation signal into another standardized instrumentation signal, and/or performing some sort of processing on that signal. Often referred to as a *converter* and sometimes as a “relay.” *Examples: I/P converter (converts 4-20 mA electric signal into 3-15 PSI pneumatic signal), P/I converter (converts 3-15 PSI pneumatic signal into 4-20 mA electric signal), square-root extractor (calculates the square root of the input signal).*

Note: in general science parlance, a “transducer” is any device converting one form of energy into another, such as a microphone or a thermocouple. In industrial instrumentation, however, we generally use “primary sensing element” to describe this concept and reserve the word “transducer” to specifically refer to a conversion device for standardized instrumentation signals.

**Transmitter**: A device translating the signal produced by a primary sensing element (PSE) into a *standardized* instrumentation signal such as 3-15 PSI air pressure, 4-20 mA DC electric current, Fieldbus digital signal packet, etc., which may then be conveyed to an indicating device, a controlling device, or both.

**Lower- and Upper-range values**, abbreviated **LRV** and **URV**, respectively: the values of process measurement deemed to be 0% and 100% of a transmitter’s calibrated range. For example, if a temperature transmitter is calibrated to measure a range of temperature starting at 300 degrees Celsius and ending at 500 degrees Celsius, its LRV would be 300 °C and its URV would be 500 °C.

**Zero** and **Span**: alternative descriptions to LRV and URV for the 0% and 100% points of an instrument’s calibrated range. “Zero” refers to the beginning-point of an instrument’s range (equivalent to LRV), while “span” refers to the width of its range ( $URV - LRV$ ). For example, if a temperature transmitter is calibrated to measure a range of temperature starting at 300 degrees Celsius and ending at 500 degrees Celsius, its zero would be 300 °C and its span would be 200 °C.

**Controller**: A device receiving a process variable (PV) signal from a primary sensing element (PSE) or transmitter, comparing that signal to the desired value (called the setpoint) for that process variable, and calculating an appropriate output signal value to be sent to a final control element (FCE) such as an electric motor or control valve.

**Final Control Element**, or **FCE**: A device receiving the signal output by a controller to directly influence the process. *Examples: variable-speed electric motor, control valve, electric heater.*

**Manipulated Variable**, or **MV**: The quantity in a process we adjust or otherwise manipulate in order to influence the process variable (PV). Also used to describe the output signal generated by a controller; i.e. the signal commanding (“manipulating”) the final control element to influence the process.

**Automatic mode:** When the controller generates an output signal based on the relationship of process variable (PV) to the setpoint (SP).

**Manual mode:** When the controller’s decision-making ability is bypassed to let a human operator directly determine the output signal sent to the final control element.

Now we will explore some practical examples of measurement and control systems so you can get a better idea of these fundamental concepts.

## 6.1 Example: boiler water level control system

Steam boilers are very common in industry, principally because steam power is so useful. Common uses for steam in industry include doing mechanical work (e.g. a steam engine moving some sort of machine), heating, producing vacuums (through the use of “steam ejectors”), and augmenting chemical processes (e.g. reforming of natural gas into hydrogen and carbon dioxide).

The process of converting water into steam is quite simple: heat up the water until it boils. Anyone who has ever boiled a pot of water for cooking knows how this process works. Making steam continuously, however, is a little more complicated. An important variable to measure and control in a continuous boiler is the level of water in the “steam drum” (the upper vessel in a water-tube boiler). In order to safely and efficiently produce a continuous flow of steam, we must ensure the steam drum never runs too low on water, or too high. If there is not enough water in the drum, the water tubes may run dry and burn through from the heat of the fire. If there is too much water in the drum, liquid water may be carried along with the flow of steam, causing problems downstream.

In this next illustration, you can see the essential elements of a water level control system, showing transmitter, controller, and control valve:

The first instrument in this control system is the *level transmitter*, or “LT”. The purpose of this device is to sense the water level in the steam drum and report (“transmit”) that measurement to the controller in the form of a signal. In this case, the type of signal is *pneumatic*: a variable air pressure sent through metal or plastic tubes. The greater the water level in the drum, the more air pressure output by the level transmitter. Since the transmitter is pneumatic, it must be supplied with a source of clean, compressed air on which to operate. This is the meaning of the “A.S.” tube (Air Supply) entering the top of the transmitter.

This pneumatic signal is sent to the next instrument in the control system, the *level indicating controller*, or “LIC”. The purpose of this instrument is to compare the level transmitter’s signal against a *setpoint* value entered by a human operator representing the desired water level in the steam drum. The controller then generates an *output* signal telling the control valve to either introduce more or less water into the boiler to maintain the steam drum water level at setpoint. As with the transmitter, the controller in this system is pneumatic, operating entirely on compressed

air. This means the output of the controller is also a variable air pressure signal, just like the signal output by the level transmitter. Naturally, the controller requires a constant supply of clean, compressed air on which to run, which explains the “A.S.” (Air Supply) tube connecting to it.

The last instrument in this control system is the control valve, operated directly by the air pressure signal output by the controller. Its purpose is to influence the flow rate of water into the boiler, “throttling” the water flow more or less as determined by controller. This particular type of control valve uses a large diaphragm and a large spring to move the valve further open with more signal pressure and further closed with less signal pressure.

When the controller is placed in the “automatic” mode, it will move the control valve to whatever position necessary to maintain a constant steam drum water level. The phrase “whatever position necessary” suggests the relationship between the controller output signal, the process variable signal (PV), and the setpoint (SP) is complex. If the controller senses a water level above setpoint, it will close off the valve as far as necessary to decrease the water level down to setpoint. Conversely, if the controller senses a water level below setpoint, it will open up the valve as far as necessary to raise the water level up to setpoint.

What this means in a practical sense is that the controller’s output signal (equating to valve position) in automatic mode is just as much a function of process load (i.e. how much steam is being used from the boiler) as it is a function of setpoint (i.e. where we wish the water level to be). Consider a situation where the steam demand from the boiler is very low. If there isn’t much steam being drawn off the boiler, this means there will be little water boiled into steam and therefore little need for additional feedwater to be pumped into the boiler. Therefore, in this situation, one would expect the control valve to hover near the fully-closed position, allowing just enough water into the boiler to keep the steam drum water level at setpoint. If, however, there is a high demand for steam from this boiler, the rate of evaporation will be much greater. This means the control system must add feedwater to the boiler at a much greater flow rate in order to maintain the steam drum water level at setpoint. In this situation we would expect to see the control valve much closer to being fully-open as the control system “works harder” to maintain a constant water level in the steam drum. Thus, we see how the controller automatically positions the control valve to react to different boiler operating conditions even when the setpoint is fixed.

A human operator supervising this boiler has the option of placing the controller into “manual” mode. In this mode the control valve position is under direct control of the human operator, with the controller essentially ignoring the signal sent from the water level transmitter. Being an indicating controller, the controller faceplate will still show how much water is in the steam drum, but it is now the human operator’s sole responsibility to move the control valve to the appropriate position to hold water level at setpoint – *in manual mode the controller takes no corrective action of its own*. Manual mode is useful to human operators during start-up and shut-down conditions. It is also useful to instrument technicians for troubleshooting misbehaving control systems. Placing a controller into manual mode is akin to disengaging the cruise control in an automobile, transferring control of engine power from the car’s computer back to the human driver. One can easily imagine an automobile mechanic needing to throttle a car’s engine “manually” (i.e. with the cruise control turned off) in order to properly diagnose an engine or drivetrain problem. This is true for industrial processes as well, where instrument technicians may need to place a controller into manual mode in order to properly diagnose transmitter or control valve problems.

As was mentioned before, this is an example of a *pneumatic* (compressed air) control system, where all the instruments operate on compressed air, and use compressed air as the signaling medium. Pneumatic instrumentation is an old technology, dating back to the early twentieth century. While most modern instruments are electronic in nature, pneumatic instruments still find application within industry. The most common industry standard for pneumatic pressure signals is 3 to 15 PSI, with 3 PSI representing low end-of-scale and 15 PSI representing high end-of-scale. Alternative pressure ranges for pneumatic signals sometimes encountered in industry include 3 to 27 PSI, and 6 to 30 PSI. The following table shows the relationship between air signal pressure and steam drum level for this boiler's 3-15 PSI level transmitter:

Transmitter air signal pressure	Steam drum water level
3 PSI	0% (Empty)
6 PSI	25%
9 PSI	50%
12 PSI	75%
15 PSI	100% (Full)

It should be noted this table assumes the transmitter measures the *full range* of water level possible in the drum. Usually, this is not the case. Instead, the transmitter will be calibrated so it only senses a narrow range of water level near the middle of the drum. Thus, 3 PSI (0%) will not represent an empty drum, and neither will 15 PSI (100%) represent a completely full drum. Calibrating the transmitter like this helps avoid the possibility of actually running the drum completely empty or completely full in the case of an operator incorrectly setting the setpoint value near either extreme end of the measurement scale.

An example table showing this kind of realistic transmitter calibration appears here:

Transmitter air signal pressure	Actual steam drum water level
3 PSI	40%
6 PSI	45%
9 PSI	50%
12 PSI	55%
15 PSI	60%

The boiler's steam drum level controller outputs a pneumatic output signal to the control valve, using the same 3 to 15 PSI standard to command different valve positions:

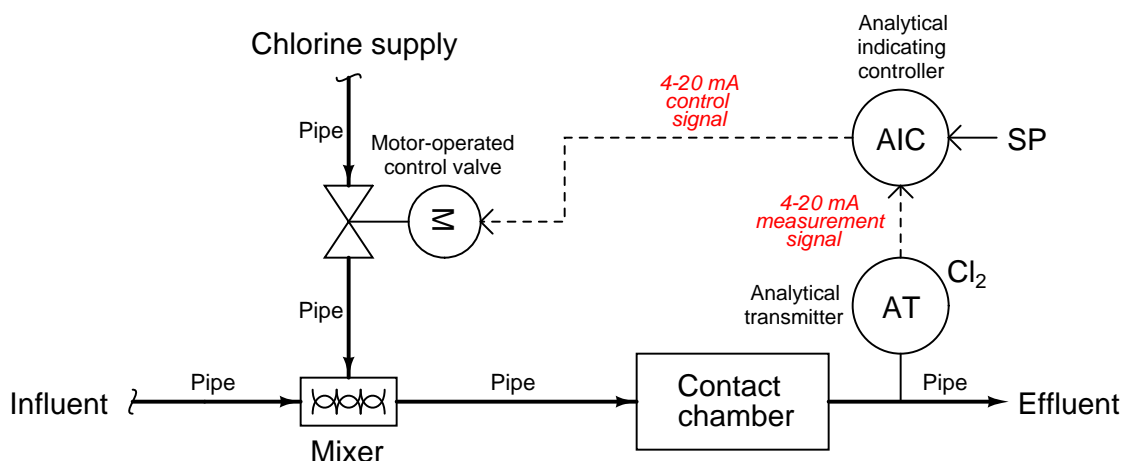

Controller output signal pressure	Control valve position
3 PSI	0% open (Fully shut)
6 PSI	25% open
9 PSI	50% open
12 PSI	75% open
15 PSI	100% (Fully open)

Even though the same range of air pressure (3 to 15 PSI) is used to represent water level in the steam drum *and* the position of the control valve, there is no simple correspondence between the two signals. A common misconception for students new to this topic is to assume the transmitter signal (PV) and controller output signal must be identical. *This is not true.* Typically the 3-15 PSI signal representing level will be at some value different from the 3-15 PSI signal driving the valve, because those two signals represent two entirely different variables in the boiler system. As we have seen previously, the output signal from a controller in automatic mode is just as much a function of process conditions as it is a function of the measured variable. This error is akin to thinking the road speed signal in an automobile cruise control system (the “process variable” or PV) must be the same value as the signal sent by the cruise control computer to the engine's accelerator control (the controller's “output” signal). Granted, these two signals are *related* to one another, but since they represent two different parameters in the controlled system we have no reason to expect their values will be *equal* except by chance.

## 6.2 Example: wastewater disinfection

The final step in treating wastewater before releasing it into the natural environment is to kill any harmful microorganisms (e.g. viruses, bacteria) in it. This is called *disinfection*, and chlorine gas is a very effective disinfecting agent. However, just as it is not good to mix too little chlorine in the outgoing water (effluent) because we might not disinfect the water thoroughly enough, there is also danger of injecting too much chlorine in the effluent because then we might begin poisoning animals and beneficial microorganisms in the natural environment.

To ensure the right amount of chlorine injection, we must use a dissolved chlorine analyzer to measure the chlorine concentration in the effluent, and use a controller to automatically adjust the chlorine control valve to inject the right amount of chlorine at all times. The following P&ID (Process and Instrument Diagram) shows how such a control system might look:

Chlorine gas coming through the control valve mixes with the incoming water (influent), then has time to disinfect in the contact chamber before exiting out to the environment.

The transmitter is labeled “AT” (Analytical Transmitter) because its function is to *analyze* the concentration of chlorine dissolved in the water and *transmit* this information to the control system. The “Cl<sub>2</sub>” (chemical notation for a chlorine molecule) written near the transmitter bubble declares this to be a chlorine analyzer. The dashed line coming out of the transmitter tells us the signal is electric in nature, not pneumatic as was the case in the previous (boiler control system) example. The most common and likely standard for electronic signaling in industry is 4 to 20 milliamps DC, which represents chlorine concentration in much the same way as the 3 to 15 PSI pneumatic signal standard represented steam drum water level in the boiler:

Transmitter signal current	Chlorine concentration
4 mA	0% (no chlorine)
8 mA	25%
12 mA	50%
16 mA	75%
20 mA	100% (Full concentration)

The controller is labeled “AIC” because it is an Analytical Indicating Controller. Controllers are always designated by the process variable they are charged with controlling, in this case the chlorine analysis of the effluent. “Indicating” means there is some form of display that a human operator or technician can read showing the chlorine concentration. “SP” refers to the setpoint value entered by the operator, which the controller tries to maintain by adjusting the position of the chlorine injection valve.

A dashed line going from the controller to the valve indicates another electronic signal: a 4 to 20 mA direct current signal again. Just as with the 3 to 15 PSI pneumatic signal standard in the pneumatic boiler control system, the amount of electric current in this signal path directly relates to a certain valve position:

Controller output signal current	Control valve position
4 mA	0% open (Fully shut)
8 mA	25% open
12 mA	50% open
16 mA	75% open
20 mA	100% (Fully open)

Note: it is possible, and in some cases even preferable, to have either a transmitter or a control valve that responds in reverse fashion to an instrument signal such as 3 to 15 PSI or 4 to 20 milliamps. For example, this valve could have been set up to be wide open at 4 mA and fully shut at 20 mA. The main point to recognize here is that both the process variable sensed by the transmitter and the position of the control valve are proportionately represented by analog signals.

Just as with the 3 to 15 PSI pneumatic signals used to represent water level and control valve position in the boiler seen previously, the two 4 to 20 milliamp current signals in this system represent two different variables in the system and therefore will not be equal to each other except by coincidence. A common misconception for people first learning about analog instrumentation signals is to assume the transmitter’s signal (“Process Variable”) must be identical in value to the control valve’s signal (“Manipulated Variable” or “Output”), but this is not true.

The letter “M” inside the control valve bubble tells us this is a motor-actuated valve. Instead of using compressed air pushing against a spring-loaded diaphragm as was the case in the boiler control system, this valve is actuated by an electric motor turning a gear-reduction mechanism. The gear reduction mechanism allows slow motion of the control valve stem even though the motor spins at a fast rate. A special electronic control circuit inside the valve actuator modulates electric power to the electric motor in order to ensure the valve position accurately matches the signal sent by the controller. In effect, this is another control system in itself, controlling valve position according to a “setpoint” signal sent by another device (in this case, the AIT controller which is telling the valve what position to go to).

### 6.3 Example: chemical reactor temperature control

Sometimes we encounter a diversity of instrument signal standards in one control system. Such is the case with the following chemical reactor temperature control system, where three different signal standards convey information between the instruments. A P&ID (Process and Instrument Diagram) shows the inter-relationships of the process piping, vessels, and instruments:

The purpose of this control system is to ensure the chemical solution inside the reactor vessel is maintained at a constant temperature. A steam-heated “jacket” envelops the reactor vessel, transferring heat from the steam into the chemical solution inside. The control system maintains a constant temperature by measuring the temperature of the reactor vessel, and throttling steam from a boiler to the steam jacket to add more or less heat as needed.

We begin as usual with the temperature transmitter, located near the bottom of the vessel. Note the different line type used to connect the temperature transmitter (TT) with the temperature-indicating controller (TIC): hollow diamonds with lines in between. This signifies a *digital electronic instrument signal* – sometimes referred to as a *fieldbus* – rather than an analog type (such as 4 to 20 mA or 3 to 15 PSI). The transmitter in this system is actually a digital computer, and so is the controller. The transmitter reports the process variable (reactor temperature) to the controller using digital bits of information. Here there is no analog scale of 4 to 20 milliamps, but rather electric voltage/current pulses representing the 0 and 1 states of binary data.

Digital instrument signals are capable of transferring multiple data points rather than single data points as is the case with analog instrument signals. This means digital instrument signals may convey device status information (such as self-diagnostic test results) as well as the basic measurement value. In other words, the digital signal coming from this transmitter not only tells the controller how hot the reactor is, but it may also communicate to the controller how well the transmitter is functioning.

The dashed line exiting the controller shows it to be analog electronic: most likely 4 to 20 milliamps DC. This electronic signal does not go directly to the control valve, however. It passes through a device labeled “TY”, which is a *transducer* to convert the 4 to 20 mA electronic signal into a 3 to 15 PSI pneumatic signal which then actuates the valve. In essence, this signal transducer acts as an electrically-controlled air pressure regulator, taking the supply air pressure (usually 20 to 25 PSI) and regulating it down to a level commanded by the controller’s electronic output signal.

At the temperature control valve (TV) the 3 to 15 PSI pneumatic pressure signal applies a force on a diaphragm to move the valve mechanism against the restraining force of a large spring. The construction and operation of this valve is the same as for the feedwater valve in the pneumatic boiler water control system. The letters “ATO” immediately below the valve symbol mean “Air-To-Open,” referring to the direction this valve mechanism will move (wider open) as more air signal pressure is applied to its actuator.

A detail not shown on this diagram, yet critically important to the operation of the temperature control system, is the *direction of action* for the controller while in automatic mode. It is possible to configure general-purpose controllers to act either in a *direct* fashion where an increasing process variable signal automatically results in an increasing output signal, or in a *reverse* fashion where an increasing process variable signal automatically results in a decreasing output signal. An effective way to identify the proper direction of action for any process controller is to perform a “thought experiment<sup>1</sup>” whereby we imagine the process variable increasing over time, and then determine which way the controller’s output needs to change in order to bring the process variable value back to setpoint based on the final control element’s influence within the process.

In this process, let us imagine the reactor temperature increasing for some reason, perhaps an increase in the temperature of the feed entering the reactor. With an increasing temperature, the controller must *reduce* the amount of steam applied to the heating jacket surrounding the reactor in order to correct for this temperature change. With an air-to-open (ATO) steam valve, this requires a *decreased* air pressure signal to the valve in order to close it further and reduce heat input to the reactor. Thus, if an increasing process variable signal requires a decreasing controller output signal, the controller in this case needs to be configured for *reverse* action.

We could easily imagine reasons why the temperature controller in this process might have to be configured for direct action instead of reverse action. If the piping were altered such that the control valve throttled the flow of *coolant* to the reactor rather than steam, an increasing temperature would require a further-open valve, which would only happen if the controller were configured for direct action. Alternatively, if the steam valve were air-to-close (ATC) rather than air-to-open (ATO), an increasing reactor temperature (requiring less steam be sent to the reactor) would necessitate the controller outputting an increased signal to the valve, so that more air signal pressure pushed the valve further closed.

---

<sup>1</sup>For more information on conducting “thought experiments,” refer to the subsection of this book titled “Using Thought Experiments” (34.3.4) beginning on page 2755.

An example of a chemical reaction temperature control system requiring *direct* controller action is shown in the following photograph. Here, we see a jacketed stainless-steel vessel used to ferment beer at cold temperatures. The jacket surrounding this vessel is pumped full of chilled glycol solution (similar to automotive antifreeze), to draw heat away from the fermenting beer and maintain its temperature well below ambient:

If the beer becomes too warm, the controller sends an increased signal to the glycol valve sending more chilled glycol through the vessel's jacket to remove heat from the beer. Since the relationship between the controller's process variable and its output is direct (i.e. rising PV results in rising Output), the controller needs to be configured for direct action.

This is why general-purpose process controllers always provide a user-selectable option for either direct or reverse action: it makes them adaptable to the needs of *any* process, no matter the physics of the process or the behavior of the other loop instruments (e.g. transmitter and final control element).

An additional instrument connected to our hypothetical chemical reactor is a pressure transmitter (PT) on the feed line. While not a part of the temperature control loop, it is shown here to illustrate yet another type of instrumentation signaling: *digital wireless*. Here, the transmitter reports its measurement data to an indicator at the control room via radio signals, using digital codes much like fieldbus to communicate not only the basic process data but also transmitter diagnostic and radio network management data.

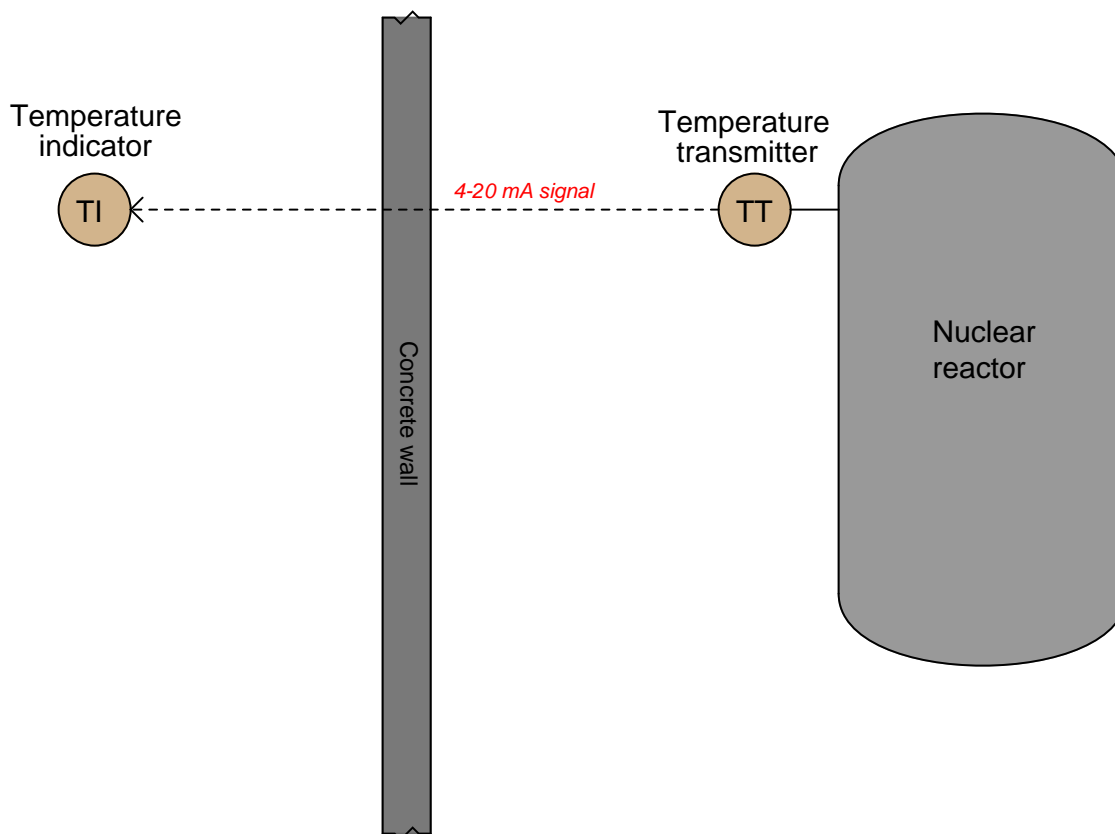

At the time of this writing (2011), wireless instrumentation is not recommended for mission-critical control applications, and finds its greatest use in low-priority monitoring instrumentation. The most obvious advantage of wireless instruments is that they do not require wires of any kind. Since wiring is a major capital cost when installing instruments, this fact makes wireless instrumentation relatively inexpensive to install. Freedom from wires also allows these instruments to be used in applications that would be impossible for wired instruments, such as communicating data from sensors installed in moving vehicles to stationary monitoring or control equipment. However, the elimination of wires means wireless instruments must provide for their own power requirements, usually with long-life batteries. Reliance on battery power alone places restrictions on how frequently these instrument perform their functions: less frequent data transmission results in longer battery life, but correspondingly reduces the instrument's practicality for real-time control. Potential blockage of the radio signals from moving objects such as large vehicles (cranes, lifts, etc.) also poses challenges to signal reliability. Despite these limitations, the total absence of signal or power wiring for a wireless instrument is an essential feature for certain applications. Wireless is just another tool to help us automate processes, and like any other tool it has its advantages and disadvantages.

## 6.4 Other types of instruments

So far we have just looked at instruments that sense, control, and influence process variables. Transmitters, controllers, and control valves are respective examples of each instrument type. However, other instruments exist to perform useful functions for us.

### 6.4.1 Indicators

One common “auxiliary” instrument is the *indicator*, the purpose of which is to provide a human-readable indication of an instrument signal. Quite often process transmitters are not equipped with readouts for whatever variable they measure: they just transmit a standard instrument signal (3 to 15 PSI, 4 to 20 mA, etc.) to another device. An indicator gives a human operator a convenient way of seeing what the output of the transmitter is without having to connect test equipment (pressure gauge for 3-15 PSI, ammeter for 4-20 mA) and perform conversion calculations. Moreover, indicators may be located far from their respective transmitters, providing readouts in locations more convenient than the location of the transmitter itself. An example where remote indication would be practical is shown here, in a nuclear reactor temperature measurement system:

It would be unsafe for human beings to approach the nuclear reactor when it is in full-power operation, due to the strong radiation flux it emits. The temperature transmitter is built to withstand the radiation, though, and it transmits a 4 to 20 milliamp electronic signal to an indicating recorder located on the other side of a thick concrete wall blocking the reactor's radiation, where it is safe for human occupancy. There is nothing preventing us from connecting multiple indicators, at multiple locations, to the same 4 to 20 milliamp signal wires coming from the temperature

transmitter. This allows us to display the reactor temperature in as many locations as we desire, since there is no absolute limit on how far we may conduct a DC milliamp signal along copper wires.

A numerical-plus-bargraph indicator appears in this next photograph, mounted in the face of a metal panel inside of a control room:

This particular indicator shows the position of a flow-control gate in a wastewater treatment facility, both by numerical value (98.06%) and by the height of a bargraph (very near full open – 100%). It is directly wired in series with the same 4-20 milliamp current signal sent to the gate actuator.

A less sophisticated style of panel-mounted indicator shows only a numeric display, such as this unit shown here:

Indicators may also be used in “field” (process) areas to provide direct indication of measured variables if the transmitter device lacks a human-readable indicator of its own. The following photograph shows a field-mounted indicator, operating directly from the electrical power available in the 4-20 mA loop. The numerical display of this indicator uses LCD technology rather than red-glowing LEDs, in order to use less electrical power:

### 6.4.2 Recorders

Another common “auxiliary” instrument is the *recorder* (sometimes specifically referred to as a *chart recorder* or a *trend recorder*), the purpose of which is to draw a graph of process variable(s) over time. Recorders usually have indications built into them for showing the instantaneous value of the instrument signal(s) simultaneously with the historical values, and for this reason are usually designated as *indicating* recorders. A temperature indicating recorder for the nuclear reactor system shown previously would be designated as a “TIR” accordingly.

Paper chart recorders are a form of instrumentation with a long history. The following image shows an illustration of a Bristol brand recording pressure gauge found on page 562 of *Cassier's Magazine* volume 8, published in 1895. Note the circular form of the paper chart, allowing the pen to draw a trace as the circular chart slowly spins. A padlock on the front glass cover prevents tampering with the chart recording:

A typical chart from one of these recording devices is shown in this illustration, taken from page 563 of the same engineering periodical:

This particular recording is of a steam boiler's pressure over a 24-hour period, showing pressure build-up beginning at 4:00 AM and boiler shut-down at 9:30 PM. This steam boiler's pressure appears to have been operated at approximately 70 PSI. Dips and peaks in the trace reflect changes in steam demand as well as irregularities in the firing of the boiler's coal furnace.

Another design of paper chart recorder is the *strip* style, using a long strip of paper between two spools (one to play out the paper and another to take it up). Like the circular chart recorder design, the strip chart recorder also has a long history. The following illustration from page 560 of the same *Cassier's Magazine* volume:

This next image shows a practical example of a strip chart's record for a city water supply company, taken from page 566 of the same periodical:

Several interesting details<sup>2</sup> may be seen on this particular recording, including pressure fluctuations caused by periodic draws of water from a fire hydrant to fill street carts used to spray

<sup>2</sup>Many interesting points may be drawn from these two illustrations. Regarding the strip chart recording instrument itself, it is worth noting the ornate design of the metal frame (quite typical of machinery design from that era), the attractive glass dome used to shield the chart and mechanism from the environment, and the intricate mechanism used to drive the strip chart and move the pen. Unlike a circular chart, the length of a strip chart is limited only by the diameter of the paper roll, and may be made long enough to record many days' worth of pressure measurements. The label seen on the front of this instrument ("Edson's Recording and Alarm Gauge") tells us this instrument has the ability to alert a human operator of abnormal conditions, and a close inspection of the mechanism reveals a bell

the city's dirt roads with water to minimize dust. Pressure drop caused by a burst 4-inch water pipe is also seen on this recording, between 5:00 PM and 6:15 PM.

Both circular and strip chart recorder designs survive to this day. Two circular chart recorders are shown in the following photograph, used to record temperatures at a powdered milk processing facility:

Two more chart recorders appear in the next photograph, a strip chart recorder on the right and a *paperless* chart recorder on the left. The strip chart recorder uses a scroll of paper drawn slowly past one or more lateral-moving pens, while the paperless recorder does away with paper entirely by plotting graphic trend lines on a computer screen:

---

on the top which presumably rings under alarm conditions. Regarding the strip chart record, note the “compressed” scale, whereby successive divisions of the vertical scale become closer in spacing, reflecting some inherent nonlinearity of the pressure-sensing mechanism.

Recorders are extremely helpful for troubleshooting process control problems. This is especially true when the recorder is configured to record not just the process variable, but also the controller's setpoint and output variables as well. Here is an example of a typical "trend" showing the relationship between process variable, setpoint, and controller output in automatic mode, as graphed by a recorder:

Here, the setpoint (SP) appears as a perfectly straight red line, the process variable as a slightly erratic blue line, and the controller output as a moderately erratic purple line. We can see from this trend that the controller is doing exactly what it should: holding the process variable value close to setpoint, manipulating the final control element as far as necessary to do so. The chaotic appearance of the output signal is not really a problem, contrary to most peoples' first impression. The fact that the process variable never deviates significantly from the setpoint tells us the control system is operating quite well. What accounts for the erratic controller output, then? The answer to this question is any factor requiring the controller to change its output in order to maintain the process variable at setpoint. Variations in process load would account for this: as other variables in the process change over time, the controller is forced to compensate for these variations in order to ensure the process variable does not drift from setpoint. Referencing our previous example of a steam boiler water level control system, one of these influencing variables is steam demand. If this trend shows the steam drum water level (PV) and feedwater valve position (Output), variations in the controller's output signal could be indicative of steam demand rising and falling, the controller modulating water flow into the boiler to properly compensate for this load and maintain a fairly constant steam drum water level. A wildly-fluctuating output signal *may* indicate a problem somewhere else in the process (placing undue demands on the control system), but there is certainly no problem with the control system itself: it is doing its job perfectly well.

Recorders become powerful diagnostic tools when coupled with the controller's manual control mode. By placing a controller in "manual" mode and allowing direct human control over the final control element (valve, motor, heater), we can tell a lot about a process. Here is an example of a

trend recording for a process in manual mode, where the process variable response is seen graphed in relation to the controller output as that output is increased and decreased in steps:

Notice the time delay between when the output signal is “stepped” to a new value and when the process variable responds to the change. This delay is called *dead time*, and it is generally detrimental to control system performance. Imagine trying to steer an automobile whose front wheels respond to your input at the steering wheel only after a 5-second delay! This would be a very challenging car to drive. The same problem plagues any industrial control system with a time lag between the final control element and the transmitter. Typical causes of this problem include *transport delay* (where there is a physical delay resulting from transit time of a process medium from the point of control to the point of measurement) and mechanical problems in the final control element.

This next example shows another type of problem revealed by a trend recording during manual-mode testing:

Here, we see the process quickly responding to all step-changes in controller output except for those involving a change in direction. This problem is usually caused by mechanical friction in the final control element (e.g. “sticky” valve stem packing in a pneumatically-actuated control valve), and is analogous to “loose” steering in an automobile, where the driver must turn the steering wheel a little bit extra after reversing steering direction. Anyone who has ever driven an old farm tractor knows what this phenomenon is like, and how it detrimentally affects one’s ability to steer the tractor in a straight line.

Sometimes it becomes useful to temporarily place a recorder into an instrumentation system for diagnostic purposes. On the simplest level, this might consist of a digital multimeter (DMM) connected to measure signal voltage or current, with its “minimum/maximum” capture mode engaged. On a more complex level, this might be a personal computer running data graphing software, connected to the instrumentation circuit through a data acquisition (DAQ) module converting the circuit’s analog voltage or current signals into digital values readable by the computer.

### 6.4.3 Process switches and alarms

Another type of instrument commonly seen in measurement and control systems is the *process switch*. The purpose of a switch is to turn on and off with varying process conditions. Usually, switches are used to activate alarms to alert human operators to take special action. In other situations, switches are directly used as control devices.

The following P&ID of a compressed air control system shows both uses of process switches:

The “PSH” (*pressure switch, high*) activates when the air pressure inside the vessel reaches its high control point. The “PSL” (*pressure switch, low*) activates when the air pressure inside the vessel drops down to its low control point. Both switches feed discrete (on/off) electrical signals to a logic control device (symbolized by the diamond) which then controls the starting and stopping of the electric motor-driven air compressor.

Another switch in this system labeled “PSHH” (*pressure switch, high-high*) activates only if the air pressure inside the vessel exceeds a level beyond the high shut-off point of the high pressure control switch (PSH). If this switch activates, something has gone wrong with the compressor control system, and the high pressure alarm (PAH, or *pressure alarm, high*) activates to notify a human operator.

All three switches in this air compressor control system are directly actuated by the air pressure in the vessel: in other words, these are direct *process-sensing* switches. It is possible, however, to build switch devices that interpret standardized instrumentation signals such as 3 to 15 PSI (pneumatic) or 4 to 20 milliamps (analog electronic), allowing us to build on/off control systems and alarms for *any* type of process variable measurable with a transmitter.

For example, the chlorine wastewater disinfection system shown earlier may be equipped with a couple of electronic alarm switches to alert an operator if the chlorine concentration ever exceeds pre-determined high or low limits:

The labels “AAL” and “AAH” refer to *analytical alarm low* and *analytical alarm high*, respectively. Note how the diagram shows these two alarm units connected to the electronic (4-20 mA) signal output by the chlorine analyzer (AT). This tells us the AAL and AAH alarm units are really just electronic circuits, alarming if the analytical transmitter’s 4-20 mA analog signal falls below (AAL) or exceeds (AAH) certain pre-set limits. As such, the AAL and AAH alarms do not *directly* sense the chlorine concentration in the water, but rather *indirectly* sense it by monitoring the chlorine analyzer’s 4-20 milliamp output signal.

Since both alarms work off the 4 to 20 milliamp electronic signal output by the chlorine analytical transmitter (AT) rather than directly sensing the process, their construction is greatly simplified. If these were process-sensing switches, each one would have to be equipped with the analytical capability of directly sensing chlorine concentration in water. In other words, each switch would have to be its own self-contained chlorine concentration analyzer, with all the attendant complexity.

An example of an electronic alarm module (triggered by a 4-20 mA current signal coming from a transmitter) is the Moore Industries model SPA (“Site Programmable Alarm”), shown here:

In addition to providing alarm capability, this SPA module also provides a digital display (a small LCD screen) to show the analog signal value for operational or diagnostic purposes.

Like all current-operated alarm modules, the Moore Industries SPA may be configured to “trip” electrical contacts when the current signal reaches a variety of different programmed thresholds. Some of the alarm types provided by this unit include high process, low process, out-of-range, and high rate-of-change.

In a similar manner, we may add pressure-actuated process alarm switches to pneumatic (3-15 PSI) signal lines coming from pneumatic transmitters to add alarm capability to a system designed for continuous measurement. For example, if high- and low-alarm capability were desired for the steam drum water level process described earlier in this chapter, one could add a pair of pressure-actuated switches to the pneumatic level transmitter's 3-15 PSI output signal line:

These two pressure-actuated switches serve as *water level* alarms, because the air pressure signal actuating them comes from the pneumatic *level* transmitter, which outputs an air pressure signal in direct proportion to water level in the boiler's steam drum. Even though the physical stimulus actuating each switch is an air *pressure*, the switches still serve the purpose of liquid *level* alarm signaling because that air pressure is an analogue (representation) of water level in the steam drum. In other words, these two alarm switches (LSL and LSH) *indirectly* sense water level by monitoring the pneumatic signal pressure output by the level transmitter (LT).

The alternative to pressure-actuated water level alarm switches would be independent level-sensing switches attached directly to the steam drum, each switch equipped with its own means<sup>3</sup> of directly sensing water level:

It should be mentioned that the choice between using process alarm switches directly actuated by the process versus alarm switches actuated by a transmitter's analog signal is not arbitrary. In the system where the two alarm switches actuate from the transmitter's 3-15 PSI output signal, the integrity of the water level control *and* that of the high- and low-level alarms all depend on the proper function of one transmitter. If that one transmitter were to fail, all three system functions would be compromised. This elevates the importance of a single instrument, which is generally not desirable from the perspective of reliability and process safety. In the system where each level alarm switch independently senses steam drum water level, one device may fail without compromising either of the other two functions. This independence is desirable because it greatly reduces the probability of "common-cause" failures, where a single fault disables multiple system functions. The final determination should be based on a rigorous analysis of device versus system reliability, which is typically the task of a process engineer.

<sup>3</sup>These might be float-driven switches, where each switch is mechanically actuated by the buoyancy of a hollow metal float resting on the surface of the water. Another technology uses metal electrodes inserted into the water from above, sensing water level by electrical conductivity: when the water level reaches the probe's tip, an electrical circuit is closed. For more information on liquid level switches, refer to section 9.6 beginning on page 673.

Process alarm switches may be used to trigger a special type of indicator device known as an *annunciator*. An annunciator is an array of indicator lights and associated circuitry designed to secure a human operator's attention<sup>4</sup> by blinking and sounding an audible buzzer when a process switch actuates into an abnormal state. The alarm state may be then “acknowledged” by an operator pushing a button, causing the alarm light to remain on (solid) rather than blink, and silencing the buzzer. The indicator light does not turn off until the actual alarm condition (the process switch) has returned to its regular state.

This photograph shows an annunciator located on a control panel for a large engine-driven pump. Each white plastic square with writing on it is a translucent pane covering a small light bulb. When an alarm condition occurs, the respective light bulb flashes, causing the translucent white plastic to glow, highlighting to the operator which alarm is active:

Note the two pushbutton switches below labeled “Test” and “Acknowledge.” Pressing the “Acknowledge” button will silence the audible buzzer and also turn any blinking alarm light into a steady (solid) alarm light until the alarm condition clears, at which time the light turns off completely. Pressing the “Test” button turns all alarm lights on, to ensure all light bulbs are still functional.

---

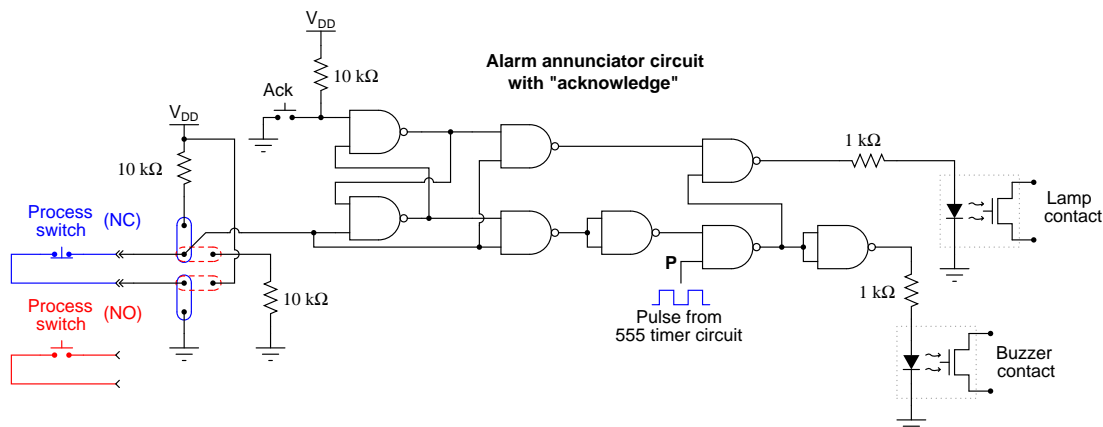

<sup>4</sup>D.A. Strobhar, writing in *The Instrument Engineers' Handbook* on the subject of alarm management, keenly observes that alarms are the only form of instrument “whose sole purpose is to alter the operator's behavior.” Other instrument devices work to control the process, but only alarms work to *control the human operator*.

Opening the front panel of this annunciator reveals modular relay units controlling the blinking and acknowledgment latch functions, one for each alarm light:

This modular design allows each alarm channel to be serviced without necessarily interrupting the function of the other channels in the annunciator panel.

A simple logic gate circuit illustrates the acknowledgment latching feature (here implemented by an S-R latch circuit) common to all process alarm annunciators:

Panel-mounted annunciators are becoming a thing of the past, as computer-based alarm displays replace them with advanced capabilities such as time logging, first-event<sup>5</sup> recording, and multiple layers of acknowledgment/access. Time logging is of particular importance in the process industries, as the sequence of events is often extremely important in investigations following an abnormal operating condition. Knowing *what happened*, and *exactly when it happened* is much more informative than simply knowing which alarms have tripped.

<sup>5</sup>When a complex machine or process with many shutdown sensors automatically shuts down, it may be difficult to discern after the fact *which* shutdown device was responsible. For instance, imagine an engine-powered generator automatically shutting down because one of the generator's "trip" sensors detected an under-voltage condition. Once the engine shuts down, though, *multiple* trip sensors will show abnormal conditions simply because the engine is not running anymore. The oil pressure sensor is one example of this: once the engine shuts down, there will no longer be any oil pressure, thus causing that alarm to activate. The under-voltage alarm falls into this category as well: once the engine shuts down, the generator will no longer be turning and therefore its output voltage *must* be zero. The problem for any human operator encountering the shut-down engine is that he or she cannot tell *which* of these alarms was the initiating cause of the shutdown versus *which* of these alarms simply activated after the fact once the engine shut off. An annunciator panel showing both an under-voltage and a low oil pressure light does not tell us which event happened first to shut down the generator. A "first-event" (sometimes called a "first-out") annunciator, however, shows which trip sensor was the *first* to activate, thus revealing the initiating cause of the event.

## 6.5 Summary

Instrument technicians maintain the safe and efficient operation of industrial measurement and control systems. This career requires a broad command of technical skill. Instrumentation is more than just physics or chemistry or mathematics or electronics or mechanics or control theory or risk analysis or troubleshooting alone. An instrument technician must know all these things to some degree, and more importantly how to synthesize and apply this knowledge to real applications.

The technical diversity of this profession is daunting. Adding to this challenge is the continued adoption of new technologies. The advent of new technologies, however, does not necessarily relegate legacy technologies to the scrap heap. It is quite common to find state-of-the-art instruments in the very same facility as decades-old instruments; digital fieldbus networks installed alongside 3 to 15 PSI pneumatic signal tubes; microprocessor-based sensors mounted right next to old mercury tilt-switches. Thus, the competent instrument technician must be comfortable working with both old and new technologies, understanding their merits, weaknesses, and especially their interactions.

This is why the most important skill for an instrument technician is the ability to teach oneself. It is impossible to fully prepare for a career like this with any amount of preparatory schooling. The profession is so broad and the responsibility so great, and the landscape so continuously subject to change, that life-long learning for the instrument technician is a matter of professional survival.

Perhaps the single greatest factor determining a person's ability to independently learn is their skill at *reading*. Being able to “digest” the written word is *the* key to learning what is difficult or impractical to directly experience. In an age where information is readily accessible, the skilled reader has the advantage of leveraging generations of experts in virtually any subject. Best of all, reading is a skill anyone can master, and everyone should.

My advice to all those desiring to become self-directed learners is to build a library of reading material on subjects that interest you (hopefully, instrumentation is one of those subjects!), and then immerse yourself in those writings. Feel free to “mark up”<sup>6</sup> your books, or take notes in a separate location, so as to actively engage in your reading. Try as much as possible to approach reading as though you were having a *conversation* with the author: pose questions, challenge concepts and ideas, and do not stop doing so until you can clearly see what the author is trying to say.

I also advise *writing* about what you learn, because explaining new ideas in your own words helps you consolidate the learning, and “makes it your own” in a way few other activities do. You don't necessarily have to write your own book, but the act of expressing what you have learned is a powerful tool not only for building understanding, but also for revealing what you do not (yet) know. A method I have used with great success is to imagine myself having to explain a new concept to a precocious child: someone with enough mental capacity to grasp the concept but lacking the necessary vocabulary and experience to grasp a sophisticated presentation of it. This mental exercise forces you to explain things as simply as possible without error (because anyone can devise an explanation that is both simple and wrong!). All teachers know the power of this technique: you never learn a subject as well as when you must teach it to someone else.

---

<sup>6</sup>A fun and informative essay to read on this subject is Mortimer Adler's *How to Mark a Book*, widely disseminated on the Internet. In it, Adler argues persuasively for the habit of annotating the books you read, and gives some practical tips for doing so. He says reading a book should be a sort of *conversation with the author* where the flow of information is not just from the author to you, but also from you to yourself as you question, consider, and even argue the author's points.

## 6.6 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader's view of this chapter's concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **Representative signal:** using a signaling medium such as compressed air, electric current, or voltage pulses to represent some range of measured variable.
- **Common-cause failures:** when multiple functions in a system depend on a single element, failure of that element will cause all dependent functions to fail. Relevant to design of process alarm switches.
- **Negative feedback:** when the output of a system is degeneratively fed back to the input of that same system, the result is decreased (overall) gain and greater stability. Relevant to loop controller action: in order for a control system to be stable, the feedback must be negative.

## Chapter 7

# Instrumentation documents

Every technical discipline has its own standardized way(s) of making descriptive diagrams, and instrumentation is no exception. The scope of instrumentation is so broad, however, that no one form of diagram is sufficient to capture all we might need to represent. This chapter will discuss three different types of instrumentation diagrams:

- Process Flow Diagrams (PFDs)
- Process and Instrument diagrams (P&IDs)
- Loop diagrams (“loop sheets”)
- Functional diagrams

At the highest level, the instrument technician is interested in the interconnections of process vessels, pipes, and flow paths of process fluids. The proper form of diagram to represent the “big picture” of a process is called a *process flow diagram*. Individual instruments are sparsely represented in a PFD, because the focus of the diagram is the process itself.

At the lowest level, the instrument technician is interested in the interconnections of individual instruments, including all the wire numbers, terminal numbers, cable types, instrument calibration ranges, etc. The proper form of diagram for this level of fine detail is called a *loop diagram*. Here, the process vessels and piping are sparsely represented, because the focus of the diagram is the instruments themselves.

*Process and instrument diagrams* (P&IDs) lie somewhere in the middle between process flow diagrams and loop diagrams. A P&ID shows the layout of all relevant process vessels, pipes, and machinery, but with instruments superimposed on the diagram showing what gets measured and what gets controlled. Here, one can view the flow of the process as well as the “flow” of information between instruments measuring and controlling the process.

*Functional* diagrams are used for an entirely different purpose: to document the *strategy* of a control system. In a functional diagram, emphasis is placed on the algorithms used to control a process, as opposed to piping, wiring, or instrument connections. These diagrams are commonly found within the power generation industry, but are sometimes used in other industries as well.

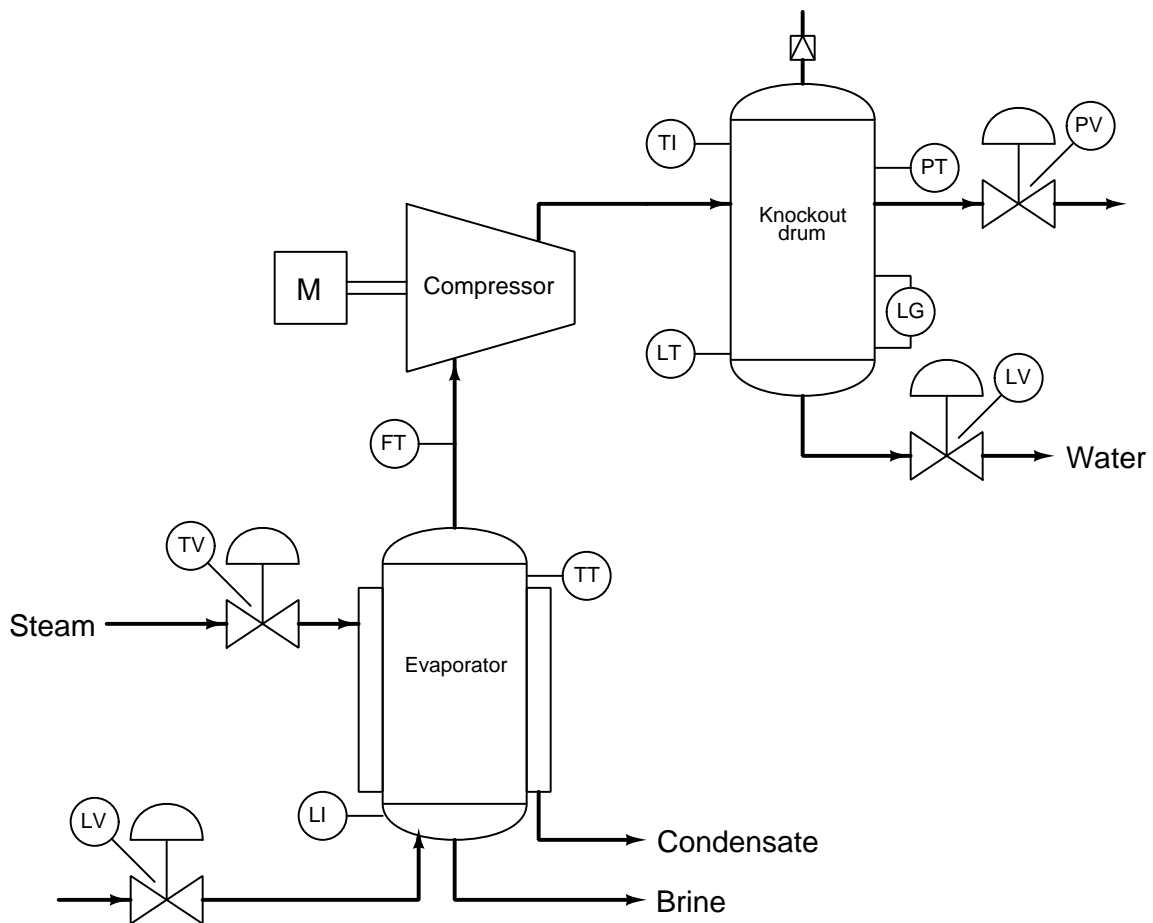

An instrument technician must often switch between different diagrams when troubleshooting a complex control system. There is simply too much detail for any one diagram to show everything. Even if the page were large enough, a “show everything” diagram would be so turgid with details that it would be difficult to focus on any particular grouping of details you happened to be interested in. The narrowing of scope with the progression from PFD to loop diagram may be visualized as a process of “zooming in,” as though one were viewing a process through the lens of a microscope at different powers. First you begin with a PFD or P&ID to get an overview of the process, to see how the major components interact. Then, once you have identified which instrument “loop” you need to investigate, you go to the appropriate loop diagram to see the interconnection details of that instrument system so you know where to connect your test equipment and what signals you expect to find when you do.

Another analogy for this progression of documents is a map, or more precisely, a globe, an atlas, and a city street map. The globe gives you the “big picture” of the Earth, countries, and major cities. An atlas allows you to “zoom in” to see details of particular provinces, states, and principalities, and the routes of travel connecting them all. A city map shows you major and minor roads, canals, alleyways, and perhaps even some addresses in order for you to find your way to a particular destination. It would be impractical to have a globe large enough to show you all the details of every city! Furthermore, a globe comprehensive enough to show you all these details would have to be updated *very* frequently to keep up with all cities’ road changes. There is a certain economy inherent to the omission of fine details, both in ease of use and in ease of maintenance.

## 7.1 Process Flow Diagrams

To show a practical process example, let's examine three diagrams for a compressor control system, beginning with a Process Flow Diagram, or PFD. In this fictitious process, water is being evaporated from a process solution under partial vacuum (provided by the compressor). The compressor then transports the vapors to a “knockout drum” where they condense into liquid form. As a typical PFD, this diagram shows the major interconnections of process vessels and equipment, but omits details such as instrument signal lines and auxiliary instruments:

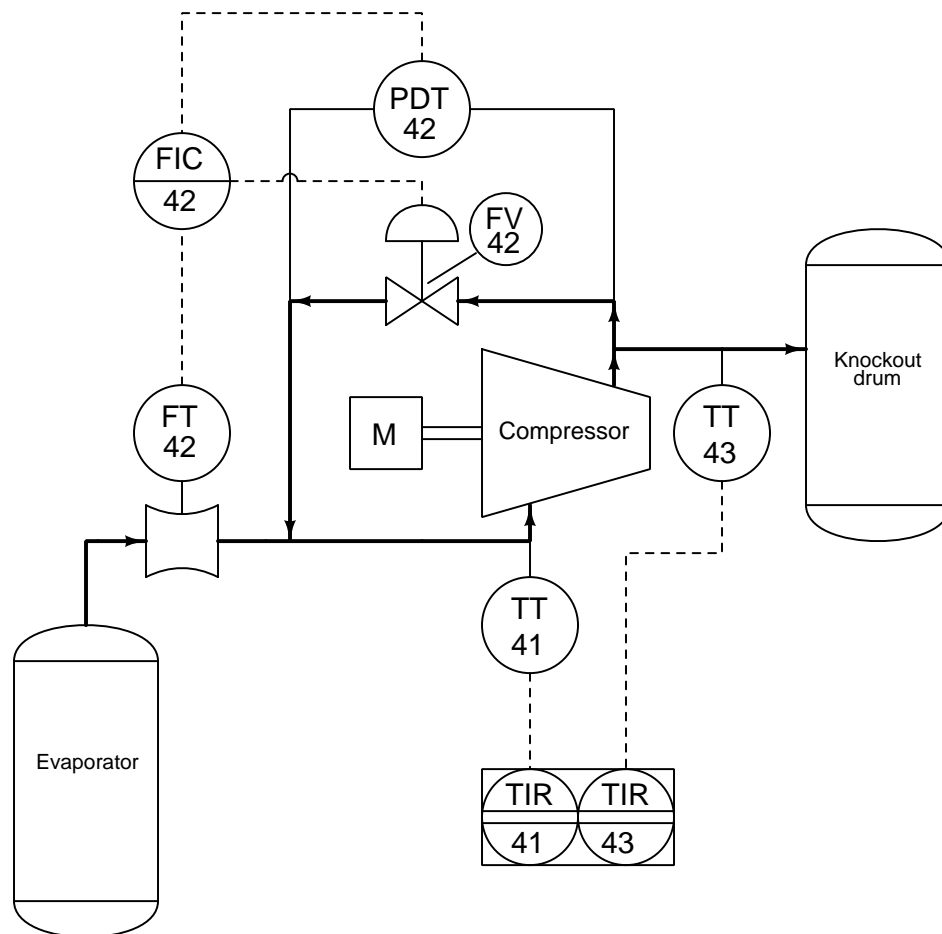

One might guess the instrument interconnections based on the instruments' labels. For instance, a good guess would be that the level transmitter (LT) on the bottom of the knockout drum might send the signal that eventually controls the level valve (LV) on the bottom of that same vessel. One might also guess that the temperature transmitter (TT) on the top of the evaporator might be part of the temperature control system that lets steam into the heating jacket of that vessel.

Based on this diagram alone, one would be hard-pressed to determine what control system, if

any, controls the compressor itself. All the PFD shows relating directly to the compressor is a flow transmitter (FT) on the suction line. This level of uncertainty is perfectly acceptable for a PFD, because its purpose is merely to show the general flow of the process itself, and only a bare minimum of control instrumentation.

## 7.2 Process and Instrument Diagrams

The next level of detail is the Process and Instrument Diagram<sup>1</sup>, or P&ID. Here, we see a “zooming in” of scope from the whole evaporator process to the compressor as a unit. The evaporator and knockout vessels almost fade into the background, with their associated instruments absent from view<sup>2</sup>:

Now we see there is more instrumentation associated with the compressor than just a flow transmitter. There is also a differential pressure transmitter (PDT), a flow indicating controller (FIC), and a “recycle” control valve allowing some of the vapor coming out of the compressor’s

<sup>1</sup>Sometimes P&ID stands for *Piping* and Instrument Diagram. Either way, it means the same thing.

<sup>2</sup>It should be noted that the “zooming in” of scope in a P&ID does not necessarily mean the scope of other areas of the process must be “zoomed out.” In fact, it is rather typical in a P&ID that the *entire* process system is shown in finer detail than in a PFD, but not all on one page. In other words, while a PFD may depict a process in its entirety on one piece of paper, a comprehensive P&ID will typically span multiple pieces of paper, each one detailing a section of the process system.

discharge line to go back around into the compressor’s suction line. Additionally, we have a pair of temperature transmitters reporting suction and discharge line temperatures to an indicating recorder.

Some other noteworthy details emerge in the P&ID as well. We see that the flow transmitter, flow controller, pressure transmitter, and flow valve all bear a common number: 42. This common “loop number” indicates these four instruments are all part of the same control system. An instrument with any other loop number is part of a different control system, measuring and/or controlling some other function in the process. Examples of this include the two temperature transmitters and their respective recorders, bearing the loop numbers 41 and 43.

Please note the differences in the instrument “bubbles” as shown on this P&ID. Some of the bubbles are just open circles, where others have lines going through the middle. Each of these symbols has meaning according to the ISA (Instrumentation, Systems, and Automation society) standard:

The type of “bubble” used for each instrument tells us something about its location. This, obviously, is quite important when working in a facility with many thousands of instruments scattered over acres of facility area, structures, and buildings.

The rectangular box enclosing both temperature recorders shows they are part of the same physical instrument. In other words, this indicates there is really only one temperature recorder instrument, and that it plots both suction and discharge temperatures (most likely on the same trend graph). This suggests that each bubble may not necessarily represent a discrete, physical instrument, but rather an instrument *function* that may reside in a multi-function device.

Details we do not see on this P&ID include cable types, wire numbers, terminal blocks, junction boxes, instrument calibration ranges, failure modes, power sources, and the like. To examine this level of detail, we must turn to another document called a *loop diagram*.

## 7.3 Loop diagrams

Finally, we arrive at the loop diagram (sometimes called a *loop sheet*) for the compressor surge control system (loop number 42):

Here we see that the P&ID didn't show us all the instruments in this control "loop." Not only do we have two transmitters, a controller, and a valve; we also have two signal transducers. Transducer 42a modifies the flow transmitter's signal before it goes into the controller, and transducer 42b converts the electronic 4 to 20 mA signal into a pneumatic 3 to 15 PSI air pressure signal. Each instrument "bubble" in a loop diagram represents an individual device, with its own terminals for connecting wires.

Note that dashed lines now represent individual copper wires instead of whole cables. Electrical terminals where these wires connect to are represented by squares with numbers in them. Fluid ports on instruments are also represented by labeled squares. Cable numbers, wire colors, junction block numbers, panel identification, and even grounding points are all shown in loop diagrams. The only type of diagram for this system more detailed than a loop diagram would be an electronic

schematic diagram for an individual instrument, which of course would only show details pertaining to that one instrument. Thus, the loop diagram is the most detailed form of diagram for a control system as a whole, and as such it must contain all details omitted by PFDs and P&IDs alike.

To the novice it may seem excessive to include such trivia as wire colors in a loop diagram. To the experienced instrument technician who has had to work on systems lacking such documented detail, this information is highly valued. The more detail you put into a loop diagram, the easier it makes the inevitable job of maintaining that system at some later date. When a loop diagram shows you exactly what wire color to expect at exactly what point in an instrumentation system, and exactly what terminal that wire should connect to, it becomes much easier to proceed with any troubleshooting, calibration, or upgrade task.

Loop diagrams are fairly constrained in their layout as per the ISA 5.1 standard. Field instruments are always placed on the left-hand side, while control-panel or control-room instruments must be located on the right-hand side. Text describing instrument tags, ranges, and notes are always placed on the bottom. Unlike PFDs and P&IDs where component layout is largely left to the whim of the designer drawing the diagram, loop sheets offer little room for creativity. This is intentional, as creativity and readability are mutually exclusive in cases where there is an immense amount of technical detail embedded in a diagram. It is simply easier to find details you're looking for when you know *exactly* where they ought to be.

An interesting detail seen on this loop diagram is an entry specifying “input calibration” and “output calibration” for each and every instrument in the system. This is actually a very important concept to keep in mind when troubleshooting a complex instrumentation system: every instrument has at least one input and at least one output, with some sort of mathematical relationship between the two. Diagnosing where a problem lies within a measurement or control system often means testing various instruments to see if their output responses appropriately match their input conditions, so it is important to document these input and output ranges.

For example, one way to test the flow transmitter in this system would be to subject it to a number of different pressures within its range (specified in the diagram as 0 to 100 inches of water column differential) and seeing whether or not the current signal output by the transmitter was consistently proportional to the applied pressure (e.g. 4 mA at 0 inches pressure, 20 mA at 100 inches pressure, 12 mA at 50 inches pressure, etc.).

Given the fact that a calibration error or malfunction in any one of these instruments can cause a problem for the control system as a whole, it is nice to know there is a way to determine which instrument is to blame and which instruments are not. This general principle holds true regardless of the instrument's type or technology. You can use the same input-versus-output test procedure to verify the proper operation of a pneumatic (3 to 15 PSI) level transmitter or an analog electronic (4 to 20 mA) flow transmitter or a digital (fieldbus) temperature transmitter alike. Each and every instrument has an input and an output, and there is always a predictable (and testable) correlation from one to the other.

Another interesting detail seen on this loop diagram is the *direction of action* of each instrument. You will notice a box and arrow (pointing either up or down) next to each instrument bubble. An “up” arrow (↑) represents a *direct-acting* instrument: one whose output signal increases as the input stimulus increases. A “down” arrow (↓) represents a *reverse-acting* instrument: one whose output signal decreases as the input stimulus increases. All the instruments in this loop are direct-acting with the exception of the pressure differential transmitter PDT-42:

Here, the “down” arrow tells us the transmitter will output a full-range signal (20 mA) when it senses zero differential pressure, and a 0% signal (4 mA) when sensing a full 200 PSI differential. While this calibration may seem confusing and unwarranted, it serves a definite purpose in this particular control system. Since the transmitter’s current signal decreases as pressure increases, and the controller must be correspondingly configured, a decreasing current signal will be interpreted by the controller as a high differential pressure. If any wire connection fails in the 4-20 mA current loop for that transmitter, the resulting 0 mA signal will be naturally “seen” by the controller as a pressure over-range condition. Excessive pressure drop across a compressor is considered dangerous because it may lead to the compressor surging<sup>3</sup>. Thus, the controller will naturally take action to prevent surge by commanding the anti-surge control valve to open, because it “thinks” the compressor is about to surge. In other words, the transmitter is intentionally calibrated to be reverse-acting such that any break in the signal wiring will naturally bring the system to its safest condition.

---

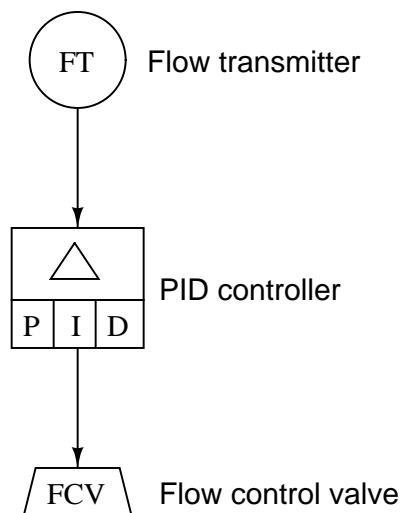

<sup>3</sup>Compressor “surge” is a violent and potentially self-destructing action experienced by a centrifugal compressor if the pressure drop across it becomes too high and the flow rate through it becomes too low. Surging may be prevented by opening up a “recycle” valve from the compressor’s discharge line to the suction line, ensuring adequate flow through the compressor while simultaneously unloading the high pressure differential across it.

## 7.4 Functional diagrams

A unique form of technical diagram for describing the abstract functions comprising a control system (e.g. PID controllers, rate limiters, manual loaders) is a *functional diagram*<sup>4</sup>. This form of document finds wide application in the power generation industry to document control strategies. Functional diagrams focus on the flow of information within a control system rather than on the process piping or instrument interconnections (wires, tubes, etc.). The general flow of a functional diagram is top-to-bottom, with the process sensing instrument (transmitter) located at the top and the final control element (valve or variable-speed motor) located at the bottom. No attempt is made to arrange symbols in a functional diagram to correspond with actual equipment layout: these diagrams are all about the *algorithms* used to make control decisions, and nothing more.

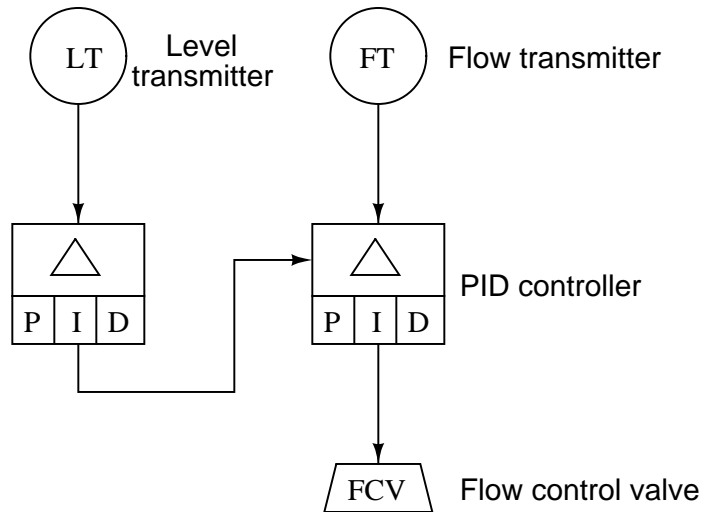

A sample functional diagram appears here, showing a flow transmitter (FT) sending a process variable signal to a PID controller, which then sends a manipulated variable signal to a flow control valve (FCV):

---

<sup>4</sup>Functional diagrams are sometimes referred to as *SAMA* diagrams in honor of the organization responsible for their standardization, the *Scientific Apparatus Makers Association*. This organization has been succeeded by the Measurement, Control, and Automation Association (MCAA), thus obsoleting the “SAMA” acronym.

A cascaded control system, where the output of one controller acts as the setpoint for another controller to follow, appears in functional diagram form like this:

In this case, the primary controller senses the level in a vessel, commanding the secondary (flow) controller to maintain the necessary amount of flow either in or out of the vessel as needed to maintain level at some setpoint.

Functional diagrams may show varying degrees of detail about the control strategies they document. For example, you may see the auto/manual controls represented as separate entities in a functional diagram, apart from the basic PID controller function. In the following example, we see a transfer block (T) and two manual adjustment blocks (A) providing a human operator the ability to separately adjust the controller's setpoint and output (manipulated) variables, and to transfer between automatic and manual modes:

Rectangular blocks such as the  $\Delta$ , P, I, and D shown in this diagram represent automatic functions. Diamond-shaped blocks such as the A and T blocks are manual functions (i.e. set by a human operator). Showing even more detail, the following functional diagram indicates the presence of *setpoint tracking* in the controller algorithm, a feature that forces the setpoint value to equal the process variable value any time the controller is in manual mode:

Here we see a new type of line: dashed instead of solid. This too has meaning in the world of functional diagrams. Solid lines represent analog (continuously variable) signals such as process variable, setpoint, and manipulated variable. Dashed lines represent discrete (on/off) signal paths, in this case the auto/manual state of the controller commanding the PID algorithm to get its setpoint either from the operator's input (A) or from the process variable input (the flow transmitter: FT).

## 7.5 Instrument and process equipment symbols

This section shows some of the many instrument symbols found in different types of technical diagrams used to document instrument systems.

## 7.5.1 Line types

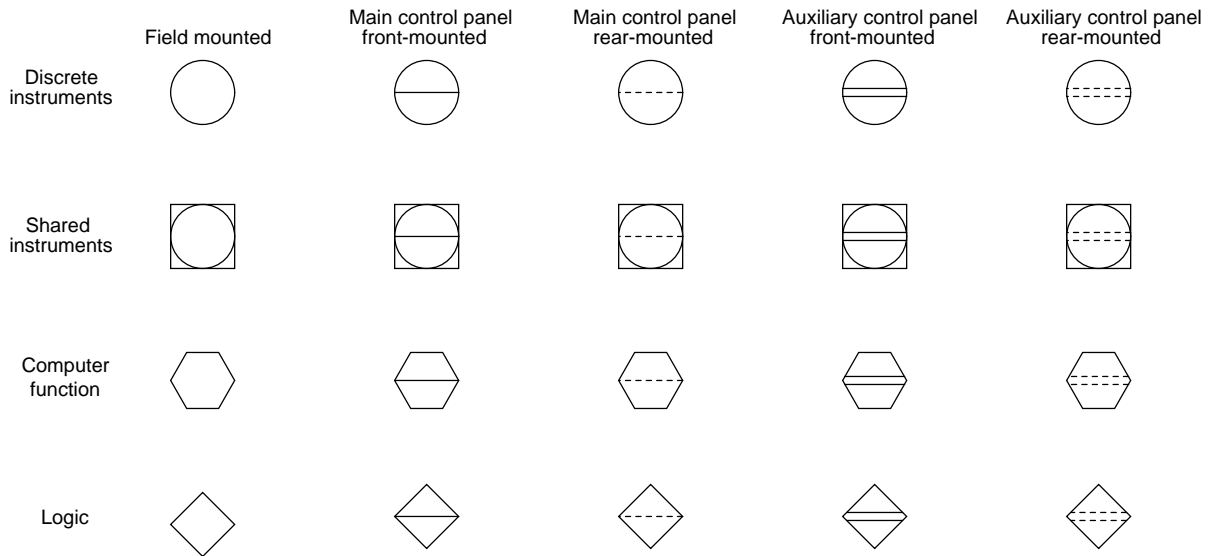

Process flow line 	Instrument supply or process connection (impulse line) 	Waveguide 	Undefined 
Pneumatic signal (continuous) 	Pneumatic signal (discrete -- on/off) 	Capillary tube 	Hydraulic signal 
Electric signal (continuous)  (or) 	Electric signal (discrete -- on/off)  (or) 	Fieldbus network 	Data link (smart instrument) 
Mechanical link 	Data link (common system) 	Data link (independent systems) 	Radio link 
Sonic or other wave 			

Note: the single backslash signifying a “discrete” or “binary” signal type has been removed from the ISA standard as of the 2009 ANSI publication. Regular pneumatic and electrical line symbols may represent either continuous or discrete states. The “triple-slash” alternative linetype for electrical symbols is also absent from the 2009 ANSI/ISA standard.

## 7.5.2 Process/Instrument line connections

## 7.5.3 Instrument bubbles

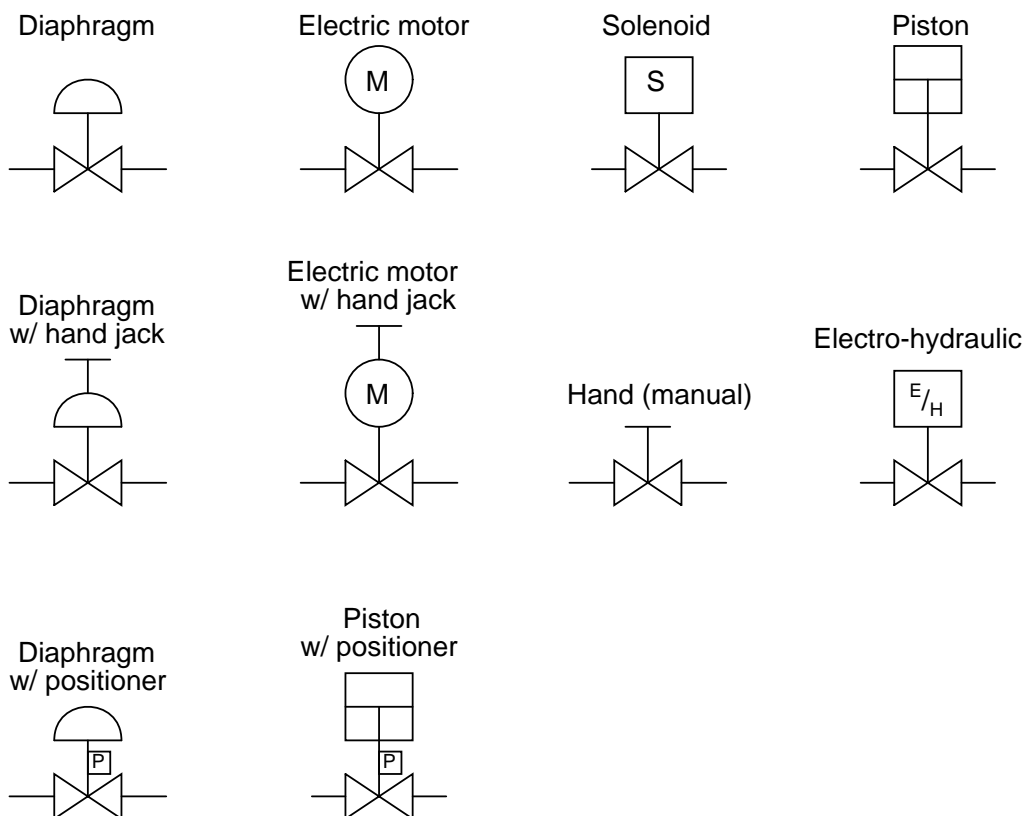

## 7.5.4 Process valve types

*Valve status may or may not be shown in a process diagram. If you happen to see solid-colored valve symbols anywhere in a diagram, you know that status is being represented. If you see no solid-colored valves anywhere in the diagram, either all valves are shown open or else status is not represented at all.*

## 7.5.5 Valve actuator types

**7.5.6 Valve failure mode**

## 7.5.7 Liquid level measurement devices

Bubbler (dip tube)

Capacitive

Tape-and-float

Hydrostatic

Hydrostatic (w/ seals)

Displacer

Radar (guided)

Radar (non-contact)

Ultrasonic

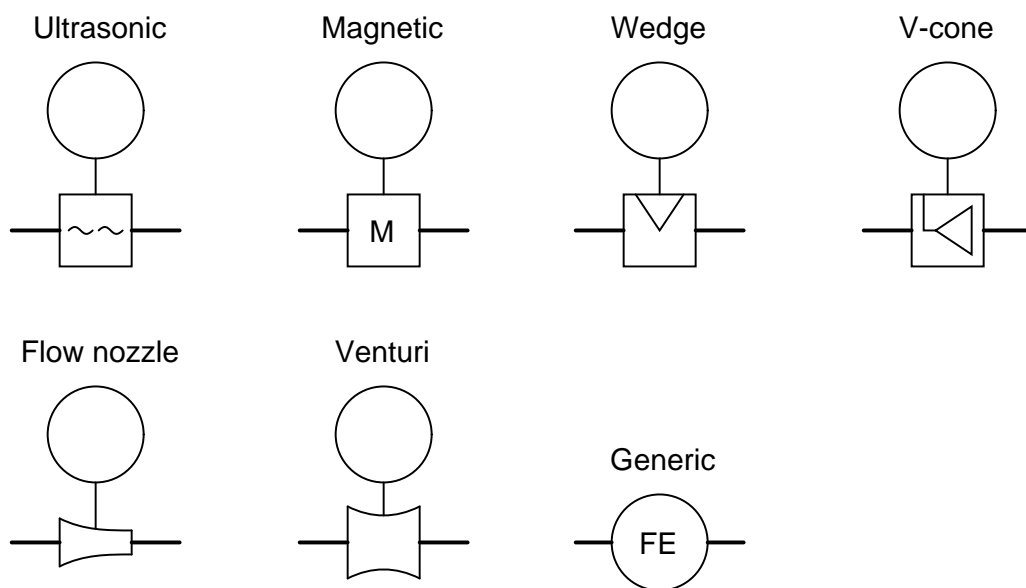

Laser

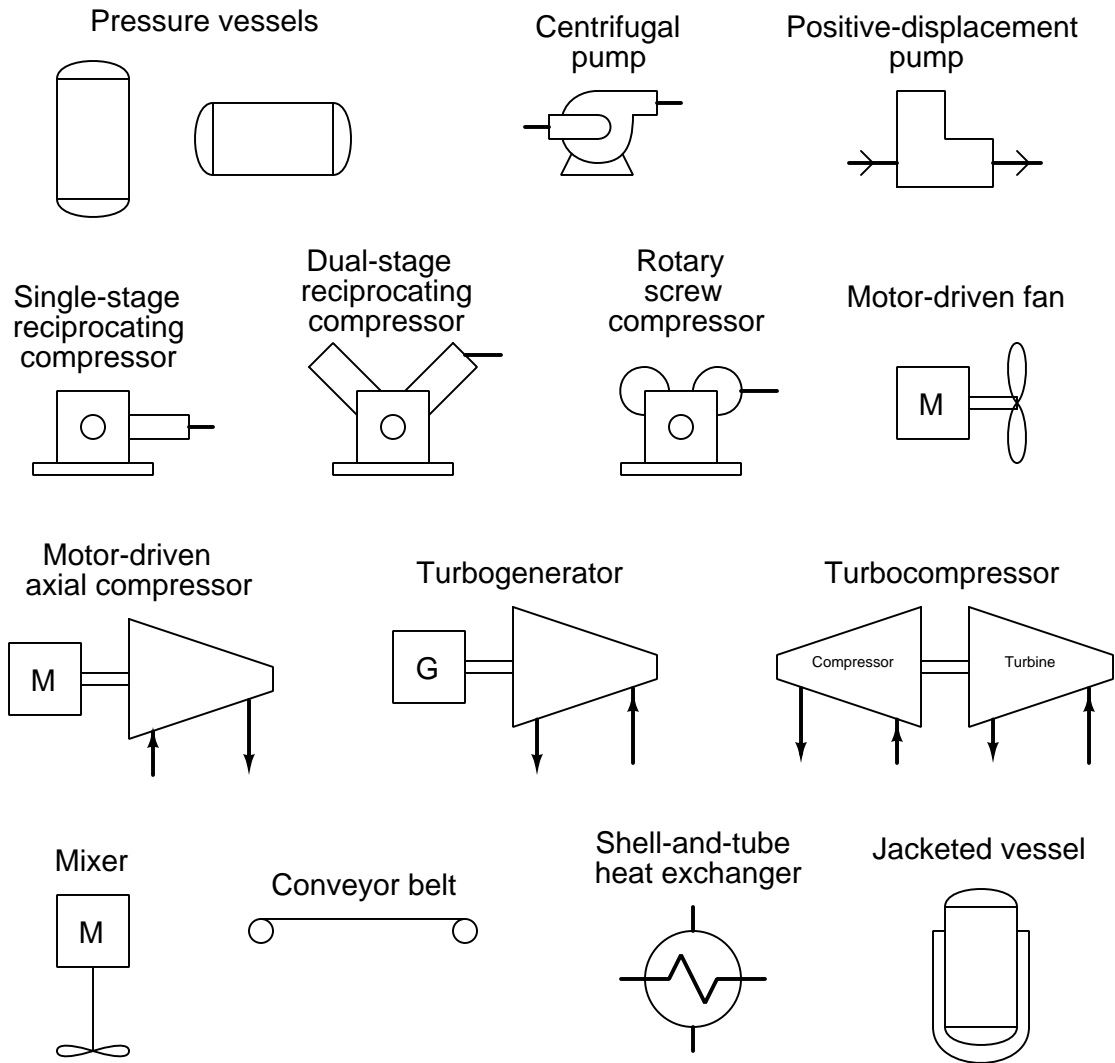

## 7.5.8 Flow measurement devices (flowing left-to-right)

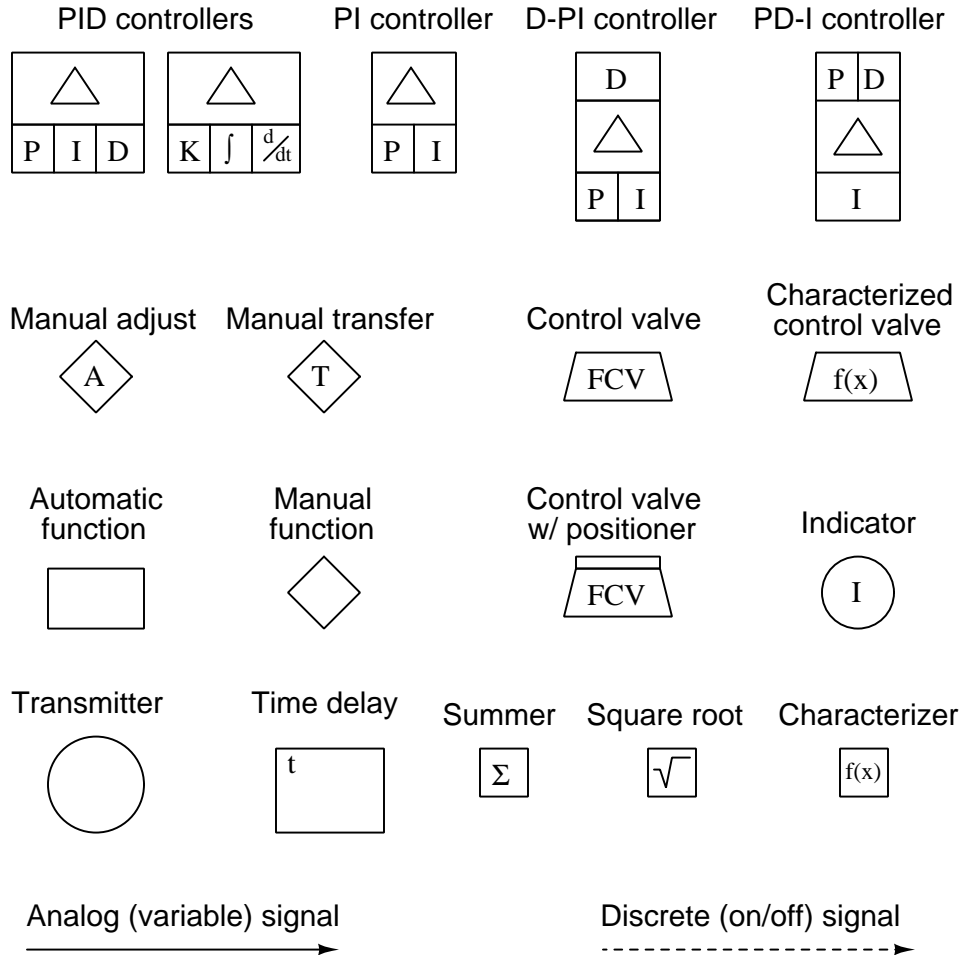

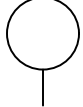

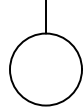

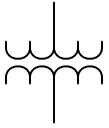

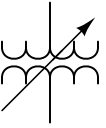

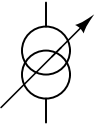

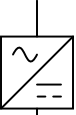

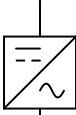

## 7.5.9 Process equipment

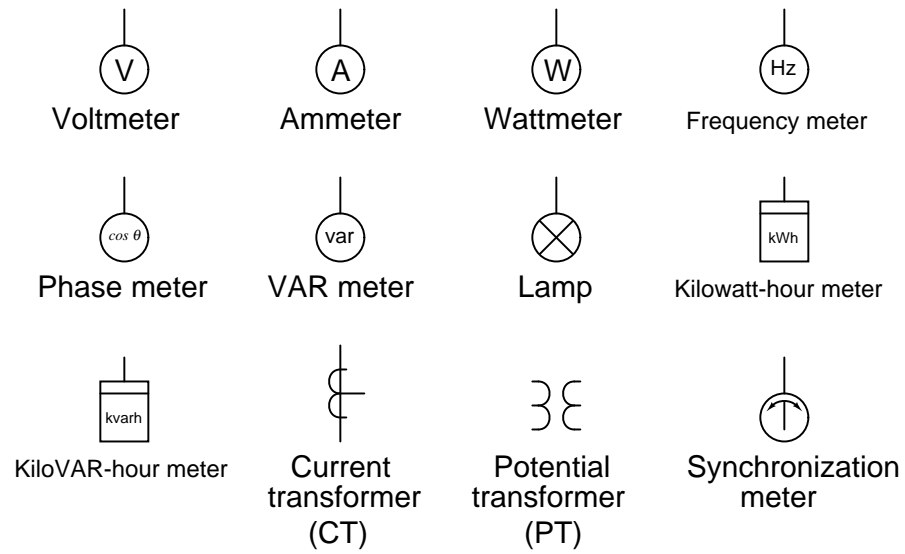

## 7.5.10 Functional diagram symbols

## 7.5.11 Single-line electrical diagram symbols

			
Fuse (600 V or less)	Fuse (> 600 V)	Circuit breaker (600 V or less)	Circuit breaker (> 600 V)
			
Disconnect	Overload heater	Draw-out circuit breaker (600 V or less)	Draw-out circuit breaker (> 600 V)
			
Lightning arrester	Contactor	Generator	Motor
			
Transformer	Transformer (alternate symbol)	Variable transformer	Variable transformer (alternate symbol)
			
Rectifier	Inverter	DC motor drive	AC motor drive

## 7.5.12 Fluid power diagram symbols

Hydraulic pump  
(fixed displacement)Hydraulic pump  
(variable displacement)Hydraulic motor  
(fixed displacement)Hydraulic motor  
(variable displacement)Air compressor  
(fixed displacement)Air compressor  
(variable displacement)Air motor

Solenoid actuator

Pressure actuator

Lever actuator

Roller actuator

Button actuator

Return spring

Pressure relief (shunt regulator)

Pressure regulator (series)

Hydraulic line

Pneumatic line

## 7.6 Instrument identification tags

Up until this point, we have explored various types of instrumentation diagram, each one making reference to different instruments by lettered identifiers such as TT (Temperature Transmitter), PDT (Pressure Differential Transmitter), or FV (Flow Valve), without formally defining all the letters used to identify instruments. Part of the ISA 5.1 standard does exactly this, which is what we will now investigate.

Each instrument within an instrumented facility should have its own unique identifying *tag* consisting of a series of letters describing that instrument's *function*, as well as a number identifying the particular *loop* it belongs to. An optional numerical prefix typically designates the larger area of the facility in which the loop resides, and an optional alphabetical suffix designates multiple instances of instruments within one loop.

For example, if we were to see an instrument bearing the tag FC-135, we would know it was a *flow controller* (FC) for loop number 135. In a large manufacturing facility with multiple processing “unit” areas, a tag such as this might be preceded by another number designating the unit area. For example, our hypothetical flow controller might be labeled 12-FC-135 (flow controller for loop #135, located in unit #12). If this loop happened to contain multiple controllers, we would need to distinguish them from each other by the use of suffix letters appended to the loop number (e.g. 12-FC-135A, 12-FC-135B, 12-FC-135C).

Each and every instrument within a particular loop is first defined by the variable that loop seeks to sense or control, regardless of the physical construction of the instrument itself. Our hypothetical flow controller FC-135, for example, may be physically identical to the level controller in loop #72 (LC-72), or to the temperature controller in loop #288 (TC-288). What makes FC-135 a *flow* controller is the fact that the transmitter sensing the main process variable measures *flow*. Likewise, the identifying tag for every other instrument within that loop<sup>5</sup> must begin with the letter “F” as well. This includes the final control element as well: in a level control loop, the transmitter is identified as an “LT” even if the actual sensing element works on *pressure* (because the variable that the loop strives to sense or control is actually level, despite the fact that liquid level is being inferred from pressure), the controller is identified as an “LC”, and the control valve throttling fluid *flow* is identified as an “LV”: every instrument in that level-controlling loop serves to help control *level*, and so its primary function is to be a “level” instrument.

---

<sup>5</sup>Exceptions do exist to this rule. For example, in a cascade or feedforward loop where multiple transmitters feed into one or more controllers, each transmitter is identified by the type of process variable *it* senses, and each controller's identifying tag follows suit.

Valid letters recognized by the ISA for defining the primary process variable of an instrument within a loop are shown in the following table. Please note that the use of a modifier defines a unique variable: for example, a “PT” is a transmitter measuring *pressure* at a single point in a process, whereas a “PDT” is a transmitter measuring a *pressure difference* between two points in a process. Likewise, a “TC” is a controller controlling temperature, whereas a “TKC” is a controller controlling the *rate-of-change of temperature*:

Letter	Variable	Modifier
A	Analytical (composition)	
B	Burner or Combustion	
C	<i>User-defined</i>	
D	<i>User-defined</i>	Differential
E	Voltage	
F	Flow	Ratio or Fraction
G	<i>User-defined</i>	
H	Hand (manual)	
I	Current	
J	Power	Scan
K	Time or Schedule	Time rate-of-change
L	Level	
M	<i>User-defined</i>	Momentary
N	<i>User-defined</i>	
O	<i>User-defined</i>	
P	Pressure or Vacuum	
Q	Quantity	Time-Integral or Total
R	Radiation	
S	Speed or Frequency	Safety
T	Temperature	
U	Multi-function	
V	Vibration	
W	Weight or Force	
X	<i>Unclassified</i>	X-axis
Y	Event, State, or Presence	Y-axis
Z	Position or Dimension	Z-axis

A “user-defined” letter represents a non-standard variable used multiple times in an instrumentation system. For example, an engineer designing an instrument system for measuring and controlling the *refractive index* of a liquid might choose to use the letter “C” for this variable. Thus, a refractive-index transmitter would be designated “CT” and a control valve for the refractive-index loop would be designated “CV”. The meaning of a user-defined variable need only be defined in one location (e.g. in a legend for the diagram).

An “unclassified” letter represents one or more non-standard variables, each used only once (or a very limited number of times) in an instrumentation system. The meaning of an unclassified variable is best described immediately near the instrument’s symbol rather than in a legend.

Succeeding letters in an instrument tag describe the function that instrument performs relative to the process variable. For example, a “PT” is an instrument *transmitting* a signal representing pressure, while a “PI” is an *indicator* for pressure and a “PC” is a *controller* for pressure. Many instruments have multiple functions designated by multiple letters, such as a TRC (Temperature *Recording Controller*). In such cases, the first function letter represents the “passive” function (usually provided to a human operator) while the second letter represents the “active” (automated) control function.

Letter	Passive function	Active function	Modifier
A	Alarm		
B	<i>User-defined</i>	<i>User-defined</i>	<i>User-defined</i>
C		Control	
E	Element (sensing)		
G	Glass or Viewport		
H			High
I	Indicate		
K		Control station	
L	Light		Low
M			Middle or Intermediate
N	<i>User-defined</i>	<i>User-defined</i>	<i>User-defined</i>
O	Orifice		
P	Test point		
R	Record		
S		Switch	
T		Transmit	
U	Multi-function	Multi-function	Multi-function
V		Valve, Damper, Louver	
W	Well		
X	<i>Unclassified</i>	<i>Unclassified</i>	<i>Unclassified</i>
Y		Relay, Compute, Convert	
Z		Driver, Actuator, or unclassified final control element	

A variety of other letter combinations are often used to identify details not standardized by the ISA. For example, chemical analyzer instruments often have their sample tube connections represented by the letter combination “SC,” although this does not appear anywhere in the ISA 5.1 standard.

Some examples of instrument tag letters are shown in the following list:

- **AIT** = Analytical Indicating Transmitter (*e.g. an oxygen concentration analyzer with a built-in display of oxygen percentage*)
- **ESL** = Voltage Switch, Low (*e.g. a switch used to detect an under-voltage condition in an electrical power system*)
- **FFI** = Flow Ratio Indicator (*e.g. a device indicating the ratio between air and fuel for a large industrial engine*)
- **FIC** = Flow Indicating Controller (*i.e. a controller designed to indicate flow to a human operator*)
- **HC** = Hand Controller (*i.e. a device allowing a human operator to set a control signal to some desired level, usually to operate a valve or other final control element*)
- **JQR** = Power Totalizing Recorder (*e.g. a watt-hour recorder, tracking total energy used*)
- **LSHH** = Level Switch, High-High (*e.g. a level-sensing switch designed to detect a dangerously high liquid level and initiate an automatic shutdown in that event*)
- **LT** = Level Transmitter (*i.e. a device sensing liquid level and reporting that level in some analog or digital form*)
- **PIT** = Pressure Indicating Transmitter (*e.g. a Rosemount model 3051 pressure transmitter with a built-in display of measured pressure*)
- **PDT** = Pressure Differential Transmitter (*i.e. a pressure transmitter built and installed to sense the difference of pressure between two points in a fluid system*)
- **PV** = Pressure Valve (*i.e. a control valve installed in a loop where the process variable is pressure*)
- **TE** = Temperature Element (*i.e. a sensing element used to directly detect the temperature of a process material; e.g. a thermocouple, thermistor, filled-bulb, bimetallic spring*)
- **TKAH** = Temperature Rate-of-change Alarm, High (*i.e. a device alarming when the rate of temperature change exceeds a pre-set limit*)
- **TV** = Temperature Valve (*i.e. a control valve installed in a loop where the process variable is temperature*)
- **TY** = Temperature Converter (*e.g. an I/P transducer in a temperature loop*)
- **VSH** = Vibration Switch, High (*i.e. a switch used to detect a high level of vibration on a piece of machinery*)
- **ZXI, ZYI, and ZZI** = Position Indicators for X, Y, and Z axes respectively (*e.g. indicators showing the three axis positions for a CNC machine tool*)

## Chapter 8

# Instrument connections

All instruments connect to their respective processes and to each other by means of pipe, tube, and/or wires. Improper installation of these connective lines can make the difference between success or failure in an installation. Safety is also impacted by improper connections between instruments and the process, and from instrument to instrument.

### 8.1 Pipe and pipe fittings

Pipe is a hollow structure designed to provide an enclosed pathway for fluids to flow, usually manufactured from cast metal (although plastic is a common pipe material for many industrial applications). This section discusses some of the more common methods for joining pipes together (and joining pipe ends to equipment such as pressure instruments).

### 8.1.1 Flanged pipe fittings

In the United States of America, most large industrial pipes are joined together by *flanges*. A pipe “flange” is a ring of metal, usually welded to the end of a pipe, with holes drilled in it parallel to the pipe centerline to accept several bolts:

Flange joints are made pressure-tight by inserting a donut-shaped gasket between the flange pairs prior to tightening the bolts. Gaskets are manufactured from materials softer than the flange material. When sandwiched between a pair of flanges, the gasket will be “crushed” between them to seal all potential leak paths.

In instrument diagrams such as P&IDs, flanges are denoted by two short parallel lines, both perpendicular to the pipe. The pipe size of the flange is often written near the flange symbol, as is the case with this 8-inch flange symbol shown below:

A photograph showing a Rosemount magnetic flowmeter installed with 4-bolt flange fittings appears here:

If you examine the flanged connections closely, you can see the gap between the flange faces created by the thickness of the gasket material “sandwiched” between the flange pairs.

In this next photograph, we see a pair of large pipe flange connections on either end of a relatively short “spool” pipe section. The large number of studs holding each flange set together gives you some indication of the pressure of the fluid within, in this case upwards of 1000 PSI!

Like the flowmeter flanges shown previously, gaps between the flange ring faces reveal the space occupied by the gasket sealing those flange surfaces together to form a pressure-tight seal.

A common method of installing such a flange gasket is to first install only half of the bolts (in the holes lower than the centerline of the pipe), drop the gasket between the flanges, insert the remaining bolts, then proceed to tighten all bolts to the proper torques:

(All views shown end-wise)

Flanges differ with regard to their sealing design and required gasket type. In the United States, one of the most common flange “face” designs is the *raised-face* (RF) flange, designed to seal against a gasket by means of a set of concentric grooves machined on the face of the flange. These grooves form a sealing surface with far greater leakage path length than if the faces were smooth, thus discouraging leakage of process fluid under pressure.

Another flange face design is called *ring-type joint* (RTJ). In this design, a special metal ring sits inside a groove machined into the faces of both mating flanges, crushing and filling that groove when the flanges are properly tightened together. RTJ flanges are typically found on high-pressure applications where leakage control is more challenging. The grooves in RTJ flanges must be completely free of foreign material, and well-formed (not distorted) in order to achieve proper sealing.

In the United States, flanges are often rated according to a system of “pressure classes” defined in the ANSI (American National Standards Institute) standard 16.5. These pressure classes are designated by numerical values followed by “pound”, “lb”, or “#”. Common ANSI ratings include the 150#, 300#, 400#, 600#, 900#, 1500#, and 2500# pressure classes. It should be noted that these class numbers do *not* refer directly to pressure ratings in units of PSI, but that they do scale with pressure (i.e. a 600# flange will have a greater pressure rating than a 300# flange, all other factors being equal). Pressure ratings not only vary with the “class” of the flange, but also with operating temperature, as metals tend to weaken at elevated temperature.

Originally, the ANSI class designations were based on the ratings of these flanges in steam line service. A 250# flange, for instance, was rated such because it was designed to be used in piping service where the fluid was saturated steam at 250 PSI (and 400 degrees Fahrenheit). As metallurgy advanced, these flanges became capable of handling higher pressures at higher temperatures, but the original “pound” rating remained<sup>1</sup>. This state of affairs is not unlike the “tonnage” rating of American light trucks: a “one-ton” truck is actually capable of hauling far more than 2000 pounds of cargo. The “one-ton” designation refers to a particular design which used to be rated for

<sup>1</sup>EBAA Iron Sales, Inc published a two-page report in 1994 (“Connections” FL-01 2-94) summarizing the history of flange “pound” ratings, from the ASME/ANSI B16 standards.

approximately 2000 pounds, but through advances in metallurgy and manufacturing is now able to carry well over that rating.

Piping flanges and components must have matching flange ratings and sizes in order to properly function. For example, a control valve with a flanged body rated as a 4-inch ANSI class 300# can only be properly joined to another 4-inch ANSI class 300# pipe flange. The physical integrity of the piping system will be jeopardized if mis-matched pressure-class flanges are connected together. Proper gasket types must also be selected to coordinate with the pressure class of the mating flanges. Thus, each and every flanged joint must be considered a complete *system*, with integrity ensured only if all components comprising that system are designed to work together.

A very important procedure to observe when tightening the bolts holding two flanges together is to evenly distribute the bolt pressure, so that no single region of the flange receives significantly more bolt pressure than any other region. In an ideal world, you would tighten all bolts to the same torque limit *simultaneously*. However, since this is impossible with just a single wrench, the best alternative is to tighten the bolts in alternating sequence, in stages of increasing torque. An illustrative torque sequence is shown in the following diagram (the numbers indicate the order in which the bolts should be tightened):

With one wrench, you would tighten each bolt to a preliminary torque in the sequence shown. Then, you would repeat the tightening sequence with additional torque for a more cycles until all bolts had been tightened to the recommended torque value. Note how the torque sequence alternates between four quadrants of the flange, ensuring the flanges are evenly compressed together as all bolts are gradually tightened. This technique of alternating quadrants around the circle is often referred to as *cross-torquing*.

Special wrenches called *torque wrenches* exist for the purpose of measuring applied torque during the tightening process. In critical, high-pressure applications, the actual *stretch* of each flange bolt is measured as a direct indication of bolting force. A special bolt sold under the brand name of *Rotabolt* contains its own built-in strain indicator, letting the mechanic know when the bolt has been sufficiently tightened regardless of the tool used to tighten it.

Another important procedure to observe when working with flanged pipe connections is to loosen the bolts on the *far* side of the flange before loosening the bolts on the side of the flange nearest you. This is strictly a precautionary measure against the spraying of process fluid toward your face or body in the event of stored pressure inside of a flanged pipe. By reaching over the pipe to first loosen flange bolts on the far side, if any pressure happens to be inside the pipe, it should leak there first, venting the pressure in a direction away from you.

A special provision of flanged pipe connections is the ability to install a blank metal plate called a *blind* over or between flange faces, thereby preventing flow. This is useful when a pipe must be blocked in a semi-permanent fashion, for example if that section of pipe has been decommissioned, or if the section of pipe must be sealed for reasons of safety during maintenance operations.

In order to install a blind, the flange joint must first be broken, then the flanges pried apart to provide the necessary space for the blind. After installing new gaskets along with the blind, the flanged bolts may then be re-installed and torqued to specification. A photograph of a stainless-steel blind (not installed on a pipe) appears here, two welded lifting tabs being clearly seen to facilitate handling this heavy piece of hardware:

In applications where “blinding” is frequent, a permanent form of blind called a *spectacle blind* may be installed to simplify the task. A spectacle blind is comprised of a regular blind plate attached to an equal-diameter ring by a short tab, the outline of which resembles a pair of spectacles:

Since the spectacle blind’s ring is exactly the same thickness as its blind plate, the piping system may be designed and built with the blind’s thickness in mind, the flange-to-flange gap remaining constant for the “open” and “blinded” states. This is especially helpful in very large piping systems, where the force required to separate formerly mated flange faces may be very large.

A spectacle blind may be seen in this next photograph, where the blind is installed in such a way that the yellow-painted “blind” half is exposed and the “open” half is sandwiched between the pipe flanges to allow flow through that pipe:

This next photograph shows a spectacle blind installed the other way, where the “open” half is exposed and the “blind” half is blocking any fluid from moving through the pipe:

### 8.1.2 Tapered thread pipe fittings

For smaller pipe sizes, *threaded fittings* are more commonly used to create connections between pipes and between pipes and equipment (including some instruments). A very common design of threaded pipe fitting is the *tapered* pipe thread design. The intent of a tapered thread is to allow the pipe and fitting to “wedge” together when engaged, creating a joint that is both mechanically rugged and leak-free.

When male and female tapered pie threads are first engaged, they form a loose junction:

After tightening, however, the tapered profile of the threads acts to wedge both male and female pieces tightly together as such:

Several different standards exist for tapered-thread pipe fittings. For each standard, the angle of the thread is fixed, as is the angle of taper. Thread *pitch* (the number of threads per unit length)

varies with the diameter of the pipe fitting<sup>2</sup>.

In the United States, the most common tapered thread standard for general-purpose piping is the *NPT*, or *National Pipe Taper* design. NPT threads have an angle of  $60^\circ$  and a taper of  $1^\circ 47'$  ( $1.7833^\circ$ ):

NPT pipe threads must have some form of *sealant* applied prior to assembly to ensure pressure-tight sealing between the threads. Teflon tape and various liquid pipe “dope” compounds work well for this purpose. Sealants are necessary with NPT threads for two reasons: to lubricate the male and female pieces (to guard against galling the metal surfaces), and also to fill the spiral gap formed between the root of the female thread and the crest of the male thread (and vice-versa).

NPTF (National Pipe Thread) pipe threads are engineered with the same thread angle and pitch as NPT threads, but carefully machined to avoid the spiral leak path inherent to NPT threads. This design – at least in theory – avoids the need to use sealant with NPTF threads to achieve a pressure-tight seal between male and female pieces, which is why NPTF threads are commonly referred to as *dryseal*. However, in practice it is still recommended that some form of sealant be used (or at the very least some form of thread *lubricant*) in order to achieve reliable sealing.

ANPT (Aeronautical National Pipe Tapered) is identical to NPT, except with a greater level of precision and quality for its intended use in aerospace and military applications.

<sup>2</sup>For example, 1/8 inch NPT pipe fittings have a thread pitch of 27 threads per inch. 1/4 inch and 3/8 inch NPT fittings are 18 threads per inch, 1/2 inch and 3/4 inch NPT fittings are 14 threads per inch, and 1 inch through 2 inch NPT fittings are 11.5 threads per inch.

Another tapered-thread standard is the *BSPT*, or *British Standard Pipe Tapered*. BSPT threads have a narrower thread angle than NPT threads ( $55^\circ$  instead of  $60^\circ$ ) but the same taper of  $1^\circ 47'$  ( $1.7833^\circ$ ):

### 8.1.3 Parallel thread pipe fittings

An alternative to tapered threads in pipe joints is the use of parallel threads, similar to the threads of machine screws and bolts. Since parallel threads are incapable of forming a pressure-tight seal on their own, the sealing action of a parallel thread pipe fitting must be achieved some other way. This function is usually met with an O-ring or gasket.

In the United States, a common design of parallel-thread pipe fitting is the *SAE straight thread*, named after the *Society of Automotive Engineers*:

Sealing is accomplished as the O-ring is compressed against the shoulder of the female fitting. The threads serve only to provide force (not fluid sealing), much like the threads of a fastener.

Another parallel-thread pipe standard is the *BSPP*, or *British Standard Pipe Parallel*. Like the BSPT (tapered) standard, the thread angle of BSPP is 55°. Like the SAE parallel-thread standard, sealing is accomplished by means of an O-ring which compresses against the shoulder of the matching female fitting:

### 8.1.4 Sanitary pipe fittings

Food processing, pharmaceuticals manufacturing, and biological research processes are naturally sensitive to the presence of micro-organisms such as bacteria, fungi, and algae. It is important in these processes to ensure the absence of harmful micro-organisms, for reasons of both human health and quality control. For this reason, the process piping and vessels in these industries is designed first and foremost to be thoroughly cleaned without the need for disassembly. Regular cleaning and sterilization cycles are planned and executed between production schedules (batches) to ensure no colonies of harmful micro-organisms can grow.

A common *Clean-In-Place* (CIP) protocol consists of draining all process piping and vessels of process liquid, then flushing them with a sequence of rinse water, detergent solution, caustic solution, and sometimes an acid solution, followed by a final water rinse. For increased sanitization, a *Steam-In-Place* (SIP) cycle may be incorporated as well, sterilizing all process pipes and vessels with hot steam to ensure the destruction of any micro-organisms.

An important design feature of any sanitary process is the elimination of any “dead ends” (often called *dead legs* in the industry), crevices, or voids where fluid may collect and stagnate. This includes any instruments contacting the process fluids. It would be unsafe, for example, to connect something as simple as a bourdon-tube pressure gauge to a pipe carrying biologically sensitive fluid(s), since the interior volume of the bourdon tube will act as a stagnant refuge for colonies of micro-organisms to grow:

Instead, any pressure gauge must use an isolating diaphragm, where the process fluid pressure is transferred to the gauge mechanism through a sterile “fill fluid” that never contacts the process fluid:

With the isolating diaphragm in place, there are no stagnant places for process fluid to collect and avoid flushing by CIP or SIP cycles.

Standard pipe fittings are problematic in sanitary systems, as tiny voids between the mating threads of male and female pipe fittings may provide refuge for micro-organisms. To avoid this problem, special *sanitary fittings* are used instead. These fittings consist of a matched pair of flanges, held together by an external clamp. An array of sanitary fittings on an instrument test bench appear in the following photograph:

The next photograph shows the installation of a pressure transmitter on an ultra-pure water line using one of these sanitary fittings. The external clamp holding the two flanges together is clearly visible in this photograph:

Sanitary pipe fittings are not limited to instrument connections, either. Here are two photographs of process equipment (a ball valve on the left, and a pump on the right) connected to process pipes using sanitary fittings:

## 8.2 Tube and tube fittings

Tube, like pipe, is a hollow structure designed to provide an enclosed pathway for fluids to flow. In the case of tubing, it is usually manufactured from rolled or extruded metal (although plastic is a common tube material for many industrial applications). This section discusses some of the more common methods for joining tubes together (and joining tube ends to equipment such as pressure instruments).

One of the fundamental differences between tube and pipe is that tube is *never* threaded at the end to form a connection. Instead, a device called a *tube fitting* must be used to couple a section of tube to another tube, or to a section of pipe, or to a piece of equipment (such as an instrument). Unlike pipes which are thick-walled by nature, tubes are thin-walled structures. The wall thickness of a typical tube is simply too thin to support threads.

Tubes are generally favored over pipe for small-diameter applications. The ability for skilled workers to readily cut and bend tube with simple hand tools, as well as the ability to repeatedly break and re-make tube connections without compromising the integrity of the seals, makes tube the preferred choice for connecting instruments to process piping. When used as the connecting units between an instrument and a process pipe or vessel, the tube is commonly referred to as an *impulse tube* or *impulse line*<sup>3</sup>.

---

<sup>3</sup>Impulse lines are alternatively called *gauge lines* or *sensing lines*.

### 8.2.1 Compression tube fittings

By far the most common type of tube fitting for instrument impulse lines is the *compression-style* fitting, which uses a compressible *ferrule* to perform the task of sealing fluid pressure. The essential components of a compression tube fitting are the *body*, the *ferrule*, and the *nut*. The ferrule and body parts have matching conical profiles designed to tightly fit together, forming a pressure-tight metal-to-metal seal. Some compression fitting designs use a two-piece ferrule assembly, such as this tube fitting shown here<sup>4</sup> (prior to full assembly):

Just prior to assembly, we see how the nut will cover the ferrule components and push them into the conical entrance of the fitting body:

After properly tightening the nut, the ferrule(s) will *compress* onto the outside circumference of the tube, slightly crimping the tube in the process and thereby locking the ferrules in place:

<sup>4</sup>This happens to be a Swagelok brass instrument tube fitting being installed on a 3/8 inch copper tube.

When initially assembling compression-style tube fittings, you should always precisely follow the manufacturer's instructions to ensure correct compression. For Swagelok-brand instrument tube fittings 1 inch in size and smaller, the general procedure to "swage" a new connector to a tube is to tighten the nut 1-1/4 turns past finger-tight. Insufficient turning of the nut will fail to properly compress the ferrule around the tube, and excessive turning will over-compress the ferrule, resulting in leakage. After this initial "swaging," the connector may be separated by loosening the nut until it no longer engages with the body, then the connection may be re-made by threading the nut back on the body until finger-tight and then gently tightening with a wrench until snug (no additional 1-1/4 turns!!!).

Swagelok provides special gauges which may be used to measure proper ferrule compression during the assembly process. The design of the gauge is such that its thickness will fit between the nut and fitting shoulder if the nut is insufficiently tightened, but will not fit if it is sufficiently tightened. Thus the gauge has the ability to reveal an under-tightened fitting, but not an over-tightened fitting. These gauges fit easily in the palm of one's hand:

Such gauges are referred to in the industry as *no-go gap gauges*, because their inability to fit between the nut and body shoulder of a tube fitting indicates a properly-tightened fitting. In other words, the gauge fit will be "no-go" if the tube fitting has been properly assembled.

Photographs showing one of these gauges testing a properly-tightened fitting (left) versus an under-tightened fitting (right) appear here:

Parker is another major manufacturer<sup>5</sup> of instrument tube fittings, and their product line uses a single-piece ferrule instead of the two-piece design preferred by Swagelok. Like Swagelok fittings, Parker instrument fitting sized 1/4 inch to 1 inch require 1-1/4 turns past hand tight to properly compress the ferrule around the circumference of the tube. Parker also sells gauges which may be used to precisely determine when the proper amount of ferrule compression is achieved.

---

<sup>5</sup>So is Gyrolok, Hoke, and a host of others. It is not my intent to advertise for different manufacturers in this textbook, but merely to point out some of the more common brands an industrial instrument technician might encounter on the job.

What a gap gauge will not indicate is *over-tightening*. Over-tightening of a compression fitting is just as bad as under-tightening, as the fitting cannot form a robust seal once the ferrule and tube have been deformed. An example of an over-tightened Swagelok two-piece ferrule (left) on a plastic tube appears in the following photograph, next to a properly swaged ferrule (right):

Note the lack of a substantial gap between the two ferrule pieces in the over-tightened example. Note also the steeper cone taper of the over-tightened front ferrule, as a result of being pushed too deep inside the fitting body.

Regardless of the brand, compression-style instrument tube fittings are incredibly strong and versatile. Unlike pipe fittings, tube fittings may be disconnected and reconnected with ease. No special procedures are required to “re-make” a disassembled instrument fitting connection: merely tighten the nut “snug” to maintain adequate force holding the ferrule to the fitting body, but not so tight that the ferrule compresses further around the tube than it did during initial assembly.

A very graphic illustration of the strength of a typical instrument tube fitting is shown in the following photograph, where a short section of 3/8 inch stainless steel instrument tube was exposed to high liquid pressure until it ruptured. Neither compression fitting on either side of the tube leaked during the test, despite the liquid pressure reaching a peak of 23000 PSI before rupturing the tube<sup>6</sup>:

---

<sup>6</sup>It should be noted that the fitting nuts became seized onto the tube due to the tube's swelling. The tube fittings may not have leaked during the test, but their constituent components are now damaged and should never be placed into service again.

### 8.2.2 Common tube fitting types and names

Tube fittings designed to connect a tube to pipe threads are called *connectors*. Tube fittings designed to connect one tube to another are called *unions*:

If a tube union joins together different tube sizes rather than tubes of the same size, it is called a *reducing union*.

A variation on the theme of tube connectors and unions is the *bulkhead* fitting. Bulkhead fittings are designed to fit through holes drilled in panels or enclosures to provide a way for a fluid line to pass through the wall of the panel or enclosure. In essence, the only difference between a bulkhead fitting and a normal fitting is the additional length of the fitting “barrel” and a special nut used to lock the fitting into place in the hole. The following illustration shows three types of bulkhead fittings:

Tubing *elbows* are tube connectors with a bend. These are useful for making turns in tube runs without having to bend the tubing itself. Like standard connectors, they may terminate in male pipe thread, female pipe threads, or in another tube end:

These elbows shown in the above illustration are all  $90^\circ$ , but this is not the only angle available.  $45^\circ$  elbows are also common.

*Tee* fittings join three fluid lines together. Tees may have one pipe end and two tube ends (*branch* tees and *run* tees), or three tube ends (*union* tees). The only difference between a branch tee and a run tee is the orientation of the pipe end with regard to the two tube ends:

Of course, branch and run tee fittings also come in female pipe thread versions as well. A variation of the theme of union tees is the *cross*, joining four tubes together:

Special tube fittings are made to terminate tube connections, so they are sealed up instead of open. A piece designed to seal off the open end of a tube fitting is called a *plug*, while a piece designed to seal off the end of an open tube is called a *cap*:

### 8.2.3 Bending instrument tubing

Tube bending is something of an art, especially when done with stainless steel tubing. It is truly magnificent to see a professionally-crafted array of stainless steel instrument tubes, all bends perfectly made, all terminations square, all tubes parallel when laid side by side and perfectly perpendicular when crossing.

If possible, a goal in tube bending is to eliminate as many connections as possible. Connections invite leaks, and leaks are problematic. Long runs of instrument tubing made from standard 20 foot tube sections, however, require junctions be made somewhere, usually in the form of tube *unions*. When multiple tube unions must be placed in parallel tube runs, it is advisable to offset the unions so it is easier to get a wrench around the tube nuts to turn them. The philosophy here, *as always*, is to build the tubing system with future work in mind. A photograph of several tube junctions shows one way to do this:

If an instrument tube must connect between a stationary object and a vibrating object, a straight (square) run of tube is actually not desirable, since it will not have much flexibility to absorb the vibration. Instead, a *vibration loop* should be made in the tube, giving it the necessary elasticity to tolerate the vibrational stresses. An example of a vibration loop placed in the air supply tube going to a control valve appears in this photograph:

When bending such a loop, it is helpful to use the circumference of a large pipe as a mandrel to form the tube rather than attempt to form a loop purely by hand.

### 8.2.4 Special tubing tools

A variety of specialized tools exist to help tubing installers work with compression-style tube fittings. One of these special devices is an electronic power tool manufactured by American Power Tool expressly for use with instrument tube fittings:

The Aeroswage SX-1 has a microprocessor-controlled electric motor programmed to rotate a tube fitting's nut to a precise angular dimension, in order to properly swage the fitting. The tool comes complete with a holding jig to engage the body of the tube fitting, in order that all tightening torque is borne by the tool and not imposed on the person operating the tool:

Not only does this feature reduce the amount of stress placed on the tube fitter's hand and wrist, but it also enables the tool to be used in the demanding environment of zero gravity, for example aboard a space station. In such an environment, torque applied to the tool operator could be disastrous, as the human operator has no weight to stabilize herself.

This next pair of photos shows how the tool is able to support itself on a piece of stiff ( $\frac{1}{2}$  inch stainless steel) tubing, and indeed may even be operated hands-free:

The amount of rotation is programmable, enabling the tool to be used with different kinds of fittings. For standard industrial Swagelok compression fitting sizes ( $\frac{1}{4}$  inch,  $\frac{3}{8}$  inch, and  $\frac{1}{2}$  inch), the recommended swaging rotation of 1-1/4 turns may be entered into the tool as a tightening angle of 450 degrees:

Being a microprocessor-controlled device, the SX-1 has the ability to digitally record all actions. This is useful in high-reliability production environments (e.g. aerospace tube installation) where individual tube fitting data are archived for safety and quality control purposes. This data may be downloaded to a personal computer through a serial port connection on the side of the tool. Here you can see the tool's digital display showing the recorded action number, tightening angle, date, and time:

For large instrument compression fittings, hydraulic swaging tools are also available to provide the force necessary to properly compress the ferrule(s) onto the tube. Instrument tube manufacturers will provide specific recommendations for the installation of non-standard tube types, sizes, and materials, and also recommend particular swaging tools to use with their fittings.

### 8.3 Electrical signal and control wiring

There is much to be said for neatness of assembly in electrical signal wiring. Even though the electrons don't "care" how neatly the wires are laid in place, human beings who must maintain the system certainly do. Not only are neat installations easier to navigate and troubleshoot, but they tend to inspire a similar standard of neatness when alterations are made<sup>7</sup>.

The following photographs illustrate excellent wiring practice. Study them carefully, and strive to emulate the same level of professionalism in your own work.

Here we see 120 volt AC power distribution wiring. Note how the hoop-shaped "jumper" wires are all cut to (nearly) the same length, and how each of the wire labels is oriented such that the printing is easy to read:

---

<sup>7</sup>No one wants to become known as the person who "messed up" someone else's neat wiring job!

This next photograph shows a great way to terminate multi-conductor signal cable to terminal blocks. Each of the pairs was twisted together using a hand drill set to very slow speed. Note how the end of the cable is wrapped in a short section of heat-shrink tubing for a neat appearance:

Beyond esthetic preferences for instrument signal wiring are several practices based on sound electrical theory. The following subsections describe and explain these wiring practices.

### 8.3.1 Connections and wire terminations

Many different techniques exist for connecting electrical conductors together: twisting, soldering, crimping (using compression connectors), and clamping (either by the tension of a spring or under the compression of a screw) are popular examples. Most industrial field wiring connections utilize a combination of compression-style crimp “lugs” (often referred to as *ferrules* or *compression terminals*) and screw clamps to attach wires to instruments and to other wires.

The following photograph shows a typical *terminal strip* or *terminal block* array whereby twisted-pair signal cables connect to other twisted-pair signal cables. Metal bars inside each plastic terminal section form connections horizontally, so that wires fastened to the left side are connected to wires fastened to the right side:

If you look closely at this photograph, you can see the bases of crimp-style ferrules at the ends of the wires, just where they insert into the terminal block modules. These terminal blocks use screws to apply force which holds the wires in close electrical contact with a metal bar inside each block, but metal ferrules have been crimped on the end of each wire to provide a more rugged tip for the terminal block screw to hold to. A close-up view shows what one of these ferrules looks like on the end of a wire:

Also evident in this photograph is the dual-level connection points on the left-hand side of each terminal block. Two pairs of twisted signal conductors connect on the left-hand side of each terminal block pair, where only one twisted pair of wires connects on the right-hand side. This also explains why each terminal block section has two screw holes on the left but only one screw hole on the right.

A close-up photograph of a single terminal block section shows how the screw-clamp system works. Into the right-hand side of this block a single wire (tipped with a straight compression ferrule) is clamped securely. No wire is inserted into the left-hand side:

If another wire were secured by the screw clamp on the left-hand side of this terminal block, it would be made electrically common with the wire on the right-hand side by virtue of the metal bar joining both sides.

Some terminal blocks are *screwless*, using a spring clip to make firm mechanical and electrical contact with the wire's end:

In order to extract or insert a wire end from or to a “screwless” terminal block, you must insert a narrow screwdriver into a hole in the block near the insertion point, then pivot the screwdriver (like a lever) to exert force on the spring clip. Screwless terminal blocks are generally faster to terminate and un-terminate than screw type terminal blocks, and the pushing action of the release tool is gentler on the body<sup>8</sup> than the twisting action required to loosen and tighten screws.

---

<sup>8</sup>An occupational hazard for technicians performing work on screw terminations is *carpal tunnel syndrome*, where repetitive wrist motion (such as the motions required to loosen and tighten screw terminals) damages portions of the wrist where tendons pass.

Many different styles of modular terminal blocks are manufactured to suit different wiring needs. Some terminal block modules, for example, have multiple “levels” instead of just one. The following photograph shows a two-level terminal block with screwless wire clamps:

The next photograph shows a three-level terminal block with screw type clamps:

Some multi-level terminal blocks provide the option of *internal jumpers* to connect two or more levels together so they will be electrically common instead of electrically isolated. This use of a multi-level terminal block is preferable to the practice of inserting multiple wires into the same terminal, when wires need to be made common to each other.

Other modular terminal blocks include such features as LED indicator lamps, switches, fuses, and even resettable circuit breakers in their narrow width, allowing the placement of actual circuit components near connection points. The following photograph shows a swing-open fused terminal block module, in the open position:

Modular terminal blocks are useful for making connections with both solid-core and stranded metal wires. The clamping force applied to the wire's tip by the screw mechanism inside one of these blocks is direct, with no sliding or other motions involved. Some terminal blocks, however, are less sophisticated in design. This next photograph shows a pair of “isothermal” terminals designed to connect thermocouple wires together. Here you can see how the bare tip of the screw applies pressure to the wire inserted into the block:

The rotary force applied to each wire's tip by these screws necessitates the use of solid wire. Stranded wire would become frayed by this combination of forces.

Many field instruments, however, do not possess “block” style connection points at all. Instead, they are equipped with pan-head machine screws designed to compress the wire tips directly between the heads of the screws and a metal plate below.

Solid wires may be adequately joined to such a screw-head connection point by partially wrapping the bare wire end around the screw’s circumference and tightening the head on top of the wire, as is the case with the two short wire stubs terminated on this instrument:

The problem with directly compressing a wire tip beneath the head of a screw is that the tip is subjected to both compressive and shear forces. As a result, the wire’s tip tends to become mangled with repeated connections. Furthermore, tension on the wire will tend to turn the screw, potentially loosening it over time.

This termination technique is wholly unsuitable for stranded wire<sup>9</sup>, because the shearing forces caused by the screw head’s rotation tends to “fray” the individual strands. The best way to attach a stranded wire tip directly to a screw-style connection point is to first crimp a compression-style *terminal* to the wire. The flat metal “lug” (ferrule) portion of the terminal is then inserted underneath the screw head, where it can easily tolerate the shearing and compressive forces exerted by the head.

---

<sup>9</sup>An exception is when the screw is equipped with a square washer underneath the head, designed to compress the end of a stranded wire with no shear forces. Many industrial instruments have termination points like this, for the express purpose of convenient termination to either solid or stranded wire ends.

This next photograph shows five such stranded-copper wires connected to screw-style connection points on a field instrument using compression-style terminals:

Compression-style terminals come in two basic varieties: *fork* and *ring*. An illustration of each type is shown here:

*Fork terminal*

*Ring terminal*

Fork terminals are easier to install and remove, since they merely require loosening of the connector screw rather than removal of the screw. Ring terminals are more secure, since they cannot “fall off” the connection point if the screw ever accidentally loosens.

Just as direct termination underneath a screw head is wholly unsuitable for stranded wires, compression-style terminals are wholly unsuitable for solid wire. Although the initial crimp may feel secure, compression terminals lose their tension rapidly on solid wire, especially when there is any motion or vibration stressing the connection. Compression wire terminals should only be crimped to stranded wire!

Properly installing a compression-type terminal on a wire end requires the use of a special *crimping* tool. The next photograph shows one of these tools in use:

Note the different places on the crimping tool, labeled for different wire sizes (gauges). One location is used for 16 gauge to 10 gauge wire, while the location being used in the photograph is for wire gauges 22 through 18 (the wire inside of the crimped terminal happens to be 18 gauge).

This particular version of a “crimping” tool performs most of the compression on the underside of the terminal barrel, leaving the top portion undisturbed. The final crimped terminal looks like this when viewed from the top:

### 8.3.2 DIN rail

An industry-standard structure for attaching terminal blocks and small electrical components to flat metal panels is something called a *DIN rail*. This is a narrow channel of metal – made of bent sheet steel or extruded aluminum – with edges designed for plastic components to “clip” on. The following photograph shows terminal blocks, relay sockets, fuses, and more terminal blocks mounted to a horizontal length of DIN rail in a control system enclosure:

Two photographs of a terminal block cluster clipped onto a length of DIN rail – one from above and one from below – shows how specially-formed arms on each terminal block module fit the edges of the DIN rail for a secure attachment:

The DIN rail itself mounts on to any flat surface by means of screws inserted through the slots in its base. In most cases, the flat surface in question is the metal subpanel of an electrical enclosure to which all electrical components in that enclosure are attached.

An obvious advantage of using DIN rail to secure electrical components versus individually attaching those components to a subpanel with their own sets of screws is convenience: much less labor is required to mount and unmount a DIN rail-attached component than a component attached with its own set of dedicated screws. This convenience significantly eases the task of altering a panel's configuration. With so many different devices manufactured for DIN rail mounting, it is easy to

upgrade or alter a panel layout simply by unclipping components, sliding them to new locations on the rail, or replacing them with other types or styles of components.

This next photograph shows some of the diversity available in DIN rail mount components. From left to right we see four relays, a power supply, and three HART protocol converters, all clipped to the same extruded aluminum DIN rail:

As previously mentioned, DIN rail is available in both stamped sheet-steel and extruded aluminum forms. A comparison of the two materials is shown here, with sheet steel on the left and aluminum on the right:

The form of DIN rail shown in all photographs so far is known as “top hat” DIN rail. A variation in DIN rail design is the so-called “G” rail, with a markedly different shape:

Fortunately, many modular terminal blocks are formed with the ability to clip to either style of DIN rail, such as these two specialty blocks, the left-hand example being a terminal block with a built-in disconnect switch, and the right-hand example being a “grounding” terminal block whose termination points are electrically common to the DIN rail itself:

If you examine the bottom structure of each block, you will see formations designed to clip either to the edges of a standard (“top hat”) DIN rail or to a “G” shaped DIN rail.

Smaller DIN rail standards also exist, although they are far less common than the standard 35mm size:

A nice feature of many DIN rail type terminal blocks is the ability to attach pre-printed terminal numbers. This makes documentation of wiring much easier, with each terminal connection having its own unique identification number:

### 8.3.3 Cable routing

In the interest of safety and longevity, one cannot simply route electrical power and signal cables randomly between different locations. Electrical cables must be properly supported to relieve mechanical stresses on the conductors, and protected from harsh conditions such as abrasion which might degrade the insulation.

A traditional and rugged technique for cable routing is *conduit*, either metal or plastic (PVC). Conduit resembles piping used to convey fluids, except that it is much thinner-walled than fluid pipe and is not rated to withstand internal pressure as pipe is. In fact, threaded conduit uses the same thread pitch and diameter standards as NPT (National Pipe Taper) fluid pipe connections.

Metal conduit naturally forms a continuously-grounded enclosure for conductors which not only provides a measure of protection against electrical shock (all enclosures and devices attached to the conduit become safely grounded through the conduit) but also shields against electrostatic interference. This is especially important for power wiring to and from devices such as rectifiers and variable-frequency motor drive (VFD) units, which have a tendency to broadcast large amounts of electromagnetic noise.

Plastic conduit, of course, provides no electrical grounding or shielding because plastic is a non-conductor of electricity. However, it is superior to metal conduit with regard to chemical corrosion resistance, which is why it is used to route wires in areas containing water, acids, caustics, and other wet chemicals.

*Thin-wall* conduit is made with metal so thin that threads cannot be cut into it. Instead, special connectors are used to join “sticks” of thin-wall conduit together, and to join thin-wall conduit to electrical enclosures. Several runs of thin-wall conduit appear in this next photograph. Two of those conduit runs have been severed following a wiring change, exposing the conductors inside:

Installing cable into an electrical conduit is a task referred to as *cable pulling*, and it is something of an art. Cable “pulls” may be especially challenging if the conduit run contains many bends, and/or is close to capacity in terms of the number and size of conductors it already holds. A good practice is to always leave a length of nylon *pull string* inside each length of conduit, ready to use for pulling a new wire or cable through. When performing a wire “pull,” a new length of nylon pull string is pulled into the conduit along with the new wires, to replace the old pull string as it is pulled out of the conduit. Special lubricating “grease” formulated for electrical wiring may be applied to conductors pulled into a conduit, to reduce friction between those new conductors and the conductors already inside the conduit.

When connecting electrical conduit to end-point devices, it is common to use flexible *liquid-tight conduit* as a connector between the rigid metal (or plastic) conduit and the final device. This provides some stress relief to the conduit in the event the device moves or vibrates, and also allows more freedom in positioning the device with respect to the conduit. Here, we see a motor-operated control valve with two runs of liquid-tight conduit routing conductors to it:

Liquid-tight conduit comes in two general varieties: metallic and non-metallic. The metallic kind contains a spiraled metal sheath just underneath the plastic outer coating to provide a continuously-

grounded shield much the same way that rigid metal conduit does. Non-metallic liquid-tight conduit is nothing more than plastic hose, providing physical protection against liquid exposure and abrasion, but no electrical grounding or shielding ability.

Another technique for cable routing is the use of *cable tray*. Trays may be made of solid steel wire for light-duty applications such as instrument signal cabling or computer network cabling, or they may be made of steel or aluminum channel for heavy-duty applications such as electrical power wiring. Unlike conduit, cable trays are open, leaving the cables exposed to the environment. This often necessitates special cable insulation rated for exposure to ultraviolet light, moisture, and other environmental wear factors. A decided advantage of cable trays is ease of cable installation, especially when compared to electrical conduit.

While cable tray does provide a continuously-grounded surface for electrical safety the same as metal conduit, cable tray does *not* naturally provide shielding for the conductors because it does not completely enclose the conductors the way metal conduit does.

An example of light-duty cable tray appears here, used to support Ethernet cabling near the ceiling of a room at a college campus. The cable tray is made of solid steel wire, bent to form a “basket” to support dozens of yellow Ethernet cables:

Heavy-duty cable tray appears throughout this next photograph, supporting large-gauge power conductors for electric generators at a gas turbine power plant. Here, the cable tray has the appearance of an aluminum ladder, with extruded metal rails and rungs providing physical support for the cables:

Similar cables trays appear in the next photograph, supporting feeder cables from a stationary transformer and switchgear cabinets:

A special form of wiring often seen in industrial facilities for power distribution is *busway*, also known as *bus duct*. These are rectangular sheet-metal tubes containing pre-fabricated copper busbars for the conduction of three-phase AC power. Special junction boxes, “tees,” and tap boxes allow busways to extend and branch to other busways and/or standard conductor wiring.

Busways are used in indoor applications, often in motor control center (MCC) and power distribution center rooms to route electrical power to and from large disconnect switches, fuses, and circuit breakers. In this photograph, we see busway used to distribute power along the ceiling of an MCC room, alongside regular rigid conduit:

As useful and neat in appearance as busways are, they are definitely limited in purpose. Busways are only used for electrical power distribution; not for instrumentation, control, or signaling purposes.

Two materials useful for neatly routing power, signal, and instrumentation conductors inside an enclosure are *wire duct* and *wire loom*. Wire duct is a plastic channel with slotted sides, designed to be attached to the subpanel of an enclosure along with all electrical devices inside that enclosure. Wires pass from the devices to the duct through the slots (gaps) in the sides of the duct, and are enclosed by a removable plastic cover that snaps onto the top of the duct. A common brand name of wire duct in the industry is *Panduit* and so you will often hear people refer to wire duct as “Panduit” whether or not that particular brand is the one being used<sup>10</sup>. Wire loom is a loose spiral

<sup>10</sup>This is similar to people referring to adhesive bandages as “Band-Aids” or tongue-and-groove joint pliers as

tube made of plastic, used to hold a group of individual wires together into a neat bundle. Wire loom is frequently used when a group of conductors must periodically flex, as is the case of a wire bundle joining devices inside a panel to other devices mounted on the hinging door of that panel.

A photograph showing both wire duct and wire loom inside an instrumentation panel appears here. The wire duct is the grey-colored rectangular plastic channel set vertically and horizontally inside the panel, while the loom is a grey-colored plastic spiral surrounding the bundle of wires near the door hinge:

---

“Channelocks,” because those particular brands have become popular enough to represent an entire class.

### 8.3.4 Signal coupling and cable separation

If sets of wires lie too close to one another, electrical signals may “couple” from one wire (or set of wires) to the other(s). This can be especially detrimental to signal integrity when the coupling occurs between AC power conductors and low-level instrument signal wiring such as thermocouple or pH sensor cables.

Two mechanisms of electrical “coupling” exist: *capacitive* and *inductive*. Capacitance is a property intrinsic to any pair of conductors separated by a dielectric (an insulating substance), whereby energy is stored in the electric field formed by voltage between the wires. The natural capacitance existing between mutually insulated wires forms a “bridge” for AC signals to cross between those wires, the strength of that “bridge” inversely proportional to the capacitive reactance ( $X_C = \frac{1}{2\pi fC}$ ). Inductance is a property intrinsic to any conductor, whereby energy is stored in the magnetic field formed by current through the wire. Mutual inductance existing between parallel wires forms another “bridge” whereby an AC current through one wire is able to induce an AC voltage along the length of another wire.

Capacitive coupling between an AC power conductor and a DC sensor signal conductor is shown in the following diagram:

If the voltage-generating sensor happens to be a thermocouple and the receiving instrument a temperature indicator, the result of this capacitive coupling will be a “noisy” temperature signal interpreted by the instrument. This noise will be proportional to both the voltage and the frequency of the AC power.

Inductive coupling between an AC power conductor and a DC sensor signal conductor is shown in the following diagram:

Whereas the amount of noise induced into a low-level signal via capacitive coupling was a function of *voltage* and frequency, the amount of noise induced into a signal via inductive coupling is a function of *current* and frequency<sup>11</sup>.

A good way to minimize signal coupling is to simply separate conductors carrying incompatible signals. This is why electrical power conductors and instrument signal cables are almost never found in the same conduit or in the same ductwork together. Separation decreases capacitance between the conductors (recall that  $C = \frac{A\epsilon}{d}$  where  $d$  is the distance between the conductive surfaces). Separation also decreases the coupling coefficient between inductors, which in turn decreases mutual inductance (recall that  $M = k\sqrt{L_1L_2}$  where  $k$  is the coupling coefficient and  $M$  is the mutual inductance between two inductances  $L_1$  and  $L_2$ ). In control panel wiring, it is customary to route AC power wires in such a way that they do not lay parallel to low-level signal wires, so that both forms of coupling may be reduced.

<sup>11</sup>The principle at work here is the strength of the *field* generated by the noise-broadcasting conductor: electric field strength (involved with capacitive coupling) is directly proportional to voltage, while magnetic field strength (involved with inductive coupling) is directly proportional to current.

If conductors carrying incompatible signals *must* cross paths, it is advisable to orient the conductors perpendicular to each other rather than parallel, like this:

Perpendicular conductor orientation reduces both inter-conductor capacitance *and* mutual inductance by two mechanisms. Capacitance between conductors is reduced by means of minimizing overlapping area ( $A$ ) resulting from the perpendicular crossing. Mutual inductance is reduced by decreasing the coupling coefficient ( $k$ ) to nearly zero since the magnetic field generated perpendicular to the current-carrying wire will be *parallel* and not perpendicular to the “receiving” wire. Since the vector for induced voltage is perpendicular to the magnetic field (i.e. parallel with the current vector in the “primary” wire) there will be no voltage induced along the length of the “receiving” wire.

The problem of power-to-signal line coupling is most severe when the signal in question is *analog* rather than *digital*. In analog signaling, even the smallest amount of coupled “noise” corrupts the signal. A digital signal, by comparison, will become corrupted only if the coupled noise is so great that it pushes the signal level above or below a detection threshold it should not cross. This disparity is best described through illustration.

Two signals are shown here, coupled with equal amounts of noise voltage:

The peak-to-peak amplitude of the noise on the analog signal is almost 20% of the entire signal range (the distance between the lower- and upper-range values), representing a substantial degradation of signal integrity. Analog signals have infinite resolution, which means *any* change in signal amplitude has meaning. Therefore, any noise whatsoever introduced into an analog signal will be interpreted as variations in the quantity that signal is supposed to represent.

That same amount of noise imposed on a digital signal, however, causes no degradation of the signal except for one point in time where the signal attempts to reach a “low” state but fails to cross the threshold due to the noise. Other than that one incident represented in the pulse waveform, the rest of the signal is completely unaffected by the noise, because digital signals only have meaning above the “high” state threshold and below the “low” state threshold. Changes in signal voltage level caused by induced noise will not affect the meaning of digital data unless and until the amplitude of that noise becomes severe enough to prevent the signal’s crossing through a threshold (when it should cross), or causes the signal to cross a threshold (when it should not).

From what we have seen here, digital signals are far more tolerant of induced noise than analog signals, all other factors being equal. If ever you find yourself in a position where you must route a signal wire near AC power conductors, and you happen to have the choice whether it will be an analog signal (e.g. 4-20 mA, 0-10 V) or a digital signal (e.g. EIA/TIA-485, Ethernet), your best option is to choose the digital signal to coexist alongside the AC power wires.

### 8.3.5 Electric field (capacitive) de-coupling

The fundamental principle invoked in *shielding* signal conductor(s) from external electric fields is that no substantial electric field can exist within a solid conductor. Electric fields exist due to imbalances of electric charge. If such an imbalance of charge ever were to exist within a conductor, charge carriers (typically electrons) in that conductor would quickly move to equalize the imbalance, thus eliminating the electric field. Another way of saying this is to state that electric fields only exist between points of different potential, and therefore cannot exist between equipotential points. Thus, electric flux lines may be found only in the dielectric (insulating media) between conductors, not within a solid conductor:

This also means electric flux lines cannot span the diameter of a hollow conductor:

The electrical conductivity of the hollow sphere's wall ensures that all points on the circumference of the sphere are equipotential to each other. This in turn prohibits the formation of any electric flux lines within the interior air space of the hollow sphere. Thus, all points within the hollow sphere are *shielded* from any electric fields originating outside of the sphere.

The only way to allow an external electric field to penetrate a hollow conductor from the outside is if that conductive shell is left “floating” with respect to another conductor placed within the shell. In this case the lines of electric flux do not exist between different points on the conductive sphere, but rather between the shell of the sphere and the conductor at the center of the sphere because those are the points between which a potential difference (voltage) exists. To illustrate:

However, if we make the hollow shell electrically common to the negative side of the high-voltage source, the flux lines inside the sphere vanish, since there is no potential difference between the internal conductor and the conductive shell:

If the conductor within the hollow sphere is elevated to a potential different from that of the high-voltage source's negative terminal, electric flux lines will once again exist inside the sphere, but they will reflect this second potential and not the potential of the original high-voltage source. In other words, an electric field will exist inside the hollow sphere, but it will be completely isolated from the electric field outside the sphere. Once again, the conductor inside is *shielded* from external electrostatic interference:

If conductors located inside the hollow shell are thus shielded from external electric fields, it means there cannot exist any capacitance between external conductors and internal (shielded) conductors. If there is no capacitance between conductors, there will never be capacitive coupling of signals between those conductors, which is what we want for industrial signal cables to protect those signals from external interference<sup>12</sup>.

<sup>12</sup>Incidentally, cable shielding likewise guards against strong electric fields *within* the cable from capacitively coupling with conductors outside the cable. This means we may elect to shield “noisy” power cables instead of (or in addition to) shielding low-level signal cables. Either way, good shielding will prevent capacitive coupling between conductors on either side of a shield.

All this discussion of hollow metal spheres is just an introduction to a discussion of *shielded cable*, where electrical cables are constructed with a conductive metal foil wrapping or conductive metal braid surrounding the interior conductors. Thus, the foil or braid creates a conductive *tube* which may be connected to ground potential (the “common” point between external and internal voltage sources) to prevent capacitive coupling between any external voltage sources and the conductors within the cable:

The following photograph shows a set of signal cables with braided shield conductors all connected to a common copper “ground bus.” This particular application happens to be in the control panel of a 500 kV circuit breaker, located at a large electrical power substation where strong electric fields abound:

This next photograph shows a four-conductor USB cable stripped at one end, revealing a metal-foil shield as well as silver-colored wire strands in direct contact with the foil, all wrapped around the four colored power and signal conductors:

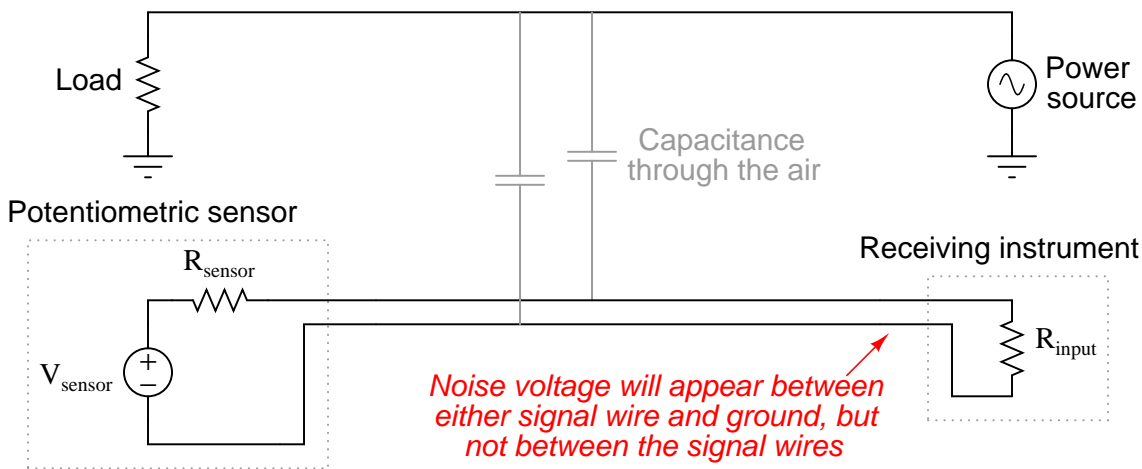

At the terminating end we typically twist the loose shield conductor strands together to form a wire which is then attached to a ground point to fix the cable’s shield at Earth potential.

It is very important to ground *only one end* of a cable's shield, or else you will create the possibility for a *ground loop*: a path for current to flow through the cable's shield resulting from differences in Earth potential at the cable ends. Not only can ground loops induce noise in a cable's conductor(s), but in severe cases it can even overheat the cable and thus present a fire hazard:

*A ground loop: something to definitely avoid!*

An important characteristic of capacitively-coupled noise voltage is that it is *common-mode* in nature: the noise appears equally on every conductor within a cable because those conductors lie so close to each other (i.e. because the amount of capacitance existing between each conductor and the noise source is the same). One way we may exploit this characteristic in order to help escape the unwanted effects of capacitive coupling is to use *differential signaling*. Instead of referencing our signal voltage to ground, we let the signal voltage “float.” The following schematic diagram illustrates how this works:

The lack of a ground connection in the DC signal circuit prevents capacitive coupling with the AC voltage from corrupting the measurement signal “seen” by the instrument. Noise voltage *will* still appear between either signal wire and ground as a common-mode voltage, but noise voltage will not appear *between* the two signal wires where our signal of interest exists. In other words, we

side-step the problem of common-mode noise voltage by making common-mode voltage irrelevant to the sensor and to the signal receiver.

Some industrial data communications standards such as EIA/TIA-485 (RS-485) use this technique to minimize the corrupting effects of electrical noise. To see a practical example of how this works in a data communications circuit, refer to the illustration in section 15.6.2 beginning on page 1055 of this book.

### 8.3.6 Magnetic field (inductive) de-coupling

Magnetic fields, unlike electric fields, are exceedingly difficult to completely shield. Magnetic flux lines do not terminate, but rather *loop*. Thus, one cannot “stop” a magnetic field, only re-direct its path. A common method for magnetically shielding a sensitive instrument is to encapsulate it in an enclosure made of some material having an extremely high magnetic permeability ( $\mu$ ): a shell offering much easier passage of magnetic flux lines than air. A material often used for this application is *mu-metal*, or  $\mu$ -metal, so named for its excellent magnetic permeability:

This sort of shielding is impractical for protecting signal cables from inductive coupling, as mu-metal is rather expensive and must be layered relatively thick in order to provide a sufficiently low-reluctance path to shunt most of the external magnetic flux lines.

The most practical method of granting magnetic field immunity to a signal cable follows the differential signaling method discussed in the electric field de-coupling section, with a twist (literally). If we *twist* a pair of wires rather than allow them to lie along parallel straight lines, the effects of electromagnetic induction are vastly minimized.

The reason this works is best illustrated by drawing a differential signal circuit with two thick wires, drawn first with no twist at all. Suppose the magnetic field shown here (with three flux lines entering the wire loop) happens to be *increasing* in strength at the moment in time captured by the illustration:

According to Lenz's Law, a current will be induced in the wire loop in such a polarity as to oppose the increase in external field strength. In other words, the induced current tries to “fight” the imposed field to maintain zero net change. According to the right-hand rule of electromagnetism (tracing current in conventional flow notation), the induced current must travel in a counter-clockwise direction as viewed from above the wire loop in order to generate a magnetic field opposing the rise of the external magnetic field. This induced current works against the DC current produced by the sensor, detracting from the signal received at the instrument.

When the external magnetic field strength diminishes, then builds in the opposite direction, the induced current will reverse. Thus, as the AC magnetic field oscillates, the induced current will also oscillate in the circuit, causing AC “noise” voltage to appear at the measuring instrument. This is precisely the effect we wish to mitigate.

Immediately we see a remarkable difference between noise voltage induced by a magnetic field versus noise voltage induced by an electric field: whereas capacitively-coupled noise was always common-mode, here we see inductively-coupled noise as *differential*<sup>13</sup>.

<sup>13</sup>This is not to say magnetic fields cannot induce common-mode noise voltage: on the contrary, magnetic fields are

If we twist the wires so as to create a series of loops instead of one large loop, we will see that the inductive effects of the external magnetic field tend to cancel:

Not all the lines of flux go through the same loop. Each loop represents a reversal of direction for current in the instrument signal circuit, and so the direction of magnetically-induced current in one loop directly opposes the direction of magnetically-induced current in the next. So long as the loops are sufficient in number and spaced close together, the net effect will be complete and total opposition between all induced currents, with the result of no net induced current and therefore no AC “noise” voltage appearing at the instrument.

In order to enjoy the benefits of magnetic *and* electric field rejection, instrument cables are generally manufactured as *twisted, shielded pairs*. The twists guard against magnetic (inductive) interference, while the grounded shield guards against electric (capacitive) interference. If multiple wire pairs are twisted within the same cable, the twist rates of each pair may be made different so as to avoid magnetic coupling from pair to pair<sup>14</sup>.

---

capable of inducing voltage in any electrically-conductive loop. For this reason, both differential and ground-referenced signals are susceptible to interference by magnetic fields.

<sup>14</sup>An example of this is the UTP (Unshielded, Twisted Pair) cabling used for Ethernet digital networks, where four pairs of wires having different twist rates are enclosed within the same cable sheath.

### 8.3.7 High-frequency signal cables

Electronic signals used in traditional instrumentation circuits are either DC or low-frequency AC in nature. Measurement and control values are represented in *analog* form by these signals, usually by the magnitude of the electronic signal (how many volts, how many milliamps, etc.). Modern electronic instruments, however, often communicate process and control data in *digital* rather than analog form. This digital data takes the form of high-frequency voltage and/or current pulses along the instrument conductors. The most capable *fieldbus* instruments do away with analog signaling entirely, communicating all data in digital form at relatively high speeds.

If the time period of a voltage or current pulse is less than the time required for the signal to travel down the length of the cable (at nearly the speed of light!), very interesting effects may occur. When a pulse propagates down a two-wire cable and reaches the end of that cable, the energy contained by that pulse must be absorbed by the receiving circuit or else be *reflected* back down the cable. To be honest, this happens in all circuits no matter how long or brief the pulses may be, but the effects of a “reflected” pulse only become apparent when the pulse time is short compared to the signal propagation time. In such short-pulse applications, it is customary to refer to the cable as a *transmission line*, and to regard it as a circuit component with its own characteristics (namely, a continuous impedance as “seen” by the traveling pulse). For more detail on this subject, refer to section 5.10 beginning on page 475.

This problem has a familiar analogy: an “echo” in a room. If you step into a large room with hard wall, floor, and ceiling surfaces, you will immediately notice echoes resulting from any sound you make. Holding a conversation in such a room can be quite difficult, as the echoed sounds superimpose upon the most recently-spoken sounds, making it difficult to discern what is being said. The larger the room, the longer the echo delay, and the greater the conversational confusion.

Echoes happen in small rooms, too, but they are generally too short to be of any concern. If the reflected sound(s) return quickly enough after being spoken, the time delay between the spoken (incident) sound and the echo (reflected) sound will be too short to notice, and conversation will proceed unhindered.

We may address the “echo” problem in two entirely different ways. One way is to eliminate the echoes entirely by adding sound-deadening coverings (carpet, acoustic ceiling tiles) and/or objects (sofas, chairs, pillows) to the room. Another way to address the problem of echoes interrupting a conversation is to *slow down the rate of speech*. If the words are spoken slowly enough, the time delay of the echoes will be relatively short compared to the period of each spoken sound, and conversation may proceed without interference<sup>15</sup> (albeit at a reduced speed).

Both the problem of and the solutions for reflected signals in electrical cables follow the same patterns as the problem of and solutions for sonic echoes in a hard-surfaced room. If an electronic circuit receiving pulses sent along a cable receives both the incident pulse and an echo (reflected pulse) with a significant time delay separating those two pulses, the digital “conversation” will be impeded in the same manner that a verbal conversation between two or more people is impeded by echoes in a room. We may address this problem either by eliminating the reflected pulses entirely (by ensuring all the pulse energy is absorbed by an appropriate load placed at the cable’s end) or by slowing down the data transfer rate (i.e. longer pulses, lower frequencies) so that the reflected and incident pulse signals virtually overlap one another at the receiver.

---

<sup>15</sup>A student of mine once noted that he has been doing this out of habit whenever he has a conversation with anyone in a racquetball court. All the hard surfaces (floor, walls) in a racquetball court create severe echoes, forcing players to speak slower in order to avoid confusion from the echoes.

High-speed “fieldbus” instrument networks apply the former solution (eliminate reflections) while the legacy HART instrument signal standard apply the latter (slow data rate). Reflections are eliminated in high-speed data networks by ensuring the two furthest cable ends are both “terminated” by a resistance value of the proper size (matching the characteristic impedance of the cable). The designers of the HART analog-digital hybrid standard chose to use slow data rates instead, so their instruments would function adequately on legacy signal cables where the characteristic impedance is not standardized.

The potential for reflected pulses in high-speed fieldbus cabling is a cause for concern among instrument technicians, because it represents a new phenomenon capable of creating faults in an instrument system. No longer is it sufficient to have tight connections, clean wire ends, good insulation, and proper shielding for a signal cable to faithfully convey a 4-20 mA DC instrument signal from one device to another. Now the technician must ensure proper termination and the absence of any discontinuities<sup>16</sup> (sharp bends or crimps) along the cable’s entire length, in addition to all the traditional criteria, in order to faithfully convey a digital fieldbus signal from one device to another.

Signal reflection problems may be investigated using a diagnostic instrument known as a *time-domain reflectometer*, or *TDR*. These devices are a combination of pulse generator and digital-storage oscilloscope, generating brief electrical pulses and analyzing the returned (echoed) signals at one end of a cable. If a TDR is used to record the pulse “signature” of a newly-installed cable, that data may be compared to future TDR measurements on the same cable to detect cable degradation or wiring changes.

## 8.4 Fiber optics

*Light* has long<sup>17</sup> been used as a long-range signaling medium. While communication by light through open air is still possible using modern technology, it is far more practical in most cases to channel the light signals through a special strand of optically transparent material called an *optical fiber*. When packaged in a protective sheath, it is known as a fiber optic cable.

The transmission of light through a “light pipe” was demonstrated as early as 1842 by Daniel Colladon and Jacques Babinet in Paris, using a running stream of water to guide a beam of light. Many modern houses in the United States are equipped with light-pipes<sup>18</sup> directing natural sunlight into rooms for illumination, without the use of “skylight” ceiling windows. Modern fiber optic cables apply similar optical principles to very small-diameter fibers of transparent material (usually ultra-pure glass), able to convey optical energy and optically-encoded information.

---

<sup>16</sup>The characteristic, or “surge,” impedance of a cable is a function of its conductor geometry (wire diameter and spacing) and dielectric value of the insulation between the conductors. Any time a signal reaches an abrupt change in impedance, some (or all) of its energy is reflected in the reverse direction. This is why reflections happen at the unterminated end of a cable: an “open” is an infinite impedance, which is a huge shift from the finite impedance “seen” by the signal as it travels along the cable. This also means any sudden change in cable geometry such as a crimp, nick, twist, or sharp bend is capable of reflecting part of the signal. Thus, high-speed digital data cables must be installed more carefully than low-frequency or DC analog signal cables.

<sup>17</sup>Smoke signals are an ancient form of light-based communication!

<sup>18</sup>These are thin plastic or sheet metal tubes with mirrored internal surfaces, extending from a collector dome (made of glass or plastic) outside the dwelling to a diffusion lens inside the dwelling.

### 8.4.1 Fiber optic data communication

Simply put, an optical fiber is a “pipe” through which light flows. This is, of course, merely an analogy for how an optical fiber works, but it conveys the basic idea. The interface between a piece of electronic equipment and an optical fiber consists of an optical *source* (typically an LED or a semiconductor laser) to generate light signals from electrical signals, and an optical *detector* (typically a photodiode or phototransistor) to generate electrical signals from received light signals.

The predominant use of optical fiber in modern industry is as a data communication medium between digital electronic devices, replacing copper-wire signal and network cabling. An illustration showing two digital electronic devices communicating over a pair of optical fibers appears here, each fiber “conducting” pulses of light (representing serial digital data) from an LED source to a photodiode detector:

The following photograph shows a serial converter (the black rectangular plastic box with a blue label) used to convert optical data pulses entering and exiting through orange-jacketed optical cables (on the left) into EIA/TIA-232 compliant electrical signals through a DB-9 connector (on the right) and vice-versa, allowing the electronic serial data device on the right-hand side of the photograph to communicate via fiber optic cabling:

Note how the two optical fiber ports on the converter body are labeled “R” and “T” for *Receive* and *Transmit*, respectively. Serial devices with built-in electronic/optical converters will similarly label their optical ports.

For this device, connection to each of the optical fibers is made using an “ST” style connector, with a quarter-turn locking ring holding each one in place (much like the quarter-turn barrel body of a “BNC” style electrical connector). The next photograph shows a pair of optical fibers terminated with ST-style connectors. White plastic caps cover the connector tips, keeping the glass fiber ends protected from dust and abrasion:

As a data pathway, optical fiber enjoys certain advantages over electrical cable, including:

- Much greater bandwidth (data-carrying capacity), estimated to be in the terahertz range
- Much less equivalent signal power loss per unit cable length (less than 1 dB per kilometer compared with 25 dB per kilometer for coaxial cable)
- Complete immunity to external “noise” sources
- No radiation of energy or data from the cable, thus will not create interference nor be liable to eavesdropping
- No electrical conductivity, allowing safe routing of cables near high voltage conductors
- Total galvanic isolation (i.e. no electrically conductive connection) between data devices, allowing operation at different electrical potentials
- Safe for use in areas with explosive vapors, dust, and/or fibers

These advantages deserve some elaboration. The superior bandwidth of fiber-optic cable is so dramatic that the present-day (2015) limitation on data transfer rates for most fiber-optic installations is the electronic devices at each end, and not the optical fiber itself! This, combined with the low inherent power loss of optical fiber, makes it an ideal medium for long-range data communication such as telephone and internet. Thousands of miles of optical fiber cable have

been buried in underground trenches, laid down on sea floors, strung as overhead lines, and used as “patch” cables in room-scale applications since the advent of affordable optical cabling in the 1980’s. The “tech boom” of the 1990’s saw an impressive amount of trans-continental and inter-continental optical fiber installation, paving the way for the global expansion of internet services into the 21st century. The limitations of electronics at each end of these long fibers means we have not yet begun to tap their full data-carrying capacity, either. Conveying data in photonic – as opposed to electronic – form means there is absolutely no such thing as capacitive or inductive coupling with external systems as there is with conductive wire cable, which not only means optical fiber communication is immune to external interference but also that the optical signals cannot create interference for any other system. Since optical fibers are customarily manufactured from glass which is electrically non-conductive, it is possible to route optical fibers alongside high-voltage power lines, and also connecting together devices at vastly different electrical potentials from each other, with no risk of bridging those differing potentials. Finally, the low power levels associated with optical fiber signals also makes this technology completely safe in areas where explosive compounds in the atmosphere might otherwise be ignited by faults in electrical communications cable.

Optical fibers also suffer from some unique limitations when compared against electrical cable, including:

- Need to avoid tight bend radii for optical cables
- Connections need to be extremely clean
- Specialized tools and skills necessary for installation and maintenance
- Expensive testing equipment

While electrical “transmission line” signal cables must also avoid sharp bends and other discontinuities caused by cramped installations, this need is especially pronounced for optical fiber (for reasons which will be explained later in this section). Since fiber-to-fiber connections consist of glass pressed against glass, the presence of even microscopic contaminants such as dust particles may damage fiber optic connectors if they aren’t cleaned<sup>19</sup> prior to insertion. Cutting, preparing, and terminating optical fiber cables requires its own set of specialized tools and skills, and is not without unique hazards<sup>20</sup>. Lastly, the test equipment necessary to check the integrity of an optical pathway is similarly specialized and typically quite expensive.

---

<sup>19</sup>Technicians working with optical fiber typically carry pressurized cans of dust-blowing air or other gas to clean connectors and sockets prior to joining the two.

<sup>20</sup>Chief of which is the potential to get optical fibers embedded in the body, where such transparent “slivers” are nearly impossible to find and extract.

### 8.4.2 Fiber optic sensing applications

Optical fibers find applications beyond electronic data cable replacement, though, which means they will be a growing presence in the field of industrial instrumentation above and beyond their use as serial data communication cables. Some industrial process transmitters use optical fibers to send and receive light between the transmitter electronics and an optically-based primary sensing element. This may be as simple as a non-contact proximity switch using light to sense the presence of an object within a gap between the two fibers' ends, or as sophisticated as a chemical analyzer relying on the absorption of specific light wavelengths to detect the presence of a chemical substance in a solution.

**Turbine flowmeter sensing**

One example of a specialized application for optical fibers is shown in this photograph of a paddlewheel-style liquid flowmeter using a pair of optical fibers to convey light to and from the paddlewheel assembly, where the spinning paddlewheel serves to “chop” the light beam and thereby represent liquid flow rate as a frequency of pulsing light:

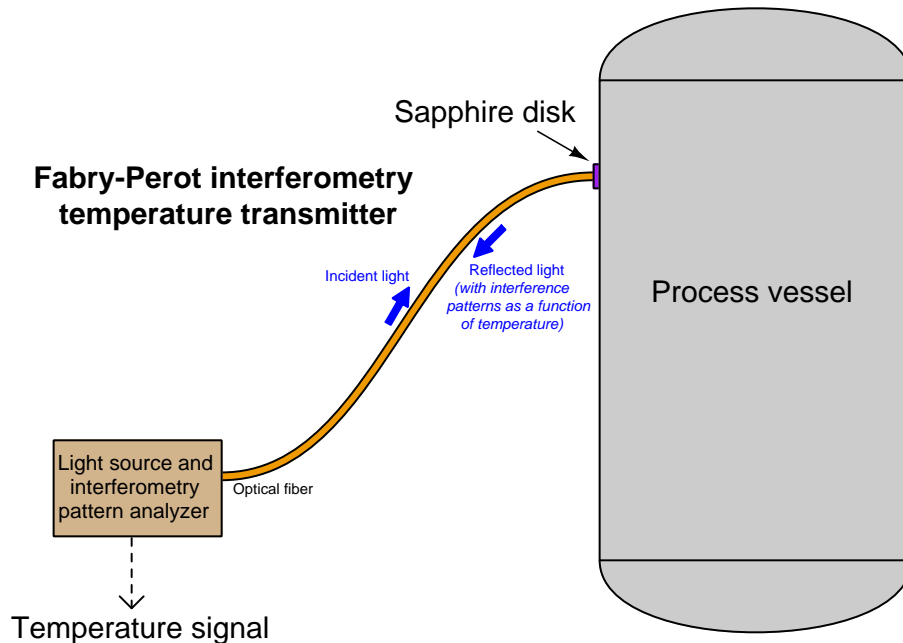

An end-view of the two optical fibers is shown in the next photograph. When installed as a working system, these two fibers will plug into a flow transmitter device sending a continuous beam of light through one fiber and sensing the pulsed light signal coming back from the paddlewheel through the other fiber:

### Fabry-Perot interferometry temperature measurement

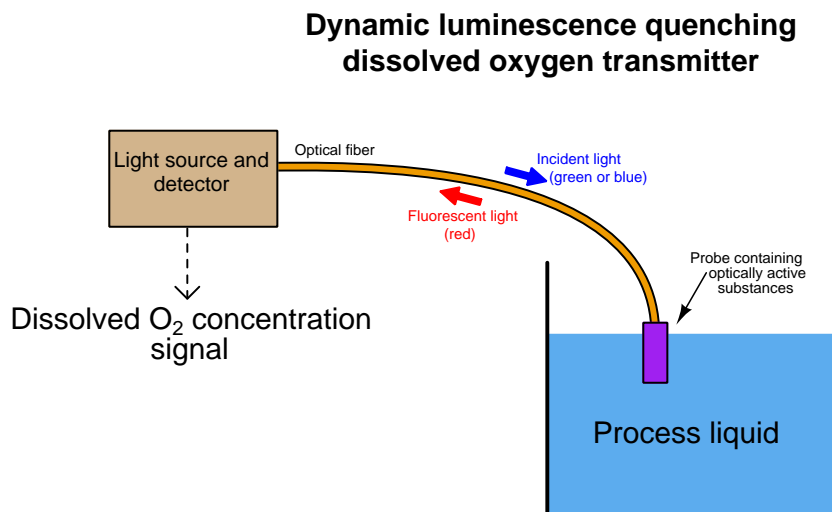

Another example of a specialized application for optical fibers is measurement of high temperatures using the *Fabry-Perot interferometry* method. This technology utilizes a small, thin disk of sapphire as a temperature sensor. The thickness of this disk as well as the speed of light through the sapphire are both temperature-dependent, which means a photon<sup>21</sup> of light shot at the face of the disk will reflect off the back face of the disk and return to the source at different times depending on the temperature of the disk. In a Fabry-Perot interferometer instrument, the “optical thickness” of the sapphire disk is measured by sending a continuous beam of white light to the disk and receiving the reflected light from the disk through a single optical fiber, the optical interference resulting from the incident and reflected light beams representing the disk’s temperature. This novel method of temperature measurement shows promise for certain challenging industrial process applications such as high-temperature measurement inside slagging coal gasifiers used to efficiently extract energy and chemical feedstocks from coal:

<sup>21</sup>A “photon” is a quantity of light energy represented as a particle, along the same scale as an electron. It isn’t entirely fair to characterize light as either consisting of waves or as consisting of particles, because light tends to manifest properties of both. Actually, this may be said of any sub-atomic particle (such as an electron) as well: under certain conditions these particles act like clumps of matter, and under different conditions they tend to act as waves of electromagnetic energy. This particle-wave duality lies at the heart of quantum physics, and continues to be something of a philosophical mystery simply because the behavior defies the macroscopic constructs we are accustomed to using when modeling the natural world.

### Dissolved oxygen measurement

Yet another example of a specialized application for optical fibers is the measurement of dissolved oxygen in aqueous solutions using the *dynamic luminescence quenching* or *fluorescence quenching* method. This technology uses a thin layer of solid material containing molecules known to fluoresce<sup>22</sup> with red light when exposed to visible light of a shorter wavelength (typically green or blue). Oxygen molecules present in the liquid solution tend to bond with the fluorescing molecules in the sensor and inhibit that fluorescence, thus providing a means of measuring oxygen concentration near the sensor: the less  $O_2$  dissolved in solution, the stronger the fluorescence (i.e. more red light received, for a longer duration); the more  $O_2$ , the less fluorescence. Optical fibers convey both the incident (green or blue) and returned (red) light between the wet sensing element and the interpreting electronics.

In both the Fabry-Perot interferometry and the fluorescence quenching sensors, the function of the fiber optic cable is to physically separate the sensing element from the sophisticated and fragile electronic transmitter needed to interpret the optical signal as a process variable measurement.

<sup>22</sup>Fluorescence is the phenomenon of a substance emitting a long-wavelength (low-energy) photon when "excited" by a short-wavelength (high-energy) photon. Perhaps the most familiar example of fluorescence is when certain materials emit visible light when exposed to ultraviolet light which is invisible to the human eye. The example of fluorescence discussed here with dissolved oxygen sensing happens to use two different colors (wavelengths) of visible light, but the basic principle is the same.

**Arc flash detection**

There is at least one application where the optical fiber itself *is* the sensing element: arc flash detection within high-voltage switchgear cabinets. “Arc flash” is the phenomenon of intense heat and light developed at a high-current electrical arc, especially a phase-to-phase arc between electric power conductors where there is little circuit resistance to limit fault current. High-voltage switchgear is constructed in such a way as to extinguish the arc normally developed at the contacts during each “opening” cycle, but certain faults within a piece of switchgear may inhibit this extinguishing function. In such cases the potential for equipment damage and threat to human health and life is severe.

If a bare (unjacketed) optical fiber is properly arranged within a piece of switchgear, an arc flash event will inject enough light through the fiber that some of it will be detected at the far end where it meets a light-sensitive receiver. Since the fiber itself is not electrically conductive, there is no risk of conducting a high-voltage arc back to this receiver. The receiver, meanwhile, serves the purpose of commanding any “upstream” switchgear to trip open in the event of a detected arc fault. The early detection of arc flash by optical means rather than the time-delayed detection of the same fault by overcurrent or current-imbalance detection results in much faster clearing of the faulted switchgear from the power grid, both limiting equipment damage and limiting the potential for injury or death.

### 8.4.3 Fiber optic cable construction

Communication-grade optical fibers are manufactured from fused silica ( $\text{SiO}_2$ ) glass of exceptional purity<sup>23</sup>. A single strand of optical fiber made from this glass called the “core” serves as a waveguide for the light. The core is surrounded by another layer of glass called the “cladding” which has a different index of refraction<sup>24</sup> necessary to “channel” the majority of the optical energy through the core and inhibit “leakage” of optical power from the cable. Additional layers of plastic and other materials around the core/cladding center provide coloring (for fiber identification in multi-fiber cables), protection against abrasion, and tensile strength so the cable will not suffer damage when pulled through conduit.

The purpose of building a fiber optic cable with a core and a cladding having different refractive indices (i.e. different speeds of light) is to exploit a phenomenon called *total internal reflection*, whereby rays of light reflect off the interface between core and cladding to prevent its unintentional escape from the core at any point along the length of the fiber.

When light crosses an interface between two materials having different speeds, the light beam will become *refracted* as a function of those two speeds as described by *Snell’s Law*:

Snell’s Law relates the sine of the incident angle to the sine of the refracted angle as a ratio to each material’s speed of light, the material possessing the greatest speed of light (i.e. the lowest refractive index value) exhibiting the greatest angle as measured from perpendicular to the interface:

$$\frac{\sin \theta_1}{v_1} = \frac{\sin \theta_2}{v_2}$$

<sup>23</sup>Impurities such as metals and water are held to values less than 1 part per *billion* (ppb) in modern optical fiber-grade glass.

<sup>24</sup>The “index of refraction” ( $n$ ) for any substance is the ratio of the speed of light through a vacuum ( $c$ ) compared to the speed of light through that substance ( $v$ ):  $n = \frac{c}{v}$ . For all substances this value will be greater than one (i.e. the speed of light will always be greatest through a vacuum, at 299792458 meters per second or 186282.4 miles per second). Thus, the refractive index for an optically transparent substance is analogous to the reciprocal of the *velocity factor* of an electrical transmission line, where the permittivity and permeability of the cable materials act to slow down the propagation of electric and magnetic fields through the cable.

According to Snell's Law, there will be a critical angle at which the incident light ray will refract to being parallel to the interface. Beyond this critical angle, the light ray ideally reflects off the interface and never enters the second material at all. This is the condition of *total internal reflection*, and it is what we desire in an optical fiber where the core is the first material and the cladding is the second material:

Both the core and cladding of an optical fiber are manufactured from the same base material of ultra-pure fused silica, but “doped” with specific impurities designed to alter the refractive index of each one (raising the refractive index of the core to decrease its optical velocity and lowering the refractive index of the cladding to increase its optical velocity).

The diameter of core and cladding vary with the type of optical fiber, but several standard sizes have emerged in the industry, each one specified by the diameter of the core followed by the diameter of the cladding expressed in *microns* (millionths of a meter). A common optical fiber standard in the United States is 62.5/125 (62.5 micron core diameter, 125 micron cladding diameter), and 50/125 in Europe. Some less common standard core/cladding diameters<sup>25</sup> include 85/125 and 100/140.

<sup>25</sup>All of these sizes refer to *glass* fibers. Plastic-based optical fibers are also manufactured, with much larger core diameters to offset the much greater optical losses through plastic compared to through ultra-pure glass. A typical plastic optical fiber (POF) standard is specified at a core diameter of 980 microns and a cladding diameter of 1000

To give some perspective on the physical size of an optical fiber core, the following photograph shows the end-view of an “ST” style fiber optic connector for a 50/125 micron cable, held by my hand. A green LED light source is shining into the other end of this cable, the tiny green dot visible at the center of the ST connector revealing the diameter of the 50 micron core:

Several other layers of material must be placed over the core and cladding to form a rugged optical fiber. A plastic *jacket* with a typical diameter of 250 microns (0.25 mm) covers the cladding, and provides a base for color-coding the fiber. This three-layer construction of core, cladding, and jacket is known in the industry as *Primary Coated Optical Fiber*, or *PCOF*.

PCOF is still too fragile for end-user applications, and so another layer of plastic is typically added (900 microns in diameter) to make the fiber *Secondary Coated Optical Fiber*, or *SCOF*. When wrapped with fiberglass or Kevlar fibers around the secondary jacket for tensile strength, and a protective PVC plastic outer layer to protect against abrasion, the cable becomes suitable for indoor use. Cables suitable for outdoor, direct burial, and undersea applications usually take the form of groups of PCOF fibers packaged within an extremely rugged encasement with metal strands for tensile strength. Sometimes a gel material helps cushion the fibers from each other within the confines of the cable sheath.

---

microns (1 millimeter)!

### 8.4.4 Multi-mode and single-mode optical fibers

In any sort of waveguide – optical, electrical, or even acoustical (sound) – the signal energy may be able to propagate down the waveguide in different orientations. This is true for optical fibers where the core diameter is relatively large<sup>26</sup> compared to the wavelength of the light: there will be many alternative pathways for light to travel along the length of a fiber’s core. Optical fibers with core diameters of 50 microns or more are referred to as *multi-mode* fibers, because multiple independent pathways, or “modes”, of light are possible within the core’s width.

If an optical fiber’s core is manufactured to be small enough, relative to the wavelength of the light used, the fiber will only support one “mode” or pathway down its core. Such fiber is called *single-mode*. Single-mode fiber cores typically range from 4 to 10 microns in diameter, with 8 micron being typical.

The purpose of single-mode optical fiber is to avoid a problem called *modal dispersion*. When multiple “modes” of light propagate down the length of an optical fiber, they don’t all have the same length. That is to say, some modes actually take a straighter (and more direct) path down the fiber’s core than others. The reason this is a problem is that this phenomenon corrupts the integrity of high-speed (i.e. short-period) pulses. An exaggerated illustration of this problem appears here, showing the relative path lengths of three different light rays, each one entering the fiber core at a slightly different angle. The light ray closest to parallel with the core’s centerline finds the shortest “mode” to the fiber’s end, and arrives in the least amount of time:

With different “modes” of light arriving at different times from the same incident pulse, the received light pulse at the exiting end of the fiber will no longer possess a crisp “square-wave” shape. Instead, the pulse will be “smeared” over time, occupying a larger time span. This poses a bandwidth limit on the fiber, as there will be some maximum pulse frequency at which adjacent pulses will begin to merge together and become indistinguishable. The longer the length of optical fiber, the more pronounced this dispersion will be. This problem is most evident in applications where the fiber length is very long (hundreds of miles) and the data rate is very high (hundreds of megahertz). Thus, it is a significant problem for long-distance data trunk cables such as those used for transcontinental and intercontinental internet traffic.

<sup>26</sup>A common core size for “multi-mode” optical fiber is 50 microns, or 50 micro-meters. If a wavelength of 1310 nanometers (1.31 microns) is used, the core’s diameter will be  $\frac{50}{1.31}$  or over 38 times the wavelength.

Single-mode optical fiber completely averts this problem by eliminating<sup>27</sup> multiple modes within the fiber core. When there is only one mode (pathway) for light to travel, there will be exactly one distance for light to travel from one end of the fiber to the other. Therefore, all portions of the incident light pulse experience the same travel time, and the light pulse arrives at the far end of the cable suffering no modal dispersion:

As you can imagine, single-mode fiber is more challenging to splice than multi-mode fiber, as the smaller core diameter provides less room for alignment error.

A compromise solution to the problem of modal dispersion in multi-mode fibers is to manufacture the core glass with a *graded* index of refraction rather than a homogeneous index of refraction. This means the concentration of doping material in the glass varies from the center of the core to the outer diameter of the core where it interfaces with the cladding. The result of this graded dispersion is that modes traveling closest to the core's centerline will experience a slower speed of light (i.e. greater index of refraction) than modes near the edge of the core, which means the difference in travel time from one mode to the next will be less pronounced than within normal "step-index" fibers. Of course, this also means graded-index optical fiber is more costly to manufacture than step-index optical fiber.

<sup>27</sup>The most straight-forward way to make an optical fiber single-mode is to manufacture it with a skinnier core. However, this is also possible to achieve by increasing the wavelength of the light used! Remember that what makes a single-mode optical fiber only have one mode is the diameter of its core *relative to the wavelength of the light*. For any optical fiber there is a *cutoff wavelength* above which it will operate as single-mode and below which it will operate as multi-mode. However, there are practical limits to how long of a wavelength we can make the light before we run into other problems, and so single-mode optical fiber is made for standard light wavelengths by manufacturing the cable with an exceptionally small core diameter.

### 8.4.5 Fiber optic cable connectors, routing, and safety

One of the most popular styles of single-fiber connector is the so-called “ST” style, which uses a quarter-turn locking barrel to secure the connector into its matching socket:

Communication patch cables such as the one shown above come in *pairs* of fibers, one for receiving and one for transmitting. Note how the plastic strain-relief grips between the metal barrel of each connector and each orange-jacketed cable are color-coded (one white, one black) for easy identification at each end of the cable.

An older style of connector based on the type used to connect small coaxial cables together is the “SMA” style, which used a threaded barrel to lock each fiber in place. The SMA-style connectors were very secure, but laborious to engage and disengage due to the fine pitch of the barrel’s threads and the subsequent need to turn the barrel multiple rotations (versus one-quarter turn of the barrel for an ST connector).

Given that communication patch cables typically have two fibers (one for each direction of data flow), connector styles have emerged to accommodate fiber pairs. One such style is the so-called “SC” connector, with a pair of side-by-side plugs accommodating twin optical fibers.

Terminating a bare cable of fibers with individual connectors is a time-consuming process, requiring the technician to unbundle the individual fibers, strip the jacketing off of each one to reveal the core and cladding, cleave each glass fiber to give it a flat end, and finally insert and secure each fiber into its respective connector. Typical fiber connectors use either a “hot-melt” or a chemical epoxy system of attachment, where the glue adheres to the strain-relief fibers of the cable for tensile strength, while the central glass fiber protrudes through a small hole in the center of the connector tip. This protruding glass fiber must be carefully cut and polished to produce a flat end suitable for engagement with another optical fiber aligned to its center.

Optical fibers may be spliced mid-way in a cable run, although this practice should be avoided whenever possible. If the fibers are multi-mode, the splicing may be done using “butt” connectors

but the power losses may be unacceptable. Alternatively, stripped fibers may be inserted into both ends of a small-diameter tube filled with gel having the same index of refraction as the core glass, to “conduct” light with as little loss as possible from one fiber core to the other.

A very good technique often applied to single-mode fiber is that of *fusion splicing*, where two single-mode fiber ends are literally melted together using an electric arc so that they form one seamless glass fiber. The alignment of fibers prior to fusion is done under the view of a microscope, and often with the aid of a light source on one end and an optical power meter on the other end to give a quantitative measurement of alignment accuracy. When the two fibers are aligned as close as possible, the electric arc is fired to melt the two fibers together, creating a single fiber. Fusion splicing is the method of choice for long-distance runs of single-mode fiber, where low power loss and high integrity of the splice are paramount factors.

When laying optical fiber in wire trays, pulling through rigid conduit, or arranging it in connection panels, an important physical consideration is to maintain a minimum bend radius<sup>28</sup> at all points along the fiber’s length. This is important because sharp bends will cause light to “leak” out of the fiber core and into the cladding where it may then escape the cable altogether. A sharp bend in an optical fiber will cause the angle between the light ray and the core/cladding interface to reach the critical point where total internal reflection no longer occurs:

The light leakage from an optical fiber may be dramatic if the bend is sharp enough. On an indoor cable, using visible laser light, you can actually see the light “leak” through to the PVC outer coating on the outside of the cable!

Junction boxes and connection panels where excess lengths of fiber optic cabling may be coiled will typically provide plastic forms over which those loops of cable may be bent, the radius of that plastic form exceeding the manufacturer’s specification for minimum bend radius.

A common way in which the minimum bend radius requirement is violated is when a cable tie is used to anchor a fiber optic cable to some sturdy surface such as a wiretray or a cabinet post. The sharp bend created by the tension of a tightened cable tie on the fiber optic cable will easily exceed the minimum bend radius for that cable, creating light leakage and subsequent performance problems. Therefore, a good installation practice for fiber optic cables is to always leave cable ties loose enough that they do not tightly grip the cable.

---

<sup>28</sup>Typically a few inches for multi-mode fiber.

There are multiple safety concerns when working with optical fibers, both when installing them and when doing maintenance-type work. Installation hazards center around dangers of the glass fiber itself, while maintenance hazards center around the light sources used to “power” the optical fibers.

Installation of fiber optic cable requires that individual glass fibers be separated from each other in a multi-fiber cable and each one terminated with a connector, and this requires at some point that the technician strip each fiber down to its glass core and cladding. Both the core and the cladding are extremely small in diameter, and are made of ultra-pure glass. If a piece of core/cladding breaks off the fiber and penetrates the skin, the resulting “sliver” will be nearly invisible due to its exceptional transparency. Its outer surface is also very smooth, making extraction difficult. Unextracted pieces of an optical fiber, if left in the body, can actually migrate through the victim’s flesh and become buried even deeper to the point where they can cause serious health problems.

Technicians working with optical fiber typically lay a length of adhesive tape, sticky-side up, on whatever workbench or table they are using to prepare the cable, as a tool to catch any loose fiber ends they cut off. At the conclusion of the job, this length of tape is carefully rolled up and then disposed of in the same manner that “sharps” may be disposed of in a medical environment.

Maintenance technicians working with functioning fiber optic systems need to be careful when disconnecting “hot” fibers, due to the intensity of the light used in some systems. This is especially true of long-distance telecommunication fibers using laser sources rather than regular LEDs, which may have power levels reaching a half watt or so. One-half of a watt doesn’t sound like very much power, but when you consider this power level is concentrated over a circular area with a diameter less than 10 microns (for single-mode fiber), the watt-per-square-meter value is actually large enough to cause significant temperature increases wherever the light beam happens to fall. In fact, you can actually damage a fiber-optic connector on such a system by disconnecting the fiber with the fiber “powered”, the laser light being intense enough to burn and pit the aluminum ferrule of the connector!

Even standard LED light sources may pose a hazard if a technician directly views the end of the cable with his or her eyes, due to the focused nature of the light beam. The retina of your eye is extremely sensitive to light, and may easily be damaged by viewing such an intensely focused beam coming out of an optical fiber, where the entire LED’s light output is channeled into a core just a fraction of a millimeter in diameter. The optical hazard is even greater when infra-red light sources are used, because there is no visible indication of the light’s presence. A technician won’t even be able to see the light coming out, yet it could still be intense enough to damage their retina(s).

Laser-sourced fibers should never be unplugged from the equipment. One should treat a laser-sourced fiber with the same respect as a “live” electrical circuit, and use the same lockout/tagout procedures to ensure personnel safety. In systems using visible light wavelengths, a safe way to view the light coming out the end of an optical fiber is to point the fiber end at a piece of paper and look for the colored dot falling on the paper. The paper’s rough surface scatters the light so that it is no longer a focused beam.

The only time it is truly safe to view the end of an optical fiber to check for light is when the light source is something diffuse such as natural sunlight or a flashlight. It is common for technicians to use a flashlight to identify fibers from one end of a multi-fiber cable to the other, one technician shining the flashlight at the end of one fiber while another technician views all the fibers at the other end of the cable to see which one is lit.

Some optical communications equipment come equipped with a feature called an *Open Fiber Control* (OFC) safety system, which turns off all light sources on a channel whenever an interruption of light is detected at the receiver port. Since most duplex (two-way) optical fiber channels consist of two fibers (one for each direction of light), a break in any one fiber will darken one receiver, which then commands the transmitter port on that equipment to darken as well to prevent anyone getting injured from the light. It also completely disrupts communication in that channel, requiring a re-initialization of the channel after the fiber is plugged back in.

#### 8.4.6 Fiber optic cable testing

Optical fibers, like electrical communications cable, may need to be tested to measure certain performance characteristics. Such testing is commonplace for new installations of fiber optic cabling to ensure all installed cable lengths and connectors are functioning properly. Repeated tests over time, compared with the initial installation test, quantifies any degradation of cables or connectors. Another common testing procedure, called *acceptance testing*, tests the optical cable while it is still on the spool prior to installation.

Two basic types of optical fiber tests are presented here: one where the power level of light is measured at the far end of the fiber from a source of known optical power, and another where a pulse of light is sent down a fiber and the light received at the same end of the fiber is analyzed. The former test is simply a measurement of optical power, while the latter test is a sophisticated analysis of light over very brief periods of time (time domain reflectometry).

### Optical power loss testing

Perhaps the simplest quantitative test of an optical fiber consists of shining a light source of known optical power at one end of a fiber and monitoring the amount of optical power received at the other end of the fiber. This type of test is typically performed with two pieces of equipment: the source and the power meter.

First, the optical power meter and light source are short-coupled together using a pair of patch cables and a single “butt” connector:

Once light is received by the optical power meter, the technician presses the “zero” button to set the baseline or reference point for all future power measurements. Although some light will be lost in the two patch cables and connector, this amount of loss will also be present in the final test and so it must be ignored.

After “zeroing” the optical power meter, the actual fiber to be tested is connected between the light source and the power meter. Any *additional* light lost within the tested fiber<sup>29</sup> will register at the power meter as a negative decibel figure:

Recall that the definition of a “decibel” is 10 times the common logarithm of the power ratio between output and input for any system:

$$\text{dB} = 10 \log \left( \frac{P_{out}}{P_{in}} \right)$$

Thus, the power loss of  $-0.6$  dB shown in the illustration represents 87.1% of the optical source power received by the optical power meter. Decibels are very commonly used as an expression of power gain and loss in communication system testing, because dB figures directly add when components are connected in series with each other. For example, if we knew that a certain type of “butt” connector for optical fiber exhibited a typical power loss of  $-1.2$  dB and that three of these connectors would be used to join a single run of fiber, we would know to expect a total connector loss of  $-3.6$  dB (i.e.  $3 \times -1.2$  dB).

<sup>29</sup>Not just light lost along the length of the fiber, but also at each connector on the fiber, since placing the test fiber within the optical path between the light source and optical power meter necessarily introduces another pair of connectors where light may be lost.

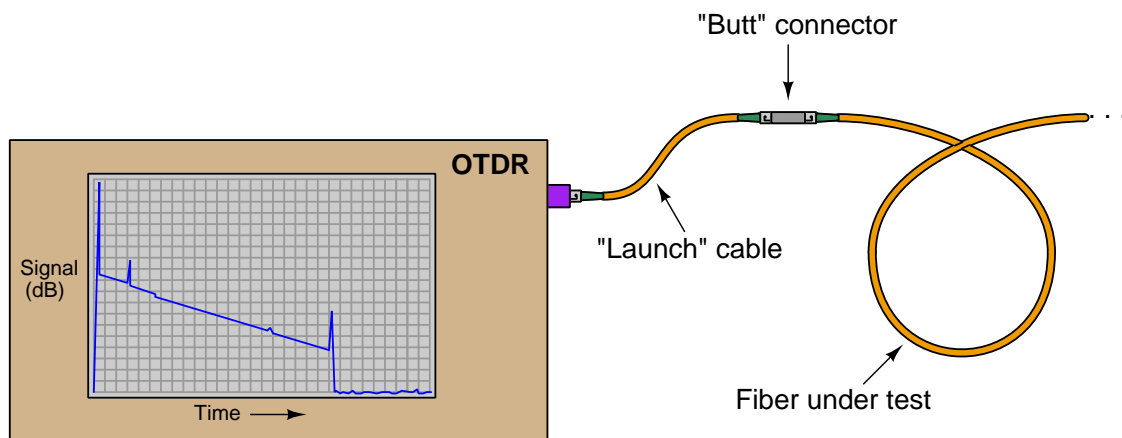

Excessive optical power losses may be caused by a number of different factors, including:

- Poor alignment between fibers in a connector
  - Connector flaw causing fibers to be mis-aligned (e.g. angular misalignment)
  - Fiber flaw causing mis-alignment in a good connector (e.g. cores not concentric)
- Mismatched fiber sizes (e.g. 62.5 micron core sending light into a 50 micron core)
- Oil or debris on the end of a connector
- Rough (improperly polished) end on one or more fibers
- Minimum bend radius violated at any point along the fiber's length
- Cracked fiber core

Unfortunately, a power meter test will not indicate what kind of flaw is causing excessive power loss, nor where that flaw might be located. If the cable in question has removable connectors mid-way in its length, the power meter and/or source may be relocated to test portions of the cable to determine which section contributes more to the power loss, but an end-to-end power test cannot pinpoint the location or the type of fault.

### OTDR testing

An *Optical Time-Domain Reflectometer* or *OTDR* is a sophisticated test instrument used to probe the characteristics of long optical fibers. They work by injecting a very brief pulse of light into one end of a long optical fiber, then monitoring any light received at that same end of the fiber. As the light pulse travels down the length of the fiber, it continuously loses some of its magnitude due to scattering in the glass. Some of this scattered light returns back to the source-end of the fiber, presenting a sort of “continuous echo” of the moving pulse. This continuous echo is analogous to the noise heard from an object moving away from the listener. As the light pulse encounters flaws and other discontinuities in the fiber and/or connectors along its length, the echoed signal changes in magnitude. This received signal is displayed as a time-domain plot on the OTDR viewing screen, and will look something like this:

The “trace” shown on the display screen of an OTDR is a plot of the received optical signal strength over time. A large “spike” at the left-hand side of this trace marks the incident pulse of light injected into the optical fiber by the OTDR from the traveling pulse as it propagates down the length of the fiber. All signals after that (to the right of that initial “spike”) represent light received from that same end of the optical fiber. In a completely uniform fiber the resulting “echo” would trace a downward-sloping straight line as the traveling light pulse gradually weakens. In an imperfect fiber, any discontinuities such as splices, connector joints, sharp bends, cracks, etc. will cause the traveling light pulse to lose more photons than usual at the location of the discontinuity: sometimes returning a strong echo back toward the OTDR and other times not. A discontinuity such as a mis-aligned fiber connector will tend to return a strong echo as part of the traveling light pulse reflects off the mis-aligned connector end and returns to the OTDR. A discontinuity such as a mal-formed fusion splice merely scatters a greater-than-normal amount of light out through the fiber’s cladding, in which case there is no echo “pulse” received by the OTDR but rather just a further weakening of the echo signal.

The OTDR trace shown in the previous illustration demands further explanation. Shown here is a magnified view of it, complete with numbers to identify each noteworthy event:

**Legend:**

1. Incident pulse output by the OTDR, and injected into the launch fiber
2. Reflection off the face of the near-end connection between the launch fiber and the fiber under test
3. Loss of light due to a non-reflective discontinuity (e.g. sharp bend, splice)
4. Loss of light due to a reflective discontinuity (e.g. mis-aligned connector)
5. Reflection off the face of the far-end connection at the end of the fiber under test
6. The “noise floor”

As you can see, an OTDR trace provides much more information about the performance of an optical fiber than a simple power test. Each flaw in the cable or its associated connectors appears as a deviation from the normal downward-sloped line of the trace, the location in time revealing the distance between the OTDR and the flaw. Thus, an OTDR not only indicates the nature of each flaw, and the amount of optical power lost at each flaw, but also the *location*<sup>30</sup> of each flaw along the fiber’s length. One important caveat exists for this distance calculation, and that is the fact that the length of a fiber in a multi-fiber cable will always be somewhat longer than the length of the cable itself, since individual fibers inside a cable are often “wound” in a spiral configuration or otherwise deviating from the straight centerline of the cable. “Loose tube” cables, for example, often exhibit fiber lengths 5% to 10% greater than the physical length of the cable itself.

<sup>30</sup>Since distance along any path is simply the product of speed and time ( $x = vt$ ), and the speed of light through an optical fiber is a well-defined quantity ( $v = \frac{c}{n}$  where  $n$  is the core’s index of refraction), the distance between the OTDR and the flaw is trivial to calculate.

## 8.5 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader's view of this chapter's concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **Sanitary applications:** In processes where bacterial growth cannot be tolerated, there must never be stagnant pockets in piping systems for cultures to reside.
- **Fluid seals:** accomplished by maintaining tight contact between solid surfaces. The shapes of these surfaces are generally conical (e.g. tapered pipe threads, tubing ferrules).
- **Electrical connection integrity:** the integrity of electrical connections is absolutely essential to system reliability. Maintaining firm, clean contact between mating conductor surfaces is necessary to ensure this.
- **Analog vs. digital signals:** analog signals have infinite resolution but are susceptible to corruption by noise. Digital signals have limited resolution but are tolerant of any noise measuring less than the difference in thresholds between the high and low states.
- **Electromagnetic induction:** occurs only when magnetic fields are perpendicular to the conductor. Relevant to signal coupling in cables, mitigated by twisting cable conductors to form opposing loops from the perspective of an external magnetic field.
- **Electrostatic coupling:** occurs when electric fields bridge between conductors, and cannot occur "behind" a grounded conductor. Relevant to signal coupling in cables, mitigated by building cables with shield conductors and grounding the shield at one cable end.
- **Lenz's Law:** any magnetic field arising from electromagnetic induction opposes the inducing field. Relevant to determining the directions of induced current in a twisted-pair cable exposed to an AC magnetic field.
- **Capacitance:**  $C = \frac{\epsilon A}{d}$ , capacitance being proportional to the area of two overlapping conductors ( $A$ ), the permittivity of the insulating (dielectric) substance between them ( $\epsilon$ ), and the distance ( $d$ ) separating the conductors. Relevant to electrostatic coupling, where the degree of coupling between two electrical conductors is directly proportional to the overlapping area and inversely proportional to the distance between the conductors.
- **Transmission lines:** short-duration (pulsed) electrical signals travel along a cable at nearly the speed of light, reflecting off the end of that cable if not properly terminated. Relevant to signal cables carrying high-frequency signals.
- **Decibels:** used to express the ratio of one power to another in logarithmic form, such that the sum of component dB values is equivalent to the product of those same component gain/loss ratios. Decibels may also be used to express a power quantity relative to some reference power value such as 1 milliwatt (dBm) or 1 watt (dBW). Decibels are an example of a mathematical *transform function*, whereby one type of mathematical problem (multiplication/division) is transformed into an easier type of problem (addition/subtraction).

- **Time-Domain Reflectometry:** the analytical technique of sending a pulse signal down a transmission line or waveguide and analyzing the characteristics of that transmission line or waveguide by the reflected signal. Relevant to the testing of electrical cables as well as optical fibers.
- **Snell's Law:** relates the angle of a refracted light ray at the interface of two transparent substances to the relative speeds of light through those two substances. Relevant to the core and cladding materials of an optical fiber, the speeds of light for those two substances altered in such a way as to produce total internal reflection of the light rays within the core. This keeps the light in the fiber, inhibiting leakage and subsequent signal loss.

## Chapter 9

# Discrete process measurement

The word “discrete” means *individual* or *distinct*. In engineering, a “discrete” variable or measurement refers to a true-or-false condition. Thus, a discrete sensor is one that is only able to indicate whether the measured variable is above or below a specified setpoint.

Discrete sensors typically take the form of *switches*, built to “trip” when the measured quantity either exceeds or falls below a specified value. These devices are less sophisticated than so-called *continuous* sensors capable of reporting an analog value, but they are quite useful in industry.

Many different types of discrete sensors exist, detecting variables such as position, fluid pressure, material level, temperature, and fluid flow rate. The output of a discrete sensor is typically electrical in nature, whether it be an active voltage signal or just resistive continuity between two terminals on the device.

## 9.1 “Normal” status of a switch

Perhaps the most confusing aspect of discrete sensors is the definition of a sensor’s *normal* status. Electrical switch contacts are typically classified as either *normally-open* or *normally-closed*, referring to the open or closed status of the contacts under “normal” conditions. But what exactly defines “normal” for a switch? The answer is not complex, but is often misunderstood due to the ambiguous nature of the word *normal*.

The “normal” status for a switch is the status its electrical contacts are in *during a condition of no physical stimulation*. Another way to think of the “normal” status is to think in terms of the switch being *at rest*. For a momentary-contact pushbutton switch, this would be the status of the switch contact when it is *not* being pressed. Electrical switches are always drawn in schematic diagrams in their “normal” statuses, regardless of their application. For instance, the following diagram shows a normally-open pushbutton switch controlling a lamp on a 120 volt AC circuit (the “hot” and “neutral” poles of the AC power source labeled L1 and L2, respectively):

We can tell this switch is a normally-open (NO) switch because it is drawn in an open position. The lamp will energize only if someone presses the switch, holding its normally-open contacts in the “closed” position. Normally-open switch contacts are sometimes referred to in the electrical industry as *form-A* contacts.

If we had used a normally-closed pushbutton switch instead, the behavior would be exactly opposite. The lamp would energize if the switch was left alone, but it would turn off if anyone pressed the switch. Normally-closed switch contacts are sometimes referred to in the electrical industry as *form-B* contacts:

This seems rather simple, don’t you think? What could possibly be confusing about the “normal” status of a switch? The confusion becomes evident, though, when you begin to consider *process* switches (i.e. switches actuated by process measurements such as pressure, flow, level, etc.). In order to better understand this concept, we will consider a simple application of a *flow* switch: a switch built to actuate when a sufficient rate of fluid flows through a pipe.

A flow switch is built to detect fluid flow through a pipe. In a schematic diagram, the switch symbol appears to be a toggle switch with a “flag” hanging below. The schematic diagram, of course, only shows the circuitry and not the pipe where the switch is physically mounted:

*A low coolant flow alarm circuit*

This particular flow switch is used to trigger an alarm light if coolant flow through the pipe ever falls to a dangerously low level, and the contacts are *normally-closed* as evidenced by the closed status in the diagram. Here is where things get confusing: even though this switch is designated as “normally-closed,” it will spend most of its lifetime being held in the open status by the presence of adequate coolant flow through the pipe. Only when the flow through the pipe slows down enough will this switch return to its “normal” status and conduct electrical power to the lamp. In other words, the “normal” status for this switch (closed) is actually an *abnormal* status for the process it operates within (low flow), for the simple reason that the switch should be stimulated and not at rest while the process is operating as it should.

Students often wonder why process switch contacts are labeled according to this convention of “no stimulation” instead of according to the typical status of the process in which the switch is used. The answer to this question is that the manufacturer of the switch has no idea whatsoever as to your intended use. A flow switch manufacturer does not know or care whether their product gets used as a low-flow detector or as a high-flow detector. In other words, the manufacturer cannot predict what the typical status of *your* process will be, and so the definition of “normal” status for the switch must be founded on some common criterion unrelated to your particular application. That common criterion is the resting status: when the sensor is exposed to the *least* (or no) amount of stimulation from the process it senses.

Here is a listing of “normal” definitions for various process switch types:

- **Limit switch:** target not contacting the switch
- **Proximity switch:** target far away
- **Pressure switch:** low pressure (or even a vacuum)
- **Level switch:** low level (empty)
- **Temperature switch:** low temperature (cold)
- **Flow switch:** low flow rate (fluid stopped)

These are the conditions represented by the switch statuses shown in a schematic diagram. These may very well *not* be the statuses of the switches when they are exposed to *typical* operating conditions in the process.

A helpful tip to remember about process switches and their respective schematic diagram symbols is that the symbols are conventionally drawn in such a way that an *upward* motion of the movable switch element represents *increasing stimulus*. Here are some examples of this, showing various process switch types and NO/NC contact configurations, comparing their states with no stimulus versus when the stimulus exceeds the each switch’s threshold or “trip” setting. The *normal* status of each switch as defined by the manufacturer is labeled in green text:

It is imperative<sup>1</sup> to remember that the way a switch is drawn in a schematic diagram merely represents its “normal” status as defined by the manufacturer. This may or may not be the switch’s status during “typical” operation of the process, and it may or may not be the status of that switch at the time of concern when you are examining the schematic! The “normal” status of a switch means just one thing: what that switch will do when subjected to minimum stimulus – that is to say, what it will do when its stimulus is less than the actuation threshold of the switch.

<sup>1</sup>Mistaken interpretations of switch status remains one of the most resilient misconceptions for students first learning this topic. It seems that a great many students prefer to think of a switch’s drawn status as its status at the present moment (e.g. when the process is running as expected). I believe the heart of this misconception is the meaning of the word “normal,” which to most peoples’ minds refers to “the way things typically are.”

For example, the LED in this circuit will turn on if the liquid level rises above 14 inches *and* the pressure falls below 22 PSI *and* either the flow is less than 3 gallons per minute *or* the temperature is greater than 125 degrees Fahrenheit:

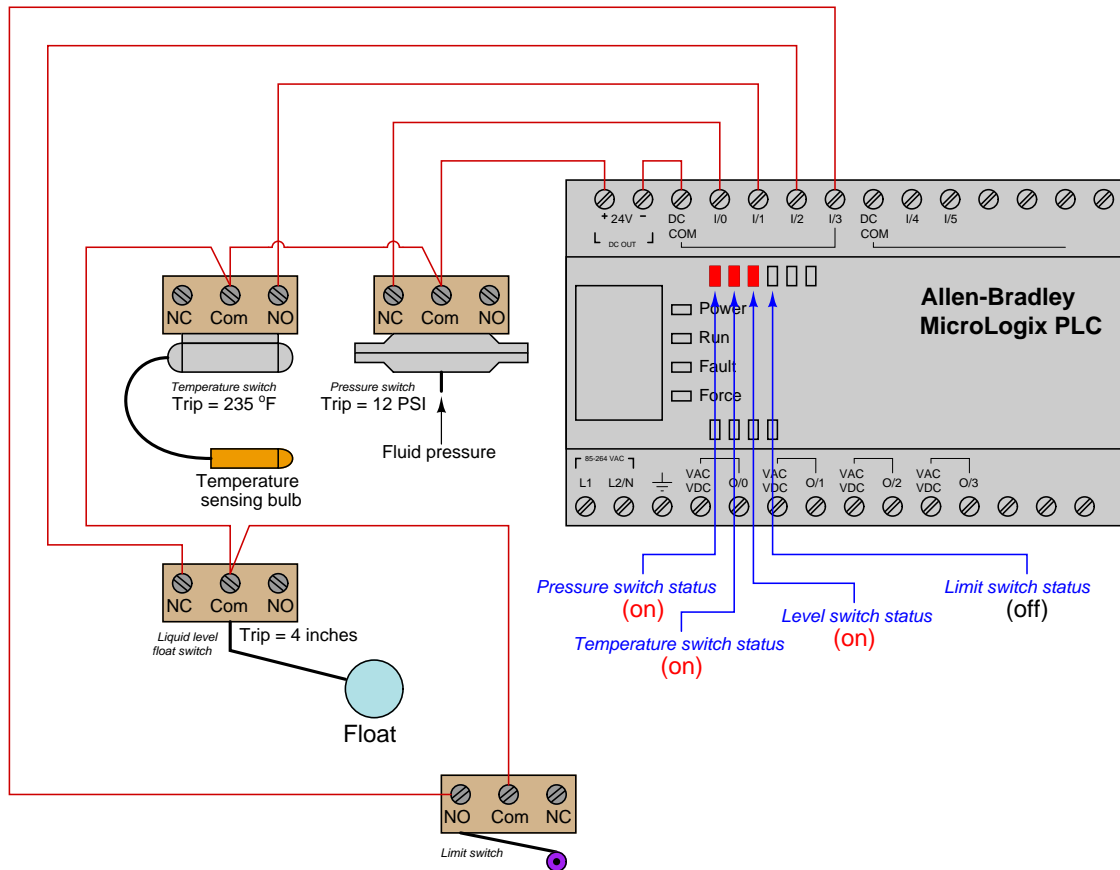

Since we know we need a switch to be *closed* in order to conduct electricity and provide a path for current in this circuit, we are looking for the necessary conditions to close each switch. For any normally-closed (NC) switch, this means a stimulus value less than the actuation threshold. For any normally-open (NO) switch, this means a stimulus value great enough to exceed the threshold and “hold” the switch in its actuated state. Since the flow and pressure switches in this circuit are both NC, we are looking for flow and pressure values less than the respective settings. Since the level and temperature switches are both NO, we are looking for level and temperature values in excess of their respective settings.

The present status of a switch may be determined by comparing its stimulating quantity against its trip (threshold) setting. A switch will be in its “normal” (resting) state when the stimulus value is less than the threshold value. Conversely, a switch will be in its “actuated” state when the stimulus value exceeds the threshold value. Determination of a switch’s status, therefore, is a matter of comparing the stimulus quantity to the threshold “trip” setting. One cannot simply look at the schematic diagram to tell what the switch is doing – one must *compare* the switch’s setting versus against a known stimulus value in order to tell whether it will be in its resting state or not.

Likewise, if we happen to know the switch’s present status in a system, we may qualitatively determine the stimulating quantity by comparing the present status against the “normal” (resting) status. If a switch is in its resting state, then the stimulating quantity must be less than the trip threshold. If a switch is in its actuated (non-normal) state, then the stimulating quantity must be greater than the trip threshold<sup>2</sup>. The next example showcases these determinations.

<sup>2</sup>In this discussion I am deliberately omitting the detail of *deadband* for process switches, for the sake of simplicity.

In this next example, we see a pictorial representation of multiple switches wired to the discrete input channels of a programmable logic controller (PLC), with red LED indicators denoting the real-time status of each input on the PLC:

We may determine a switch's degree of stimulation by comparing its present status with its "normal" status. If a switch happens to be in the same state as its normal state (i.e. resting), we know its stimulus must be less than the threshold (trip) value. If a switch happens to be in the opposite state as its normal state (i.e. actuated), we know its stimulus has exceeded the threshold (trip) value. The states of these four switches may be shown in a table:

Switch	Normal status	Present status	Trip value	Stimulus
Pressure	Normally-closed (NC)	Closed	12 PSI	$P < 12 \text{ PSI}$
Temperature	Normally-open (NO)	Closed	235 °F	$T > 235 \text{ °F}$
Level	Normally-closed (NC)	Closed	4 inches	$L < 4 \text{ inches}$
Limit	Normally-open (NO)	Open	n/a	<i>no contact</i>

## 9.2 Hand switches

A *hand switch* is exactly what the name implies: an electrical switch actuated by a person's hand motion. These may take the form of toggle, pushbutton, rotary, pull-chain, etc. A common form of industrial pushbutton switch looks something like this:

The threaded neck inserts through a hole cut into a metal or plastic panel, with a matching nut to hold it in place. Thus, the button faces the human operator(s) while the switch contacts reside on the other side of the panel.

When pressed, the downward motion of the actuator breaks the electrical bridge between the two NC contacts, forming a new bridge between the two NO contacts:

The schematic diagram symbol for this type of switch looks much like the real thing, with the normally-closed contact set on top and the normally-open contact set below:

Connecting two of the terminals together makes this form of switch electrically identical to a *Form C*:

This switch contact arrangement is sometimes referred to as a *form-C* contact set, since it incorporates both a form-A contact (normally-open) as well as a form-B contact (normally-closed).

Most industrial hand switches are available in modular form, where sets of switch contact blocks may be “stacked” together to be actuated by the same pushbutton or rotary knob. This allows an almost unlimited number of switch contacts to be simultaneously actuated by a single actuating mechanism. Different actuator types such as pushbuttons, rotary selectors, knobs, and keyswitches may also be interchanged with contact modules for maximum flexibility:

## 9.3 Limit switches

### Limit switch symbols

A *limit switch* detects the physical motion of an object by direct contact with that object. An example of a limit switch is the switch detecting the open position of an automobile door, automatically energizing the cabin light when the door opens.

Recall from section 9.1 that the “normal” status of a switch is the resting condition of *no stimulation*. A limit switch will be in its “normal” status when it is not in contact with anything (i.e. nothing touching the switch actuator mechanism).

Limit switches find many uses in industry, particular in robotic control and CNC (Computer Numerical Control) machine tool systems. In many motion-control systems, the moving elements have “home” positions where the computer assigns a position value of zero. For example, the axis controls on a CNC machine tool such as a lathe or mill all return to their “home” positions upon start-up, so the computer can know with confidence the starting locations of each piece. These home positions are detected by means of limit switches. The computer commands each servo motor to travel fully in one direction until a limit switch on each axis trips. The position counter for each axis resets to zero as soon as the respective limit switch detects that the home position has been reached.

A typical limit switch design uses a roller-tipped lever to make contact with the moving part. Screw terminals on the switch body provide connection points with the NC and NO contacts inside the switch. Most limit switches of this design share a “common” terminal between the NC and NO contacts like this:

### Equivalent schematic

This switch contact arrangement is sometimes referred to as a *form-C* contact set, since it incorporates both a form-A contact (normally-open) as well as a form-B contact (normally-closed).

A close-up view of several limit switches (used on a drum sequencer) shows the arrangement of connection terminals for form-C contacts. Each limit switch has its own “NO” (normally-open), “NC” (normally-closed), and “C” (common) screw terminal for wires to attach:

A limit switch assembly attached to the stem of a rotary valve – used to detect the fully-closed and fully-open positions of the valve – is shown in the following photograph:

## 9.4 Proximity switches

A *proximity switch* is one detecting the proximity (closeness) of some object. By definition, these switches are *non-contact sensors*, using magnetic, electric, or optical means to sense the proximity of objects.

Recall from section 9.1 that the “normal” status of a switch is the resting condition of *no stimulation*. A proximity switch will be in its “normal” status when it is distant from any detectable object.

Being non-contact in nature, proximity switches are often used instead of direct-contact limit switches for the same purpose of detecting the position of a machine part, with the advantage of never wearing out over time due to repeated physical contact.

Most proximity switches are *active* in design. That is, they incorporate a powered electronic circuit to sense the proximity of an object. *Inductive* proximity switches sense the presence of metallic objects through the use of a high-frequency magnetic field. *Capacitive* proximity switches sense the presence of non-metallic objects through the use of a high-frequency electric field. *Optical* proximity switches detect the interruption of a light beam by an object. *Ultrasonic* proximity switches sense the presence of dense matter by the reflection of sound waves.

The schematic diagram symbol for a proximity switch with mechanical contacts is the same as for a mechanical limit switch, except the switch symbol is enclosed by a diamond shape, indicating a powered (active) device:

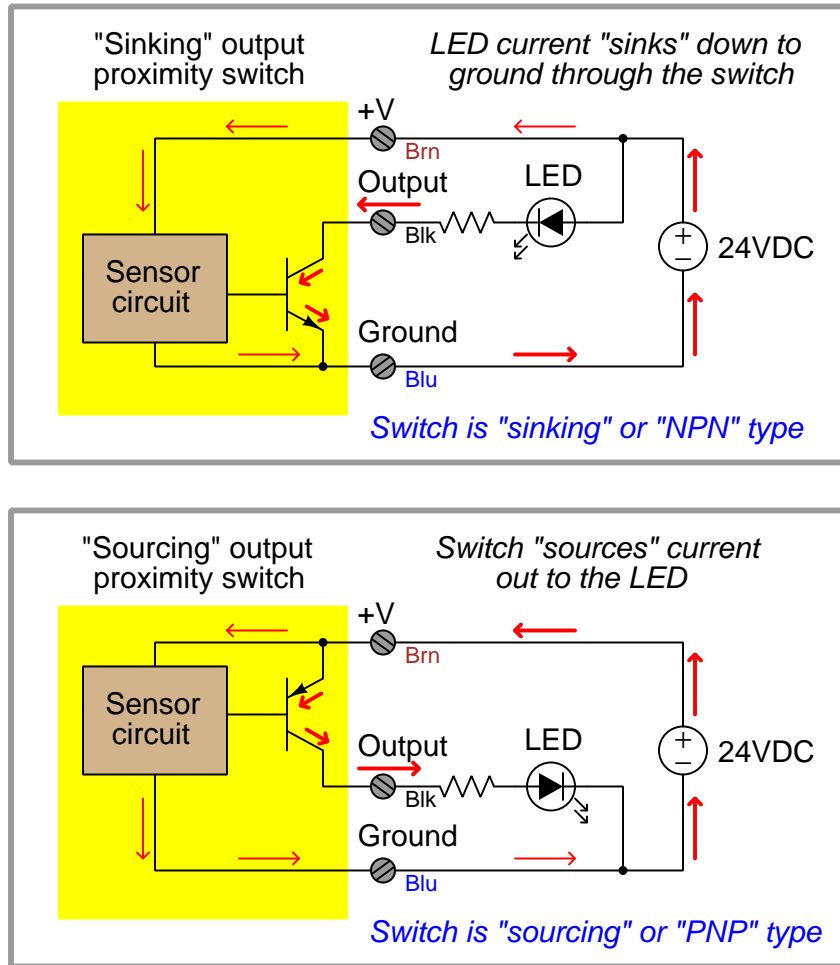

Many proximity switches, though, do not provide “dry contact<sup>3</sup>” outputs. Instead, their output elements are transistors configured either to *source* current or *sink* current. The terms “sourcing” and “sinking” are best understood by visualizing electric current in the direction of *conventional flow* rather than *electron flow*.

---

<sup>3</sup>This curious label is used to describe switch contacts lacking their own built-in power source, as opposed to a switch contained in a device that also provides power to drive the switch circuit. Dry contacts may be mechanical in nature, or they may be electronic (e.g. transistor). By contrast, a “wet” contact is one already connected to an internal power source, ready to drive a load with no other external components needed.

The following schematic diagrams contrast the two modes of switch operation, using red arrows to show the direction of current (conventional flow notation). In both examples, the load being driven by each proximity switch is a light-emitting diode (LED):

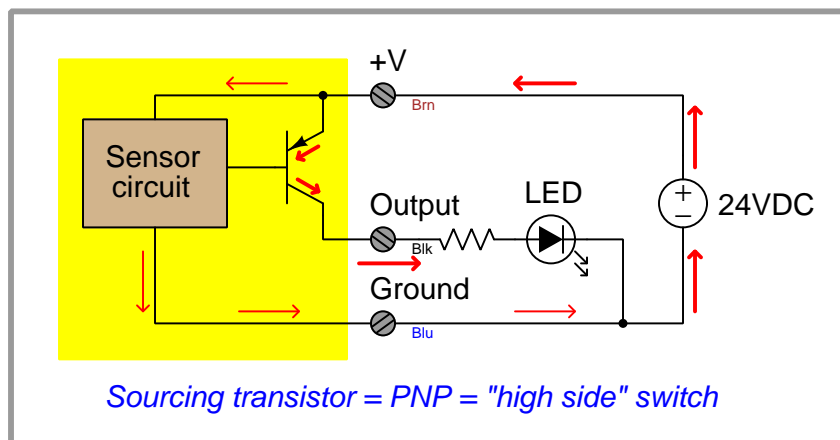

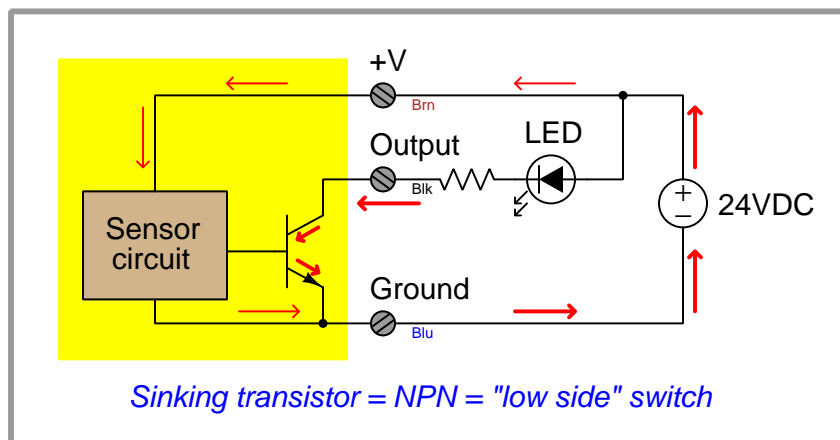

A common coloring convention for electronic proximity switches is brown for +V power supply, blue for ground (– pole of power supply), and black for the switched output signal. This convention is common to sinking and sourcing proximity switches alike.

An electronic switch designed to sink current through its signal wire is alternatively referred to as an *NPN* switch due to the type of transistor used in its output. Conversely, an electronic switch designed to source current through its signal wire may be referred to as a *PNP* switch. The key to understanding these labels is to recognize the emitter terminal of the output transistor is always the one connected to the power supply rail. For a sinking switch, this means the emitter must connect to the negative rail, necessitating<sup>4</sup> an NPN transistor to do the switching. For a sourcing switch,

<sup>4</sup>To be honest, one *could* use an NPN transistor to source current or a PNP to sink, but it would require the

this means the emitter must connect to the positive rail, in which case only a PNP transistor will suffice.

Yet another convention for describing sourcing and sinking transistor switches is to refer to them as *high-side* switches and *low-side* switches, respectively. A sourcing transistor (PNP) has its emitter terminal attached directly to the “high” rail (+) of the DC power supply. A sinking transistor (NPN), by contrast, has its emitter terminal attached directly to the “low” rail (–) of the DC power supply.

transistor be used in the *common-collector* configuration which does not allow for saturation. The engineers designing these proximity switches strive for complete saturation of the transistor, in order to achieve minimum “on” resistance, and that requires a common-emitter configuration.

These photographs show two different styles of electronic proximity switch:

Many industrial proximity switches have built-in LED indicator lamps to help technicians diagnose circuit problems by directly indicating switch status. With just a glance, one may tell whether or not the proximity switch is detecting the presence of an object.

The next photograph shows a proximity switch detecting the passing of teeth on a chain sprocket, generating a slow square-wave electrical signal as the sprocket rotates. Such a switch may be used as a rotational speed sensor (sprocket speed proportional to signal frequency) or as a broken chain sensor (when sensing the rotation of the driven sprocket instead of the drive sprocket):

Like other types of process switches, proximity switches come in both “normally open” (NO) and “normally closed” (NC) varieties. This distinction has nothing whatsoever to do with sourcing versus sinking (PNP vs. NPN), but rather what the status of the proximity switch will be when no objects are near. Thus, it is possible to find normally-open proximity switches that are sinking (NPN) as well as normally-open proximity switches that are sourcing (PNP), and normally-closed proximity switches in either sinking or sourcing designs as well.

These switch characteristics are commonly fixed, and must be specified when ordering the device. Likewise, the detection range of a proximity switch is usually a fixed parameter rather than being adjustable.

## 9.5 Pressure switches

A *pressure switch* is one detecting the presence of fluid pressure. Pressure switches often use diaphragms or bellows as the pressure-sensing element, the motion of which actuates one or more switch contacts.

Recall from section 9.1 that the “normal” status of a switch is the resting condition of *no stimulation*. A pressure switch will be in its “normal” status when it senses minimum pressure (e.g. an applied pressure, or in some cases a vacuum condition)<sup>5</sup>. For a pressure switch, “normal” status is any fluid pressure *below* the trip threshold of the switch.

### *Pressure switch symbols*

The following photograph shows two pressure switches sensing the same fluid pressure as an electronic pressure transmitter (the device on the far left) because they are all plumbed to a common tube:

---

<sup>5</sup>If the trip setting of a pressure switch is below atmospheric pressure, then it will be “actuated” at atmospheric pressure and in its “normal” status only when the pressure falls below that trip point (i.e. a vacuum).

A legacy design of pressure switch uses a bourdon tube as the pressure-sensing element, and a glass bulb partially filled with mercury as the electrical switching element. When applied pressure causes the bourdon tube to flex sufficiently, the glass bulb tilts far enough to cause the mercury to fall against a pair of electrodes, thus completing an electrical circuit. A great many pressure switches of this design were sold under the brand name of “Mercoid,” with a few appearing in this photograph of a steam boiler (the round-shaped units with glass covers allowing inspection of the bourdon tube and mercury tilt switch):

A close-up photograph of one of these pressure switches appears here. The bourdon tube is grey in color, and almost as wide in diameter as the circular switch housing. The mercury tilt switch bottles have yellow-colored plastic caps covering up their external electrical contacts:

The next set of photographs show a mercury tilt switch removed from the pressure switch mechanism, so you may see the switch in two different states (contact open on the left, and closed on the right):

Advantages of mercury tilt switches include immunity to switch contact degradation from harmful atmospheres (oil mist, dirt, dust, corrosion) as well as safety in explosive atmospheres (since a spark

contained within a hermetically sealed glass bulb cannot touch off an explosion in the surrounding atmosphere). Disadvantages include the possibility of intermittent electrical contact resulting from mechanical vibration, as well as sensitivity to mounting angle (i.e. you would *not* want to use this kind of switch aboard a moving vehicle!).

A pressure switch manufactured by the Danfoss corporation appears in the next photograph. This particular model of pressure switch has windows on the front cover allowing a technician to see the pressure limit setting inside:

This switch balances the force generated by a pressure-sensing element against a mechanical spring. Tension on the spring may be adjusted by a technician, which means the trip point of this switch is adjustable.

One of the settings on this switch is the *deadband* or *differential* pressure setting, seen in the lower window. This setting determines the amount of pressure change required to re-set the switch to its normal state after it has tripped. For example, a high-pressure switch with a trip point of 67 PSI (changes state at 67 PSI, increasing) that re-sets back to its normal state at a pressure of 63 PSI decreasing has a “deadband” or “differential” pressure setting of 4 PSI ( $67 \text{ PSI} - 63 \text{ PSI} = 4 \text{ PSI}$ ).

The “differential” pressure setting of a gauge pressure switch is not to be confused with a true *differential pressure* switch. In the next photograph, we see a pressure switch truly actuated by *differential* pressure (the difference in fluid pressure sensed between two ports):

The electrical switch element is located underneath the blue cover, while the diaphragm pressure element is located within the grey metal housing. The net force exerted on the diaphragm by the two fluid pressures varies in magnitude and direction with the magnitude of those pressures. If the two fluid pressures are precisely equal, the diaphragm experiences no net force (zero differential pressure).

Like the Danfoss gauge pressure switch seen previously, this differential pressure switch has a “trip” or “limit” setting as well as a “dead-band” or “differential” setting. It is important to recognize and clearly distinguish the two meanings of *differential pressure* in the context of this device. It senses differences in pressure between two input ports (“differential pressure” – the difference between two different fluid pressure connections), but being a switch, it also exhibits some dead band in its action (“differential pressure” – a change in pressure required to re-set the switch’s state).

## 9.6 Level switches

A *level switch* is one detecting the level of liquid or solid (granules or powder) in a vessel. Level switches often use floats as the level-sensing element, the motion of which actuates one or more switch contacts.

Recall from section 9.1 that the “normal” status of a switch is the resting condition of *no stimulation*. A level switch will be in its “normal” status when it senses minimum level (e.g. an empty vessel). For a level switch, “normal” status is any fluid level *below* the trip threshold of the switch.

### *Level switch symbols*

### 9.6.1 Float-type level switches

Some level switches use a *float* to sense the level of a liquid surface, actuating an electrical switch by the motion of the float. The electrical schematic symbol for a level switch is actually based on this type of mechanism, with a round “ball” float drawn as the actuating element:

#### *Level switch symbols*

An example of this technology is a level switch manufactured by Magnetrol, with two such switches shown in the following photograph of a steam boiler. These switches sense water level in the steam drum of the boiler:

The Magnetrol float switch mechanism uses a mercury tilt bulb, tilted by a magnet's attraction to a steel rod lifted into position by a float. The float directly senses liquid level, positioning the steel rod either closer to or farther away from the magnet. If the rod comes close enough to the magnet, the mercury bottle tilts to change the switch's electrical status:

A feature of this design is complete isolation between the electrical components and the “wet” components sensing the liquid level. The steel rod moves inside a non-magnetic metal tube, with the tube sealing process fluid pressure from escape while still allowing the magnetic tilt switch to sense float position.

Simpler float switch designs also exist for direct installation in open (vented) process vessels, resembling the float valve assembly on a water-flush toilet. Any “limit” style switching element will work here, including inductive proximity switches, to sense the float's position in an environment where no isolation need exist between the switch and the process fluid(s):

### 9.6.2 Tuning fork level switches

This level switch uses a metal *tuning fork* structure to detect the presence of a liquid or solid (powder or granules) in a vessel:

An electronic circuit continuously excites the tuning fork, causing it to mechanically vibrate. When the prongs of the fork contact anything with substantial mass, the resonant frequency of the fork decreases. The circuit detects this frequency change and indicates the presence of mass contacting the fork. The forks' vibrating motion tends to shake off any accumulated material, such that this style of level switch tends to be resistant to fouling.

It should be noted that the previous photograph of the tuning-fork style level switch is complete: the fork "paddles" are only a couple of inches long and require no physical extensions in order to properly detect liquid or solid material at that point.

### 9.6.3 Paddle-wheel level switches

A more primitive variation on the theme of a “tuning fork” level switch is the *rotating paddle* switch, used to detect the level of powder or granular solid material. This level switch uses an electric motor to slowly rotate a metal paddle inside the process vessel. If solid material rises to the level of the paddle, the material’s bulk will place a mechanical load on the paddle. A torque-sensitive switch mechanically linked to the motor actuates when enough torsional effort is detected on the part of the motor. A great many level switches of this design sold in the United States under the trade-name *Bindicator* (so-called because they detected the level of solid material in storage *bins*).

A “Bindicator” style of level switch appears in this photograph (painted black, against a white-painted hopper), used to detect the presence of soda ash powder in a hopper at a water treatment plant:

#### 9.6.4 Ultrasonic level switches

Yet another style of electronic level switch uses ultrasonic sound waves to detect the presence of process material (either solid or liquid) at one point:

Sound waves pass back and forth within the gap of the probe, sent and received by piezoelectric transducers. The presence of any substance other than gas within that gap affects the received audio power, thus signaling to the electronic circuit within the bulkier portion of the device that process level has reached the detection point. The lack of moving parts makes this probe quite reliable, although it may become “fooled” by heavy fouling.

### 9.6.5 Capacitive level switches

Another electronic liquid level switch technology is *capacitive*: sensing level by changes in electrical capacitance between the switch and the liquid. The following photograph shows a couple of capacitive switches sensing the presence of water in a plastic storage vessel:

### 9.6.6 Conductive level switches

Perhaps the simplest (and oldest) form of electrical level detection is where a pair of metal electrodes contacts the process material to form a complete electrical circuit, actuating a relay. This type of switch, of course, only works with granular solids and liquids that are electrically conductive (e.g. potable or dirty water, acids, caustics, food liquids, coal, metal powders) and not with non-conducting materials (e.g. ultra-pure water, oils, ceramic powders).

A legacy design for conductive level switches is the model 1500 “induction relay” originally manufactured by B/W Controls, using a special transformer/relay to generate an isolated AC probe voltage and sense the presence of liquid:

Line voltage (120 VAC) energizes the primary coil, sending a magnetic field through the laminated ferrous<sup>6</sup> core of the relay. This magnetic field easily passes through the center of the secondary coil when the secondary circuit is open (no liquid closing the probe circuit), thus completing the magnetic “circuit” in the core. With the magnetic circuit thus completed, the armature will not be attracted to the core. However, when a circuit is completed by liquid level rising to contact both probes, the secondary coil’s resulting current “bucks” the magnetic flux<sup>7</sup> through its center, causing more

<sup>6</sup> “Ferrous” simply means any iron-containing substance.

<sup>7</sup> The reason for this opposition is rooted in the roles of primary and secondary coils as power *load* and *source*, respectively. The voltage across each coil is a function of Faraday’s Law of Electromagnetic Induction:  $V = N \frac{d\phi}{dt}$ . However, since the primary coil acts as a load (drawing power from the 120 VAC source) and the secondary coil acts as a source (sending power to the probes), the directions of current through the two coils will be opposite despite their common voltage polarities. The secondary coil’s opposite current direction causes an opposing magnetic force in that section of the core, reducing the magnetic flux there. In a normal power transformer, this reduction in magnetic

magnetic flux to bypass to the end poles where it attracts the ferrous armature toward the core frame. This physical attraction actuates switch contacts which then signal the presence of liquid level at the probes.

The following pair of illustrations shows the two conditions of this level switch, with the magnetic lines of flux highlighted as dashed lines through the core:

The “transformer” design of this particular conductive level switch not only provides electrical isolation between the probes and the energizing (120 VAC) circuit, but it also enables a wide range of detection voltages to be generated for the probes just by altering the number of wire “turns” in the secondary coil. The B/W Controls model 1500 inductive relay is available in a variety of AC voltage output levels, ranging from 12 VAC (for detecting metallic substances) to 800 VAC for use with demineralized water such as that found in steam boiler systems.

More modern variations on the same design theme use much lower AC voltages<sup>8</sup> to energize the probes, employing sensitive semiconductor amplifier circuits to detect probe current and signal liquid level.

flux caused by secondary current is also felt by the primary coil (since there is only one magnetic “path” in a power transformer’s core), which then causes the primary coil to draw more current and re-establish the core flux at its original magnitude. With the inductive relay, however, the opposing magnetic force created by the secondary coil simply forces more of the primary coil’s magnetic flux to bypass to the alternate route: through the armature.

<sup>8</sup>The B/W Controls model 5200 solid-state relay, for example, uses only 8 volts AC at the probe tips.

## 9.7 Temperature switches

A *temperature switch* is one detecting the temperature of some substance. Temperature switches often use bimetallic strips as the temperature-sensing element, the motion of which actuates one or more switch contacts. An alternative design uses a metal bulb filled with a fluid that expands with temperature, causing the switch mechanism to actuate based on the pressure this fluid exerts against a diaphragm or bellows. This latter temperature switch design is really a pressure switch, whose pressure is a direct function of process temperature by virtue of the physics of the entrapped fluid inside the sensing bulb.

Recall from section 9.1 that the “normal” status of a switch is the resting condition of *no stimulation*. A temperature switch will be in its “normal” status when it senses minimum temperature (i.e. cold, in some cases a condition colder than ambient)<sup>9</sup>. For a temperature switch, “normal” status is any sensed temperature *below* the trip threshold of the switch.

### *Temperature switch symbols*

---

<sup>9</sup>If the trip setting of a temperature switch is below ambient temperature, then it will be “actuated” at ambient temperature and in its “normal” status only when the temperature falls below that trip point (i.e. colder than ambient).

The following photograph shows a temperature-actuated switch manufactured by the Ashcroft corporation:

Like all other process switches, temperature switches exhibit a certain amount of *deadband* in their switching action. A temperature switch that trips at 300 °F *rising*, for example, will not re-set at 300 °F *falling*. That switch would more likely reset at some lower temperature such as 295 °F. With mechanical switch designs, some amount of deadband is inevitable due to friction inside the mechanism. However, process switch deadband is actually a useful characteristic as it helps avoid repeated “nuisance” alarms from happening.

To understand this concept, it is helpful to imagine a scenario where the process variable is at or very near the trip point. For our hypothetical temperature switch with a trip point of 300 °F (rising), imagine a situation where the process temperature is precisely 300.0 °F. Any further rise in temperature will of course trip the switch (sounding an alarm). With no deadband, however, the switch will immediately re-set when the temperature falls back down to 300.0 °F. This means the switch may possibly “cycle” back and forth between its trip and reset states with just a minute change in process temperature (300.0 °F to 300.1 °F and back again). If the temperature switch is activating an alarm every time it trips, it will create a series of alarm events prompting operators to repeatedly acknowledge the alarm. This is a nuisance to operations personnel, as it distracts them

from addressing what they already realize is a process problem. It is better for the switch to trip at 300.0 °F rising *and remain in that tripped state* until the temperature falls down to some degree substantially below the trip point. This way, the operators only receive *one* alarm event rather than multiple alarm events for each process temperature excursion.

Some mechanical temperature switches come equipped with a separate adjustment for deadband (also called *differential*). Setting this deadband adjustment in a mechanical temperature switch requires the technician to repeatedly subject the sensing element to a rising and falling temperature, to check that the switch trips at the proper setting and resets at the proper setting. This is analogous to cycling the process variable back and forth when adjusting the “zero” and “span” settings of an analog transmitter: checking to see that the transmitter repeatedly outputs a 0% signal at the lower range value (LRV) and a 100% signal at the upper range value (URV).

For discrete temperature-sensing applications demanding high accuracy and repeatability, *electronic* temperature switch circuits using thermocouples, RTDs, or thermistors may be used instead of a mechanical (bi-metallic or filled bulb) sensing element. The operation and configuration of discrete electronic temperature switches is very similar to that of continuous electronic temperature transmitters.

An example of an electronic temperature switch module is the Moore Industries model SPA (“Site Programmable Alarm”), shown here:

Not only is this particular model capable of directly interpreting both RTD and thermocouple signals, but it will also input 4-20 mA loop current signals as well. This means you may build a temperature switch system out of a 4-20 mA loop-powered temperature transmitter (located in the field) and an SPA switch module (located in a protected environment such as a control room or electrical enclosure). Many other manufacturers and models of electronic switching units exist, with the Moore Industries SPA being just one example.

With electronic temperature switches, the adjustment of deadband (differential) is both precise and flexible. Unlike mechanical switches where deadband is primarily a function of friction, and therefore liable to change over time as the device wears, electronic switching circuits may be precisely set for any trip and reset points along its measurement range, remaining very stable over time.

## 9.8 Flow switches

A *flow switch* is one detecting the flow of some fluid through a pipe. Flow switches often use “paddles” as the flow-sensing element, the motion of which actuates one or more switch contacts.

Recall from section 9.1 that the “normal” status of a switch is the resting condition of *no stimulation*. A flow switch will be in its “normal” status when it senses minimum flow (i.e. no fluid moving through the pipe). For a flow switch, “normal” status is any fluid flow rate *below* the trip threshold of the switch.

### *Flow switch symbols*

## 9.9 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader's view of this chapter's concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **“Normal” switch status:** the “normal” status of a switch contact as defined by the manufacturer is its *resting* condition (minimum stimulus).
- **Sourcing versus sinking:** whether the electronic device in question is outputting (conventional flow) current or inputting current. Relevant to the proper connection of electronic switches (especially proximity switches).
- **Deadband and hysteresis:** the difference in response with the independent variable increasing versus decreasing. Usually caused by friction in a mechanism. Relevant to the “trip” settings of process switches: the value at which a switch changes state when its stimulus increases is not the same value it changes state when its stimulus decreases.

## Chapter 10

# Discrete control elements

The word “discrete” means *individual* or *distinct*. In engineering, a “discrete” variable or measurement refers to a true-or-false condition. Thus, a discrete control element is one that has but a limited number of states (usually two: on and off). In the case of valves, this means a valve designed to operate either in “open” mode or “closed” mode, not in-between.

## 10.1 On/off valves

An on/off valve is the fluid equivalent of an electrical switch: a device that either allows unimpeded flow or acts to prevent flow altogether. These valves are often used for routing process fluid to different locations, starting and stopping batch processes, and engaging automated safety (shutdown) functions.

Valve styles commonly used for on/off service include ball, plug, butterfly (or disk), gate, and globe. Large on/off valves are generally of such a design that the full-open position provides a nearly unimpeded path for fluid to travel through. Ball, plug<sup>1</sup>, and gate valves provide just this characteristic:

<sup>1</sup>A *plug* valve is very much like a ball valve, the difference being the shape of the rotating element. Rather than a spherical ball, the plug valve uses a truncated cone as the rotary element, a slot cut through the cone serving as the passageway for fluid. The conical shape of a plug valve's rotating element allows it to wedge tightly into the "closed" (shut) position for exceptional sealing.

A series of photographs showing a cut-away ball valve (hand-actuated) in three different positions reveals the inner workings common to all ball valve mechanisms:

The left-hand image shows the valve in the shut position, with the bore axis facing the viewer (preventing fluid flow). The right-hand image shows the valve in the open position, with the bore axis perpendicular to view and allowing flow. The middle image shows the valve in a partially-open condition.

## 10.2 Fluid power systems

Given the ability of pressurized fluids to transmit force over long distances, it is not surprising that many practical “fluid power systems” have been built using fluid as a mechanical power-conducting media. Fluid systems may be broadly grouped into *pneumatic* (gas, usually air) and *hydraulic* (liquid, usually oil<sup>2</sup>).

Although there is no particular reason why a fluid power system must be discrete and not continuous, the majority of fluid power systems operate in an on/off control mode rather than throttling, which is why this subject is covered in the “Discrete Control Elements” chapter.

As usual for technical specialties, fluid power has its own unique symbology for describing various components and their interconnections. The following diagram shows some common symbols used in fluid power system diagrams. Lines connecting components together in a fluid power diagram indicate pipes, hoses, or tubes, much like lines connecting components together in an electronic schematic diagram represent wires:

<sup>2</sup>While it would be technically possible to use water instead of oil in a hydraulic power system, oil enjoys some distinct advantages. First, oil is a lubricating substance, and non-corrosive, unlike water. Second, oil enjoys a wider operating temperature range than water, which tends to both freeze and boil more readily.

Many of these symbols are self-explanatory, especially the pumps, motors, and cylinders. What seems to cause the most confusion for people new to this symbology are the spool valve symbols. A “spool” valve is a special type of flow-directing valve used in pneumatic and hydraulic systems to direct the pressurized fluid to different locations. The symbology for a spool valve is a set of boxes, each box containing arrows or other symbols showing the intended direction(s) for the fluid’s travel. Take for instance this pneumatic reversing cylinder control system:

The proper way to interpret a spool valve symbol is to see only one “box” active at any given time. As the actuator (in this case, a hand-actuated lever) is moved one way or the other, the boxes “shift” laterally to redirect the flow of fluid from source to load.

For example, when the spool valve in this reversing control system is in its center position, the outer boxes in the symbol are inactive. This is emphasized in the following diagram by coloring the outer boxes grey. In this position, the spool valve neither admits compressed air to the cylinder nor vents any air from the cylinder. As a result, the piston within the cylinder holds its position:

If the spool valve is actuated in one direction, the spool piece inside the valve assembly shifts, directing compressed air to one side of the cylinder while venting air from the other side. This is shown in the following diagram by shifting the boxes to one side, lining up the “active” box with the cylinder and air supply/vent connections:

If the spool valve is actuated in the other direction, the spool piece inside the valve assembly shifts again, switching the directions of air flow to and from the cylinder. Compressed air still flows from the supply to the vent, but the direction within the cylinder is reversed. This causes the piston to reverse its mechanical travel:

Note that the boxes in a spool valve symbol are never shifted or grayed-out in color like this to represent the valve’s state in a real fluid power diagram. The previous illustrations were drawn this way only as an aid to your understanding, teaching you how to interpret the meaning of the symbols when you see them in real fluid power diagrams. Like electrical switches represented in schematic diagrams, spool valve symbols are always drawn with the boxes aligned in their “resting” states, and with all portions identically colored.

Hydraulic systems require more components, including filters and pressure regulators, to ensure proper operation. Shown here is a simple uni-directional hydraulic motor control system:

Note the placement of the pressure relief valve: it is a *shunt* regulator, bleeding excess pressure from the discharge of the hydraulic pump back to the reservoir<sup>3</sup>. A “shunt” regulator is necessary because hydraulic pumps are *positive displacement*, meaning they discharge a fixed volume of fluid with every revolution of the shaft. If the discharge of a positive-displacement pump is blocked (as it would be if the spool valve were placed in its default “off” position, with no shunt regulator to bleed pressure back to the reservoir), it will mechanically “lock” and refuse to turn. This would overload the electric motor coupled to the pump, if not for the pressure regulating valve providing an alternative route for oil to flow back to the reservoir. This shunt regulator allows the pump to discharge a fixed rate of oil flow (for a constant electric motor speed) under all hydraulic operating conditions.

<sup>3</sup>Note also how identical reservoir symbols may be placed at different locations of the diagram although they represent the exact same reservoir. This is analogous to “ground” symbols in electronic schematic diagrams, every ground symbol representing a common connection to the same zero-potential point.

An alternative to using a shunt regulating valve in a hydraulic system is to use a *variable-displacement pump*. Variable-displacement pumps still output a certain volume of hydraulic oil per shaft revolution, but that volumetric quantity may be varied by moving a component within the pump. In other words, the pump's per-revolution displacement of oil may be externally adjusted.

If we connect the variable-displacement mechanism of such a hydraulic pump to a pressure-sensing element such as a bellows, in a way where the pump senses its own discharge pressure and adjusts its volumetric output accordingly, we will have a pressure-regulating hydraulic system that not only prevents the pump from “locking” when the spool valve turns off, but also saves energy by not circulating pressurized oil all the time:

Note the placement of a filter at the inlet of the pump in all hydraulic systems. Filtration is an absolute essential for any hydraulic system, given the extremely tight dimensional tolerances of components inside pumps, motors, spool valves, and cylinders. Even very small concentrations of particulate impurities in the hydraulic fluid may drastically shorten the life of these precision-machined components.

Hydraulic fluid also acts as a heat-transfer medium, and as such must be kept cool enough to prevent thermal damage to components. Large hydraulic systems are equipped with coolers, which are just heat exchangers designed to extract heat energy from the fluid and transfer it to either cooling water or ambient air. Small hydraulic systems dissipate heat at a fast enough rate through their components that coolers are often unnecessary.

An interior view of a simple “2-way” spool valve such as that used in the hydraulic motor system previously examined reveals why cleanliness and temperature stability is important. The spool valve is shown here in both positions, with its accompanying schematic symbol:

Both the spool and the valve body it moves in are circular in cross-section. The spool has wide areas called “lands” that act to cover and uncover ports in the valve body for fluid to flow through. The precise fit between the outside diameter of the lands and the inside diameter of the valve body’s bore is the only factor limiting leakage through this spool valve in the closed state. Dirty hydraulic fluid will wear at this precise fit over time until the valve is no longer capable of sealing fluid in its “closed” position. Extreme cycles in temperature will also compromise the precise fit between the spool and the valve body.

Pneumatic fluid power systems require cleanliness as well, since any particulate contamination in the air will likewise cause undue wear in the close-tolerance compressors, motors, valves, and cylinders. Unlike hydraulic oil, compressed air is not a natural lubricant, which means many pneumatic power devices benefit from a small concentration of oil vapor in the air. Pneumatic “oilers” designed to introduce lubricating oil into a flowing air stream are generally located very near the point of use (e.g. the motor or the cylinder) to ensure the oil does not condense and “settle” in the air piping.

Fluid power systems in general tend to be inefficient, requiring much more energy input to the fluid than what is extracted at the points of use<sup>4</sup>. When large amounts of energy need to be transmitted over long distances, electricity is the a more practical medium for the task. However, fluid power systems enjoy certain advantages over electric power, a few of which are listed here:

- Fluid power motors and cylinders do not overload at low speeds or under locked conditions
- Fluid power systems present little hazard of accidentally igniting flammable atmospheres (i.e. no sparks produced)
- Fluid power systems present little or no fire hazard<sup>5</sup>
- Fluid power systems present no hazard of electric shock or arc flash
- Fluid power systems are often easier to understand and troubleshoot than electric systems
- Fluid power systems may be safely used in submerged (underwater) environments
- Pneumatic systems are relatively easy to equip with back-up energy reserve (e.g. liquefied nitrogen serving as a back-up gas supply in the event of compressor shut-down)
- Pneumatic systems are self-purging (i.e. enclosures housing pneumatic devices will be naturally purged of dusts and vapors by leaking air)

Another important consideration for fluid power systems is the ongoing maintenance work they require for reliable operation. Hydraulic power systems will suffer rapid wear if the hydraulic oil is not clean and chemically stable. The fluid in a hydraulic system not only transmits mechanical power, but it also lubricates and stabilizes the temperature of components as they transfer that power between different forms. Regular filter changes and oil changes (especially if the fluid is subject to contamination from the process) is necessary for long service life of any hydraulic system.

Pneumatic (instrument air) systems must be free of water vapor and particulate contamination for much the same reason. Water is perhaps the most common contaminant in instrument air systems, causing corrosion of metal components and subsequent clogging of orifices. Special devices called *air dryers* installed in instrument air systems use solid materials called *desiccants* to absorb water entrained in the compressed air. The desiccant material is “regenerated” by the dryer mechanism on a regular cycle, but must be periodically replaced when its water-absorbing ability wanes.

---

<sup>4</sup>Close-coupled hydraulic systems with variable-displacement pumps and/or motors may achieve high efficiency, but they are the exception rather than the rule. One such system I have seen was used to couple a diesel engine to the drive axle of a large commercial truck, using a variable-displacement pump as a continuously-variable transmission to keep the diesel engine in its optimum speed range. The system was so efficient, it did not require a cooler for the hydraulic oil!

<sup>5</sup>Many kinds of hydraulic oils are flammable, so this is not a perfectly true statement. However, fire-resistant fluids such as *Skydrol* (introduced to the aviation industry for safety) are commercially available.

This next photograph shows a high-capacity industrial air dryer, with two large chambers holding desiccant:

A valving system directs the main flow of compressed air through one of these desiccant chambers at a time, allowing the desiccant to absorb water vapor in the air. Meanwhile, the unused chamber is purged of its collected water by venting low-pressure air through it to the atmosphere. An electronic timer unit (or PLC) controls the cycling of this valve system to ensure adequate drying and maximized desiccant service life.

Moisture content in instrument air is often expressed by the term *dew point*. This is the temperature at which water vapor suspended in the instrument air will condense into water droplets, at atmospheric pressure. The “drier” the air, the lower the dew point temperature; the “wetter” the air, the higher the dew point temperature. Sometimes the “dryness” of instrument air is expressed in terms of *pressure dew point* (PDP), which is the temperature of water condensation at system pressure rather than at atmospheric pressure. Pressure dew point is always a higher temperature value than atmospheric dew point, since greater air pressures force condensation to occur more readily. Pressure dew point is a more practical value than atmospheric dew point for an instrument air system, as PDP directly indicates the ambient temperature at which water will condense in an *operating* pneumatic system. A low dew point value means that the air dryer is working as it should. A high dew point value means condensation is more likely to form in the compressed air system piping.

A simple way to help extract water from an instrument air system is an accessory called a *water trap*, usually found on air pressure regulators. The following photograph shows a Fisher pneumatic regulator equipped with such a trap on the bottom:

A shiny metal “wingnut” drain appears at the very bottom of the regulator, acting as a manual valve for purging collected water from the basin where compressed air enters the regulator mechanism. Periodic opening of this drain valve by maintenance or operations personnel allows collected water to be blown out of the regulator.

Another way to help minimize the amount of water reaching pneumatic devices is to properly orient all connections to the main air pipe (called a *header*). Ideally, each instrument air tap coming off a header should do so on the *top* of the header, not the bottom. This way, collected condensation inside the header will not go directly to the points of use, but rather will drain downhill to the lowest point in the header where a drain valve may be placed.

This next photograph shows an *incorrect* installation, where air is drawn off the bottom of the main header line:

Such an installation invites trouble, as every bit of water condensed inside the header pipe is *guaranteed* to find its way by gravity to the instruments connected to the underside of that header.

One good feature of this installation is the use of stainless steel as the piping material. Copper, brass, plastic<sup>6</sup>, and stainless steel are the preferred materials for instrument air piping, tubing, valves, and fittings, as standard (iron) pipe will inevitably rust in the presence of condensation. Particles of rust created inside an instrument air system plays havoc with the tiny ports, nozzles, and orifices of pneumatic instruments.

---

<sup>6</sup>Certain types of plastic pipe such as PVC should never be used in compressed air systems because it becomes brittle and liable to fracture over time. If you are considering the use of plastic for a high-pressure compressed air system, be sure the type of plastic is engineered for air pressure service!

The proper way to make instrument air connections to the air header is as such:

In order to facilitate draining of the header, the header should be slightly inclined, with the drain valve installed at the lowest point. This drain valve should then be periodically opened on a regular maintenance schedule in order to prevent the header from slowly filling up with condensed water over time.

### 10.3 Solenoid valves

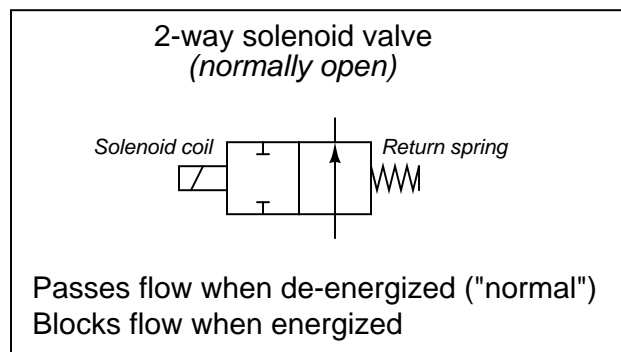

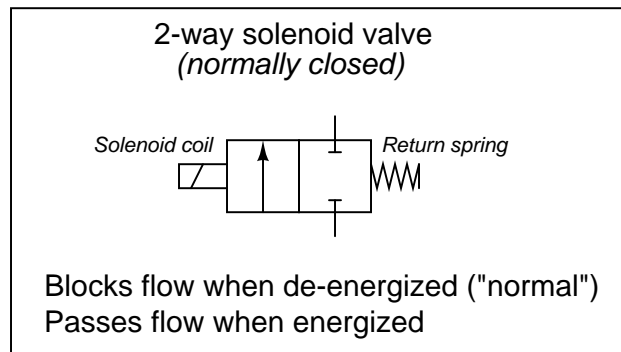

A very common form of on/off valve used for pneumatic and hydraulic systems alike is the *solenoid valve*. A “solenoid” is nothing more than a coil of wire designed to produce a magnetic field when energized. Solenoid actuators work by attracting a movable ferrous *armature* into the center of the solenoid coil when energized, the force of this attraction working to actuate a small valve mechanism.

Solenoid-actuated valves are usually classified according to the number of ports (“ways”). A simple on/off solenoid valve controlling flow into one port and out of another port is called a *2-way* valve. Another style of solenoid valve, where flow is directed in one path or to another path – much like a single-pole double-throw (SPDT) electrical switch – is called a *3-way* valve because it has three fluid ports.

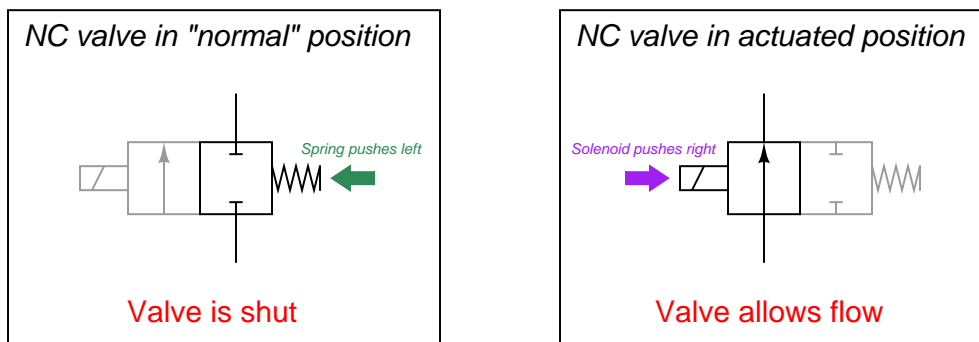

### 10.3.1 2-way solenoid valves

2-way solenoid valves operate in a manner analogous to single-pole single-throw (SPST) electrical switches: with only one path for flow.

Solenoid valve symbols often appear identical to fluid power valve symbols, with “boxes” representing flow paths and directions between ports in each of the valve’s states. Like electrical switches, these valve symbols are always drawn in their “normal” (resting) state, where the return spring’s action determines the valve position:

A good way to make sense of these “box” valve symbols is to imagine the boxes sliding back and forth as the actuating elements work. For example, the two boxes in a normally-closed solenoid valve symbol may be thought of in terms of being *pushed* to the left by the spring when de-energized and *pushed* to the right by the solenoid’s force when energized. Here, the color grey de-emphasizes the unselected box in each of the valve’s two states:

As with electrical switches in schematic diagrams, fluid control valve symbols are always drawn in their “normal” (resting) states. For example, a normally-closed valve will always be drawn so that the box with the blocked ports aligns with the tubes leading to and from the valve. What you see in the above illustration are “dramatized” symbols, highlighting the valve’s action by color and by re-positioning the boxes, strictly for the purpose of making it easier for you to grasp the concept. This sort of coloring and re-positioning is *never* shown in a real schematic diagram. In a fluid control schematic, it is left to the reader to visualize the valve symbol boxes moving to and fro, determining the flow path of fluid through the valve.

Unlike electrical switches, of course, the terms *open* and *closed* have opposite meanings for valves. An “open” electrical switch constitutes a break in the circuit, ensuring no current; an “open” valve, by contrast, freely allows fluid flow through it. A “closed” electrical switch has continuity, allowing current through it; a “closed” valve, on the other hand, shuts off fluid flow.

The arrow inside a solenoid valve symbol actually denotes a preferred direction of flow. Most solenoid valves use a “globe” or “poppet” style of valve element, where a metal plug covers up a hole (called the “seat”). Process fluid pressure should be applied to the valve in such a way that the pressure difference tends to hold the solenoid valve in its “normal” position (the same position as driven by the return spring). Otherwise<sup>7</sup>, enough fluid pressure might override the return spring’s action, preventing the valve from achieving its “normal” state when de-energized. Thus, we see that the label “2-way” does not refer to two directions of flow as one might assume, but rather two *ports* on the valve for fluid to travel through.

Some solenoid valves are designed in such a way that the direction of fluid flow through them is irrelevant. In such valves, the arrow symbols will be double-headed (one head at each end, pointing in opposite directions) to show the possibility of flow in either direction.

#### *Bidirectional solenoid valve*

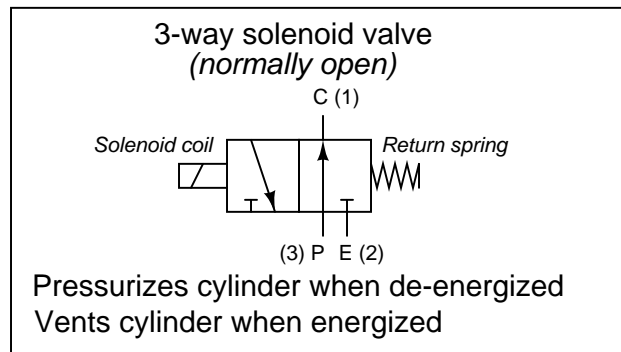

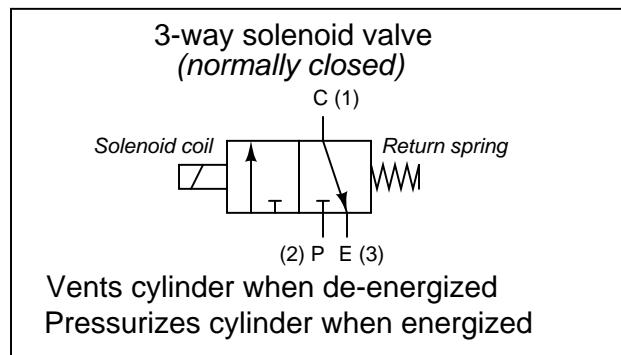

---

<sup>7</sup>One could argue that enough fluid pressure could override the solenoid’s energized state as well, so why choose to have the fluid pressure act in the direction of helping the return spring? The answer to this (very good) question is that the solenoid’s energized force greatly exceeds that of the return spring. This is immediately obvious on first inspection, as the solenoid *must* be stronger than the return spring or else the solenoid valve would never actuate! Furthermore, the solenoid’s force must be *significantly* stronger than the spring, or else the valve would open rather slowly. Fast valve action demands a solenoid force that greatly exceeds spring force. Realizing this, now, we see that the spring is the weaker of the two forces, and thus it makes perfect sense why we should use the valve in such a way that the process pressure helps the spring: the solenoid’s force has the best chance of overcoming the force on the plug produced by process pressure, so those two forces should be placed in opposition, while the return spring’s force should work *with* (not against) the process pressure.

### 10.3.2 3-way solenoid valves

3-way solenoid valves operate in a manner analogous to single-pole double-throw (SPDT) electrical switches: with two paths for flow sharing one common terminal.

3-way solenoid valves have three ports for fluid, and like 2-way valves may be referred to either as *normally-open* and *normally-closed*. Ports on a pneumatic 3-way valve are commonly labeled with the letters “P,” “E,” and “C,” representing *Pressure* (compressed air supply), *Exhaust* (vent to atmosphere), and *Cylinder* (the actuating mechanism), respectively. Alternatively, you may see the cylinder port labeled “A” (for *actuator*) instead of “C”. If the solenoid valve is intended for use in a hydraulic (liquid) system, the letter “T” is customarily used to identify the return port rather than “E” (i.e. *Tank* rather than *Exhaust*):

The letters used to label ports on a valve such as this not only denote those ports’ destinations, but also serve to mark which “box” of the valve’s symbol is the normal (resting) state. In all fluid power diagrams you will see that only one of the boxes on each spool valve will have lines connecting to it and/or labels at the fluid ports, and that box is the one which will be aligned when the valve is not being actuated.

Alternatively, the numbers 1, 2, and 3 may be used to label the same ports. However, the numbers do not consistently refer to pressure source (P) and exhaust (E) ports, but rather to the 3-way valve's “normal” versus “actuated” statuses. A 3-way valve will pass fluid between ports 1 and 3 in its “normal” (resting) state, and pass fluid between ports 1 and 2 in its energized state. The following table shows the correspondence between port numbers and port letters for both styles of 3-way solenoid valve:

Valve type	Pressure port (P)	Exhaust port (E)	Cylinder port (C)
Normally-closed	2	3	1
Normally-open	3	2	1

Another way to think of this labeling is to consider port 1 the *common*, port 2 the *normally-closed*, and port 3 the *normally-open*, in a manner similar to SPDT (form-C) electrical switches. Again, bear in mind that the words “open” and “closed” do not mean the same for fluid valves as they do for electrical switches. A “normally-open” port on the valve permits fluid flow in its “normal” state, whereas a “normally-open” switch contact *prevents* electric current flow in its “normal” state.

As with 2-way solenoid valves, the arrows denote preferred direction of fluid flow. Bidirectional 3-way valves will be drawn with double-headed arrows (pointing both directions).

A different symbology is used in loop diagrams and P&IDs than that found in fluid power diagrams – one more resembling general instrumentation (ISA) valve symbols:

2-way solenoid valve

3-way solenoid valve

Regrettably, these symbols are not nearly as descriptive as those used in fluid power diagrams. In order to show directions of flow (especially for 3-way valves), one must add arrows showing “normal” (resting, *DE*) flow directions:

3-way solenoid valve  
(normally-closed)3-way solenoid valve  
(normally-open)

Alternatively, a *pair* of arrows shows the directions of flow in both energized ( $E$ ) and de-energized ( $D$ ) states:

3-way solenoid valve  
(normally-closed)

3-way solenoid valve  
(normally-open)

Photographs of an actual 3-way solenoid valve (this one manufactured by ASCO) appear here:

A view of the nameplate for this particular solenoid valve reveals some of its ratings and characteristics:

### 10.3.3 4-way solenoid valves

When a pneumatic actuator requires air pressure applied to two different ports in order to move two different directions (such as the case for cylinders lacking a return spring), the solenoid valve supplying air to that actuator must have four ports: one for air supply (P), one for exhaust (E), and two for the cylinder ports (typically labeled A and B). The following diagram shows a 4-way solenoid valve connected to the piston actuator of a larger (process) ball valve:

The same diagram could be drawn using the “triangle” solenoid valve symbols rather than the “block” symbols more common to fluid power diagrams:

Here, the letters “D” and “E” specify which directions air is allowed to flow when the solenoid is de-energized and energized, respectively.

In both of the examples shown above, the solenoid valve forces the piston-actuated valve stem to move down (shut off) when the solenoid is de-energized. When the solenoid is energized, air is directed to the bottom of the piston (with the top of the piston becoming vented to atmosphere), causing the piston-actuated valve stem to move up (open wide).

An interior view of a standard spool-type 4-way valve of the kind commonly used for directional hydraulic<sup>8</sup> controls is shown here, along with its accompanying schematic symbol:

Cut-away illustration

Schematic symbol

Note that the actuator (e.g. hand lever, solenoid armature, etc.) has been omitted from this illustration for simplicity. Only the spool and valve body are shown.

<sup>8</sup>In hydraulics, it is common to use the letter “T” to represent the *tank* or *reservoir* return connection rather than the letter “E” for *exhaust*, which is why the supply and vent lines on this valve are labeled “P” and “T”, respectively.

A variation on this theme uses a shorter spool allowing the two control ports to freely pass fluid in the “normal” position:

*Cut-away illustration*

*Schematic symbol*

Such a 4-way valve is useful for applications where the final control element (motor, cylinder) must be free to move rather than be locked in place with the valve in the middle position.

If no center “off” position is needed, the lands may be shortened in such a way that they cannot fully cover the “P,” “1,” and “2” ports simultaneously, making the valve useful only in its two extreme positions:

*Cut-away illustration**Schematic symbol*

Not all 4-way valves use the spool-type design. However, the spool valve enjoys the advantage of having *pressure balance* on its one moving part. If you examine these cut-away illustrations closely, you will see that the two lands present equal surface areas to the two pressures (pump and tank, “P” and “T”) in perfect vertical symmetry, such that any forces acting on the two lands from fluid pressure do so in opposite directions. This means there will be no net hydraulic force acting on the spool to interfere with its positioning, thus making it very easy to position by hand lever, solenoid, piston, etc.

A photograph of a Parker brand 4-way pneumatic solenoid valve appears here:

This particular solenoid valve is spring-centered, with one solenoid coil at each end to provide actuation in two different directions. The middle position is one where all ports are blocked, providing a “locked” control position for the pneumatic actuating element fed air by this solenoid valve.

### 10.3.4 Normal energization states

Solenoid valves may be used in such a way that they spend most of their time de-energized, energizing only for brief periods of time when some special function is required. Alternatively, solenoids may be maintained in an energized state, and de-energized to perform their design function. The choice to use a solenoid's energized or de-energized state to perform a specific function is left to the system designer, but nevertheless it is important for all maintenance personnel to know in order to perform work on a solenoid-controlled system.

Take the following segment of an actual P&ID for a steam turbine-driven pump control system for example, where a pair of 3-way solenoid valves control instrument air pressure<sup>9</sup> to a piston-actuated steam valve to start the turbine in the event that an electric motor-driven pump happens to fail:

If *either*<sup>10</sup> of the two solenoid valves de-energizes, instrument air pressure will vent from the top of the piston actuator to atmosphere, causing the steam valve to “fail” to the full-open position and send steam to the turbine. This much is evident from the curved arrows showing air flowing to the “Vent” ports in a de-energized (DE) condition. An additional valve (PY-590) guarantees the piston actuator’s upward motion by simultaneously applying air pressure to the bottom<sup>11</sup> of the actuator

<sup>9</sup>The letters “IAS” refer to *instrument air supply*.

<sup>10</sup>This solenoid valve arrangement would be designated *1oo2* from the perspective of starting the turbine, since only one out of the two solenoids needs to trip in order to initiate the turbine start-up.

<sup>11</sup>If you examine this diagram closely, you will notice an error in it: it shows the top and bottom of the piston actuator *connected together* by air tubing, which if implemented in real life would prevent air pressure from imparting any force to the valve stem at all! Connecting the top and bottom of the actuator together would ensure the piston always sees zero differential pressure, and thus would never develop a resultant force. The output tube of PY-590

if ever air is vented from the top. As an additional feature, the left-hand solenoid valve (SOV-590A) has a manual “Reset” lever on it, symbolized by the letter “R” inside a diamond outline.

The only indication of the solenoids’ typical status (energized or de-energized) comes from the letters “NE” next to each solenoid coil. In this case, “NE” stands for *normally energized*. Therefore, this steam turbine control system, which serves as a back-up to an electric motor-driven pump, relies on either (or both) of the solenoid valves *de-energizing* to make the turbine start up. Under “normal” conditions, where the turbine is not needed, the solenoids remain energized and the steam valve remains shut.

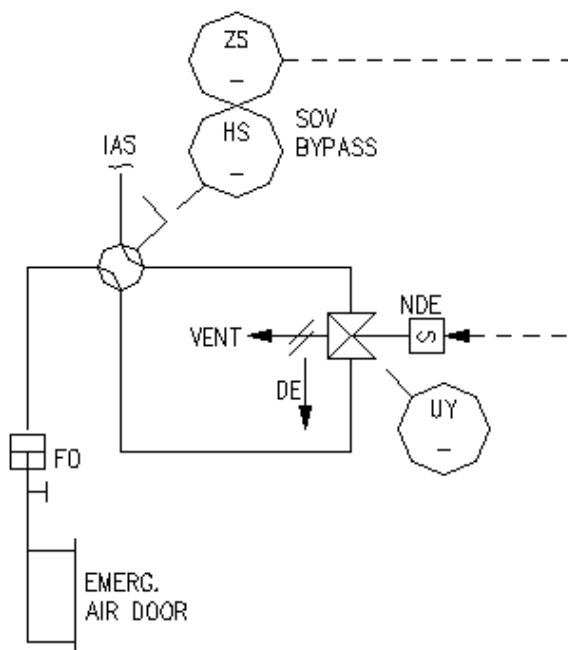

Unfortunately, this use of the word “normal” is altogether different from the use of the word “normal” when describing a solenoid valve’s open/close characteristics. Recall that a *normally open* solenoid valve allows fluid to pass through when it is de-energized. A *normally closed* solenoid valve, by contrast, shuts off fluid flow when de-energized. In this context, the word “normally” refers to the *unpowered* state of the solenoid valve. This is quite similar to how the word “normally” is used to describe switch contact status: a normally-open (NO) electrical switch is open when unactuated (at rest); a normally-closed (NC) electrical switch is closed when unactuated (at rest). In both cases, with solenoid valves and with electrical switches, the word “normally” refers to the resting condition of *no stimulation*.

However, when an engineer designs a solenoid control system and declares a solenoid to be “normally energized,” that engineer is describing the *typical* status of the solenoid valve *as it is intended to function in the process*. This may or may not correspond to the *manufacturer’s* definition of “normally,” since the solenoid manufacturer cannot possibly know which state any of their customers intends to have their solenoid valve typically operate in. To illustrate using the previous steam turbine control system P&ID, those two solenoid valves would be considered *normally closed* by the manufacturer, since their de-energized states block air flow from the “P” port to the “C” port and vent air pressure from the “C” port to the “E” (vent) port. However, the engineer who designed this system wanted both solenoids to be energized whenever the turbine was not needed to run (the “normal” state of the process), and so the engineer labeled both solenoid coils as *normally energized*, which means both solenoids will be actuated to pass air pressure from their “P” ports to their “C” ports (and close off the vent ports) under typical conditions. Here, we see the manufacturer’s definition of “normal” for the solenoid valve body (i.e. the *resting* condition) is precisely opposite that of the process engineer’s definition of “normal” for the solenoid coil (i.e. the typical operating status of the process) in this particular application.

---

should only connect to the bottom of the piston actuator, not to the bottom *and* the top. A more minor error in this diagram snippet is the labeling of SOV-590A: it actually reads “SOV-59DA” if you look closely enough! My first inclination when sampling this real P&ID for inclusion in the book was to correct the errors, but I think an important lesson may be taught by leaving them in: documentation errors are a realistic challenge you will contend with on the job as an instrumentation professional!

The manufacturer's and process engineer's definitions of "normally" are not always in conflict. Take for example this P&ID segment, showing the solenoid control of an air vent door on a large furnace, designed to open up if the forced-draft fan (blowing combustion air into the furnace) happens to stop for any reason:

Here we have a *normally open* solenoid valve, designed by the manufacturer to pass instrument air pressure from the pressure ("P") port to the cylinder ("C") port when de-energized. The straight arrow with the "DE" label next to it reveals this to be the case. Instrument air pressure sent to the air door actuator holds the door shut, meaning the air door will swing open if ever instrument air pressure is vented by the solenoid. For this particular solenoid, this would require an *energized* condition.

The process engineer designing this Emergency Air Door control system chose to let the solenoid be in its de-energized state under typical operating conditions (when the furnace air door should be shut), a fact revealed by the letters "NDE" (normally de-energized) next to the solenoid coil symbol. Therefore, the "normal" process operating condition for this solenoid happens to be de-energized, which makes the manufacturer's definition of "normal" match the engineer's definition of "normal." The solenoid valve should be open (passing air to the door's actuating cylinder) under "normal" operating conditions.

## 10.4 On/off electric motor control circuits

An electric motor is often used as a discrete control element in a control system if driving a pump, conveyor belt, or other machine for the transportation of a process substance. As such, it is important to understand the functioning of motor control circuits.

Of all the available electric motor types, the most common found in industrial applications (by far) is the three-phase AC induction motor. For this reason, this section of the book will focus exclusively on this type of motor as a final control element.

### 10.4.1 AC induction motors

The basic principle of an AC induction motor is that one or more out-of-phase AC (sinusoidal) currents energize sets of electromagnet coils (called *stator* coils or windings) arranged around the circumference of a circle. As these currents alternately energize the coils, a magnetic field is produced which “appears” to rotate around the circle. This *rotating magnetic field* is not unlike the appearance of motion produced by an array of *chaser lights* blinking on and off in sequence: although the bulbs themselves are stationary, the out-of-phase sequence of their on-and-off blinking makes it appear as though a pattern of light “moves” or “chases” along the length of the array<sup>12</sup>. Likewise, the superposition of magnetic fields created by the out-of-phase coils resembles a magnetic field of constant intensity revolving around the circle. The following images show how the magnetic field vector (the red arrow) is generated by a superposition of magnetic poles through one complete cycle (1 revolution), viewing the images from left to right, top to bottom (the same order as you would read words in an English sentence)<sup>13</sup>:

It should come as no surprise that the combined effect of these three-phase currents will be to create a resultant magnetic field vector rotating in a particular direction. After all, this is precisely how three-phase electric power is generated: by spinning a single magnet at the center of three sets of coils offset by 120 degrees. The rotating magnetic field generated by the stator windings of a three-phase motor is merely a reproduction of the rotor’s magnetic field inside the generator supplying the three-phase power!

<sup>12</sup>To view a flip-book animation of this sequence, turn to Appendix A.1 beginning on page 2813.

<sup>13</sup>To view a flip-book animation of this same sequence, turn to Appendix A.2 beginning on page 2840.

If a permanent magnet were placed within the center of this machine on a shaft such that it was free to rotate, the magnet would spin at the exact same speed as the rotating magnetic field. If the magnetic field completes one full revolution in  $\frac{1}{60}$  of a second, the rotating speed of the magnet will be 60 revolutions per second, or 3600 revolutions per minute (3600 RPM). Since the magnet follows in lock-step with the rotating magnetic field, its rotational speed is said to be *synchronous*. We would thus identify this motor as a *synchronous AC motor*.

If an electrically conductive object were placed within the center of this same machine on a shaft such that it was free to rotate, the relative motion between the rotating magnetic field and the conductive object (rotor) would induce electric currents in the conductive object, producing magnetic fields of their own. Lenz's Law tells us that the effect of these induced magnetic fields would be to try to oppose change: in other words, the induced fields react against the rotating magnetic field of the stator coils in such a way as to minimize the relative motion. This means the conductive object would begin to rotate in the same direction as stator's rotating magnetic field, always trying to "catch up" to the rotating magnetic field. However, the conductive rotor could never exactly match the speed of the rotating magnetic field as in the case of a synchronous motor. If the rotor ever did achieve synchronous speed, there would no longer be any relative motion between the rotor and the rotating magnetic field, which means the induction would cease. No induction would mean no electric currents induced in the rotor, which would mean no reactive magnetic field, which would mean no torque to motivate the rotor. Thus, the electrically conductive rotor's speed must always slightly lag ("slip") behind the rotating magnetic field's synchronous speed in order to experience induction and thereby be able to create a torque<sup>14</sup>. We call this type of motor an *induction AC motor*.

It may come as a surprise for some to learn that *any* conductive object – ferromagnetic or not – will experience a torque when placed inside the rotating magnetic field generated by the stator coils. So long as the object is electrically conductive<sup>15</sup>, electromagnetic induction will ensure the creation of electric currents in the rotor, and these currents will produce their own magnetic fields which react against the stator's rotating magnetic field to produce a torque on the rotor.

---

<sup>14</sup>A helpful analogy for this effect is to imagine a sailboat traveling directly downwind, its motive force provided by a sail oriented perpendicular to the direction of travel. It should be obvious that in this configuration the sailboat cannot travel faster than the wind. What is less obvious is the fact that the sailboat can't even travel as fast as the wind, its top speed in this configuration being slightly less than the wind speed. If the sailboat somehow did manage to travel exactly at the wind's speed, the sail would go slack because there would be no relative motion between the sail and the wind, and therefore the sail would cease to provide any motive force. Thus, the sailboat must "slip" or "lag" behind the wind speed just enough to fill the sails with enough force to overcome water friction and maintain speed.

<sup>15</sup>As a vivid illustration of this concept, I once worked at an aluminum foundry where an AC induction motor stator assembly was used to electromagnetically spin molten aluminum inside the mold as it cooled from molten to solid state. Even though aluminum is a non-magnetic material, it was still spun by the stator's rotating magnetic field due to electromagnetic induction and Lenz's Law.

The effect of Lenz's Law between a magnet and a conductive object may be demonstrated by using a powerful permanent magnet and a strip of light-weight aluminum foil. Aluminum, of course, is electrically conductive but non-magnetic. However, despite the lack of magnetic attraction between the magnet and the foil, the foil will nevertheless experience a motive force if the magnet is swept past its surface rapidly, due to Lenz's Law:

**Demonstration of Lenz's Law between a moving magnet and a strip of conductive metal**

This very same principle is what makes an induction AC motor function: a rotating magnetic field induces electric currents in an electrically-conductive rotor, which then spins in the same direction as the magnetic field. An induction motor's rotor can never achieve synchronous speed on its own, for if it ever did the induction would cease due to a lack of relative motion between the rotating magnetic field and the rotor. The same is true of the aluminum foil strip experiments: the foil strip can never fully "catch up" to the moving magnet, for if it ever did the induction would cease and the motive force would disappear. Thus, induction machines always spin a bit slower than synchronous speed.

A typical "two-pole"<sup>16</sup> induction motor operating at a power line frequency of 60 Hz has a synchronous speed of 3600 RPM (i.e. the rotating magnetic field is spinning 60 revolutions per second), but the rotor may only achieve a full-load speed of approximately 3540 RPM. Similarly, a typical "four-pole" induction motor with a synchronous speed of 1800 RPM<sup>17</sup> may only attain a rotor speed of approximately 1760 RPM.

Induction motors are by far the most popular design in industry. The most common variant of the induction motor is the so-called *squirrel-cage* design, where the rotor is made up of aluminum bars joining two aluminum "shorting rings," one at either end of the rotor. Ferrous metal (iron alloy) fills

<sup>16</sup>Two magnetic poles in the stator *per phase*, which is the lowest number possible because each phase naturally produces both a "north" and a "south" pole when energized. In the case of a three-phase induction or synchronous motor, this means a total of *six* magnetic stator poles.

<sup>17</sup>Doubling the number of magnetic poles increases the number of AC power cycles required for the rotating magnetic field to complete one full revolution. This effect is not unlike doubling the number of light bulbs in a chaser light array of fixed length, making it seem as though the light sequence is moving slower because there are more bulbs to blink along the same distance.

the spaces between the rotor bars to provide a lower-reluctance magnetic “circuit” between stator poles than would otherwise be a large air gap if the rotor were simply made of aluminum. If the ferrous metal were removed from the rotor, the remaining aluminum bars and shorting rings would resemble the cage-wheel exercise machine used by hamsters and other pet rodents, hence the name.

A photograph of a small, disassembled three-phase AC induction “squirrel-cage” motor is shown here, revealing the construction of the stator coils and the rotor:

Given the extremely simple construction of AC induction motors, they tend to be very reliable. So long as the stator coil insulation is not damaged by excessive moisture, heat, or chemical exposure, these motors will continue to operate indefinitely. The only “wearing” components are the bearings supporting the rotor shaft, and those are easily replaced.

Starting a three-phase induction motor is as simple as applying full power to the stator windings. The stator coils will instantly produce a magnetic field rotating at a speed determined by the frequency of the applied AC power, and the rotor will experience a large torque as this high-speed (relative to the rotor’s stand-still speed of zero) magnetic field induces large electric currents in it. As the rotor comes up to speed, the relative speed between the rotating magnetic field and the rotating rotor diminishes, weakening the induced currents and also the rotor’s torque.

One way to “model” an AC induction motor is to think of it as an AC transformer with a short-circuited, movable secondary winding. When full power is first applied, the initial current drawn by the stator (primary) windings will be very large, because it “sees” a short-circuit in the rotor (secondary) winding. As the rotor begins to turn, however, this short-circuit draws less and less current until the motor reaches full speed<sup>18</sup> and the line current approaches normal. As with

---

<sup>18</sup>As mentioned previously, the rotor can never fully achieve synchronous speed, because if it did there would be zero relative motion between the rotating magnetic field and the rotating rotor, and thus no induction of currents in the rotor bars to create the induced magnetic fields necessary to produce a reaction torque. Thus, the rotor must “slip” behind the speed of the rotating magnetic field in order to produce a torque, which is why the full-load speed of an induction motor is always just a bit slower than the synchronous speed of the rotating magnetic field (e.g. a 4-pole motor with a synchronous speed of 1800 RPM will rotate at approximately 1750 RPM).

a transformer, where a reduction in secondary current (from a load change) results in a reduction in primary current, the reduction in induced rotor current (from reduced slip speed) results in a reduction in stator winding current.

The huge surge of current at start-up time (as much as ten times the normal running current!) is called *inrush* current, causing the rotor to produce a large mechanical torque. As the rotor gains speed, the current reduces to a normal level, with the speed approaching the “synchronous” speed of the rotating magnetic field. If somehow the rotor achieves synchronous speed (i.e. the slip speed becomes zero), stator current will fall to an absolute minimum. If a mechanical power source “over-drives” a powered induction motor, forcing it to spin faster than synchronous speed, it will actually begin to function as a generator<sup>19</sup> and source electrical power.

Any mechanical load causing the motor to spin slower likewise causes the stator windings to draw more current from the power supply. This is due to the greater slip speed causing stronger currents<sup>20</sup> to be induced in the rotor. Stronger rotor currents equate to stronger stator currents, just like a transformer where a heavier load on the secondary winding causes greater currents in both secondary and primary windings.

Reversing the rotational direction of a three-phase motor is as simple as swapping any two out of three power conductor connections. This has the effect of reversing the *phase sequence* of the power “seen” by the motor<sup>21</sup>. The flip-book animation beginning in Appendix A.1 beginning on page 2813 shows how reversing two of the three lines has the effect of reversing phase sequence.

An interesting problem to consider is whether it is possible to make an AC induction motor function on *single-phase* power rather than polyphase power. After all, it is the three-step phase sequence of three-phase AC power that gives the stator windings’ magnetic field its definite rotational direction. If we have only one sine wave supplied by the AC power source, is it possible to generate a truly *rotating* magnetic field? At best, it seems all we could ever produce with single-phase AC power is a *pulsing* or “blinking” magnetic field. If you imagine a string of light bulbs blinking on and off 180° out of phase (i.e. ABABABAB), one could argue the sequence is marching from A to B, or alternatively from B to A – there is no definite direction to the lights’ “motion.”

---

<sup>19</sup>In this mode, the machine is called an *induction alternator* rather than an *induction motor*.

<sup>20</sup>Faraday’s Law of Electromagnetic Induction describes the voltage induced in a wire coil of  $N$  turns as proportional to the *rate of change* of the magnetic flux:  $V = N \frac{d\phi}{dt}$ . The greater the difference in speed between the rotor and the rotating magnetic field, the greater  $\frac{d\phi}{dt}$ , inducing greater voltages in the rotor and thus greater currents in the rotor.

<sup>21</sup>This principle is not difficult to visualize if you consider the phase sequence as a repeating pattern of letters, such as ABCABCABC. Obviously, the reverse of this sequence would be CBACBACBA, which is nothing more than the original sequence with letters A and C transposed. However, you will find that transposing *any* two letters of the original sequence transforms it into the opposite order: for example, transposing letters A and B turns the sequence ABCABCABC into BACBACBAC, which is the same *order* as the sequence CBACBACBA.

Since single-phase AC induction motors obviously exist, there must be a solution to this problem. In order to give the magnetic field within a single-phase stator assembly a definite rotation, we must *artificially create a second phase* within the motor itself. One common way to do this is to add a second set of stator windings offset from the first and energize those windings through a high-voltage capacitor, which creates a leading phase shift in winding current. This phase shift creates an out-of-step magnetic field in the second winding set, providing a definite direction of rotation. Once the motor comes up to speed, this auxiliary winding may be disconnected by a speed-sensing switch, since a spinning motor will happily run<sup>22</sup> on single-phase AC. This is called a *capacitor-start* induction motor, and it is the design used for most single-phase AC induction motors requiring a high starting torque (e.g. pumps, shop grinders, drill presses, etc.):

### Single-phase, capacitor-start induction motor

One of the major principles to grasp about AC induction motors is that they *must start as polyphase machines, although they may continue to run as single-phase machines*.

<sup>22</sup>I once encountered a washing machine induction motor with an “open” fault in the start winding. When energized, this motor remained still and hummed because it had no second phase to give its magnetic field a rotation. However, if you used your hand to give the motor a spin in either direction, *the motor would accelerate to full speed in that direction!*

A capacitor-start, single-phase electric motor is shown in the following photograph. My hand is touching the capacitor enclosure for the motor's starting winding. The speed switch is internal to the motor and cannot be seen in this photograph:

Capacitor-start motors are often designed in such a way that the starting winding draws much more current than the “run” winding, in order to provide a strong starting torque. This is important when the mechanical load being turned by the motor requires a great deal of torque to get moving, such as in the case of a reciprocating gas compressor or a fully-loaded conveyor belt. Due to this high current draw, starting windings are not rated for continuous duty, but rather must be de-energized shortly after starting the motor in order to avoid overheating.

Smaller AC motors, such as those used inside bench-top and rack-mount electronic equipment, use a completely different method for generating a rotating magnetic field from single-phase AC power. The following photograph shows one such motor, employing copper *shading coils* at the corners of the magnetic stator poles. The rotor has been removed, held by my fingers for inspection:

Instead of a capacitor creating a leading phase-shift for current through a special stator winding, this “shaded-pole” induction motor uses a pair of copper loops wrapped around the corners of the magnetic poles to produce a lagging phase shift in the magnetic field at those corners. The copper shading coils act as inductors, delaying the magnetic field through them by  $-90^\circ$ , creating a secondary magnetic field that is out-of-step with the main magnetic field generated by the rest of the pole face. The out-of-step magnetic field together with the main magnetic field adjacent to it creates a definite direction of rotation<sup>23</sup>.

An interesting experiment you can try yourself is to obtain<sup>24</sup> one of these small shaded-pole AC motors and make it rotate by applying pulsed DC power to it, from a battery. Every time you connect the stator winding to the battery, the increasing magnetic flux will lead at the non-shaded

<sup>23</sup>In this example, the direction of rotation is counter-clockwise. The shaded poles are oriented counter-clockwise of center, which means their delayed magnetic fields create an “appearance” of rotation in that direction: the magnetic field achieves its peak strength first at the pole centers, and then later (delayed) at the shaded poles, as though there were an actual magnet rotating in that direction.

<sup>24</sup>A convenient source of small shaded-pole motors is your nearest home improvement or hardware store, where they likely sell replacement electric motors for bathroom fans. Of course, you may also find such motors inside of a variety of discarded electric appliances as well. Being rather rugged devices, it is quite common to find the shaded-pole motor inside of an electrical appliance in perfect condition even though other parts of that appliance may have failed with age. In fact, the shaded-pole motor shown in the preceding photograph was salvaged from a “water-pic” electric toothbrush, the motor used to drive a small water pump (which in this case had mechanically failed) delivering water to the head of the toothbrush.

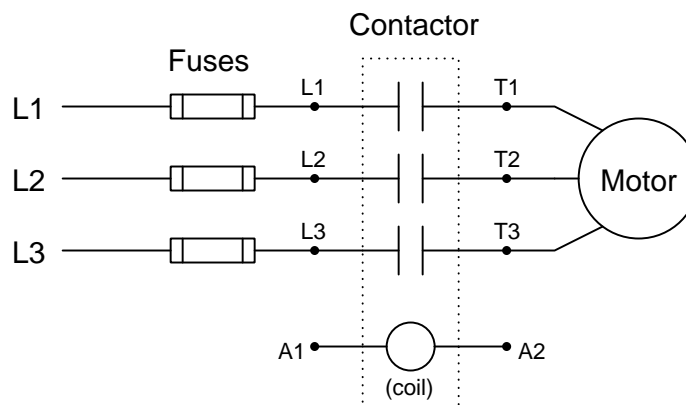

pole faces and lag at the shaded pole faces. Every time you disconnect the stator winding from the battery, the decreasing magnetic flux will lead at the non-shaded pole faces and lag at the shaded pole faces. In either case, the shaded poles' magnetic flux will lag behind that of the non-shaded poles, causing the rotor to rotate slightly in one definite direction.

The fact that all AC induction motors must start as polyphase machines even though they can run as single-phase machines means that an AC motor designed to run on three-phase power may actually continue to run if one or more of its phases are “lost” due to an open wire connection or blown fuse. The motor cannot deliver full-rated mechanical power in this condition, but if the mechanical load is light enough the motor will continue to spin even though it no longer has multiple phases powering it! A three-phase motor, however, *cannot start from a stand-still* on just one phase of AC power. The loss of phases to an AC induction motor is called *single-phasing*, and it may cause a great deal of trouble in an industrial facility. Three-phase electric motors that become “single-phased” from a fault in one of the three-phase power lines will refuse to start. Those that were already running under heavy (high-torque) mechanical load will stall. In either case, the stopped motors will simply “hum” and draw large amounts of current.

### 10.4.2 Motor contactors

To start up and shut down a three-phase AC induction motor, any three-pole switch with a suitable current rating will suffice. Simply closing such a switch to send three-phase power to the motor will cause it to start up, while opening the three-pole switch will cut power to the motor to make it turn off. If we desire to have *remote* start and stop control over a three-phase motor, we need a special relay with switch contacts big enough to safely conduct the motor's inrush current over many start and stop cycles. Large, high-current-rated electromechanical relays built for this very purpose are commonly referred to as *contactors* in industry.

A schematic diagram of a three-phase contactor connected to a three-phase motor (with fuses for overcurrent protection) is shown here:

Energizing terminals A1 and A2 magnetizes the electromagnet coil, causing all three switch contacts to simultaneously close, sending three-phase AC power to the motor. De-energizing the coil causes it to de-magnetize, releasing the armature and enabling a return spring inside the contactor to snap all three contacts to the open (off) position.

A contactor rated at 75 horsepower (at 480 volt AC 3-phase power) is shown here, both assembled and with the top cover removed to reveal the three sets of high-current electrical switch contacts:

Each phase switch contact is actually a series pair of contacts that make and break simultaneously with the actuation of a ferrous armature attracted by an electromagnet coil in the base of the contactor assembly. The operation of the three contact sets may be seen in this pair of photographs, the left-hand image showing the contacts in their normal (open) state, and the right-hand image showing the contacts closed (the armature “pulled in”) by the force of my finger:

Of course, it would be very dangerous to touch or manually actuate the contacts of a motor starting relay with the cover removed as shown. Not only would there be an electric shock hazard from touching any one of the bare copper contacts with your finger, but the arcing produced by closing and opening such contacts would pose *arc flash* and *arc blast* hazards. This is why all modern motor contactors are equipped with arc shield covers. The actual switch contact pads are not made of pure copper, but rather silver (or a silver alloy) designed to survive the repeated arcing and blasting action of large AC currents being initiated and interrupted.

Below the main power connection terminals (L1-L3, T1-T3) on this contactor hide two small screw terminals (commonly denoted A1 and A2) providing connection points to the electromagnet coil actuating the contactor:

Like most three-phase contactors, this one's coil is rated for 120 volts AC. Although the electric motor may operate on three-phase, 480 volt AC power, the contactor coil and the rest of the control circuitry operates on a lower voltage for reasons of safety. Like all electromechanical relays, motor contactors use a low-power signal to control higher-power electric current to the load. This

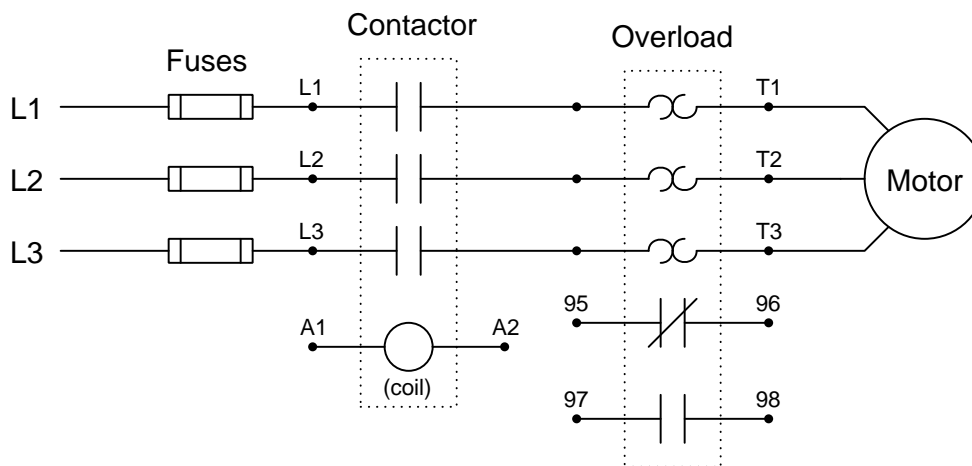

“amplifying” action enables relatively small control switches, PLCs, and relay circuits to start and stop relatively large (high-current) electric motors.

### 10.4.3 Motor protection

An essential component of any high-power motor control circuit is some device to detect a condition of excessive *overload* and interrupt power to the motor before thermal damage occurs. A very simple and common overload protective device is known as an *overload heater*, consisting of resistive elements connected in series with the three lines of a 3-phase AC motor, designed to heat and to cool at rates modeling the thermal characteristics of the motor itself.

Fuses and circuit breakers also protect against overcurrent, but for different reasons and for different parts of the motor circuit. Both fuses and circuit breakers tend to be fast-acting devices, intended to interrupt overcurrent resulting from an electrical fault such as a phase-to-ground short circuit. They are sized to protect the wiring delivering power to a load, not (necessarily) the load itself. Thermal overload heaters, by contrast, are specifically designed to protect an electric motor from damage resulting from mild overcurrent conditions, such as what might be experienced if the motor becomes mechanically overloaded. The sizing of overload heaters is unrelated to wire ampacity, and therefore unrelated to the ratings of the fuses or circuit breakers delivering line power to the motor.

A schematic diagram of a three-phase overload connected to a three-phase contactor and three-phase motor is shown here:

Both contacts inside the overload assembly will remain in their resting (“normal”) states so long as the heater elements (the back-to-back “hook” symbols seen in the above diagram) remain cool. If one or more of the resistive heaters becomes too warm, however, the contacts will actuate and change state. The normally-closed overload contact (terminals 95 and 96) is typically wired in series with the contactor coil (terminals A1 and A2), so that a detected overload condition forces the contactor to de-energize and interrupt power to the motor.

The following photograph shows a three-phase contactor relay joined together with a set of three “overload heaters” through which all of the motor’s current flows. The overload heaters appear as three brass-colored metal strips near a red push-bar labeled “Reset”. The entire assembly – contactor plus overload heaters – is referred to as a *starter*:

Removing one of the heater elements reveals its mechanical nature: a small toothed wheel on one side engages with a lever when it is bolted into place in the overload assembly. That lever connects to a spring-loaded mechanism charged by the manual actuation of the red “Reset” push-bar, which in turn actuates a small set of electrical switch contacts:

The purpose of the overload heater is to heat up as the motor draws excessive current. The small toothed wheel is held in place by a rod immersed in a solidified mass of solder, encased in a brass cylinder underneath the heater strip. The next photograph shows the underside of the heater element, with the toothed wheel and brass cylinder plainly visible:

If the heater element becomes too hot (due to excessive motor current), the solder inside the brass cylinder will melt, allowing the toothed wheel to spin. This will release spring tension in the overload mechanism, allowing the small electrical switch to spring to an open state. This “overload contact” then interrupts current to the contactor’s electromagnet coil, causing the contactor to de-energize and the motor to stop.

Manually pressing the “Reset” push-bar will re-set the spring mechanism and re-close the overload contact, allowing the contactor to energize once more, but only once the overload heater element has cooled down enough for the solder inside the brass cylinder to re-solidify. Thus, this simple mechanism prevents the overloaded motor from being immediately re-started after a thermal overload “trip” event, giving it time to cool down as well.

A typical “trip curve” for a thermal overload unit is shown here, with time plotted against the severity of the overcurrent level:

In contrast to a circuit breaker or fuse – which is sized to protect the power wiring from overcurrent heating – the overload heater elements are sized specifically to protect the *motor*. As such, they act as thermal models of the motor itself, heating to the “trip” point just as fast as the motor itself will heat to the point of maximum rated temperature, and taking just as long to cool to a safe temperature as the motor will. Another difference between overload heaters and breakers/fuses is that the heaters are not designed to directly interrupt current by opening<sup>25</sup>, as fuses or breakers do. Rather, each overload heater serves the simple purpose of *warming* proportionately to the magnitude and time duration of motor overcurrent, causing a different electrical contact to open, which in turn triggers the contactor to open and interrupt motor current.

Of course, overload heaters only work to protect the motor from thermal overload if they experience similar ambient temperature conditions. If the motor is situated in a very hot area of the industrial process unit, whereas the overload elements are located in a climate-controlled “motor control center” (MCC) room, they may fail to protect the motor as designed. Conversely, if the overload heaters are located in a hot room while the motor is located in a freezing-cold environment (e.g. the MCC room lacks air conditioning while the motor is located in a freezer), they may “trip” the motor prematurely.

<sup>25</sup>This is not to say overload heaters cannot fail open, because they can and will under extraordinary circumstances. However, opening like a fuse is not the design function of an overload heater.

An interesting “trick” to keep in mind for motor control circuit diagnosis is that overload heaters are nothing more than low-value resistors. As such, they will drop small amounts of voltage (usually quite a bit less than 1 volt AC) under full load current. This voltage drop may be used as a simple, qualitative measure of motor phase current. By measuring the voltage dropped across each overload heater (with the motor running), one may ascertain whether or not all phases are carrying equal currents. Of course, overload heaters are not precise enough in their resistance to serve as true current-measuring “shunts,” but they are more than adequate as qualitative indicators of relative phase current, to aid you in determining (for instance) if the motor suffers from an open or high-resistance phase winding:

As useful as thermal overload “heaters” are for motor protection, there are more effective technologies available. An alternative way to detect overloading conditions is to monitor the temperature of the stator windings directly, using thermocouples or (more commonly) RTDs, which report winding temperatures to an electronic “trip” unit with the same control responsibilities as an overload heater assembly. This sophisticated approach is used on large (thousands of horsepower) electric motors, and/or in critical process applications where motor reliability is paramount. Machine vibration equipment used to monitor and protect against excessive vibration in rotary machines is often equipped with such temperature-sensing “trip” modules just for this purpose. Not only can motor winding temperatures be monitored, but also bearing temperatures and other temperature-sensitive machine components so that the protective function extends beyond the health of the electric motor.

Devices specifically constructed to monitor the condition of electrical power components such as motors, generators, transformers, or distribution lines, and take action to protect those components in the event their parameters fall outside safe limits, are generally known as *protective relays*<sup>26</sup>. A protective relay is designed to monitor physical variables such as line currents and winding temperatures relevant to a large electrical component, then automatically initiate a “trip” action to shut off power to that component by sending a signal to the nearest circuit breaker or other automatic disconnect device<sup>27</sup>.

Originally, protective relays were electromechanical in nature, using coils, magnets, springs, rotating disks, and other components to detect and act upon out-of-spec electrical measurements. Modern protective relays – for electric motors or for other electric power components such as generators, power lines, and transformers – use microprocessors instead of electromagnetic mechanisms to perform the same basic functions. With microprocessor technology comes vast increases in responsiveness and precision of timing, as well as digital networking capability to share system data among other components and to human operators.

---

<sup>26</sup>For a more complete coverage of protective relays, refer to section 25.7 beginning on page 1985.

<sup>27</sup>One way to help clarify the function of a protective relay is to envision circuit protection without one. Household and low-current industrial circuit breakers are constructed to have their own internal current-sensing elements (either thermal or magnetic) to force the circuit breaker open automatically when current exceeds a pre-set limit. With protective relays, the circuit breaker instead has a “trip coil” which will cause the breaker to trip when energized. The breaker then relies entirely on the (external) protective relay to tell it when to trip. By relegating the function of event detection to a sophisticated, external relay, the circuit breaker may act much “smarter” in protecting against a wider variety of faults and abnormal conditions than if it relied entirely on its own internal overcurrent-sensing mechanism.

A diagram showing how a modern (digital) protective relay would monitor various parameters on a medium-voltage (4160 volts AC, three-phase) industrial electric motor is shown here:

In this example, line voltage (4160 volts AC) and line current are both too great to be directly connected to the protective relay, and so the relay senses line voltage and line current via *potential transformers* (PTs) and *current transformers* (CTs), respectively. A potential transformer<sup>28</sup> is a precision device providing a known accurate step-down ratio, usually down to 120 volts or 240 volts AC full-scale, for the protective relay to directly sense. Likewise, a current transformer is a precision device providing a known and accurate step-down ratio for current (actually a step-up from the perspective of voltage), usually down to 1 amp or 5 amps AC full-scale, for the protective relay to directly sense. Both transformers provide *galvanic isolation* (a complete lack of electrical conductivity) between the medium-voltage motor power conductors and the protective relay electronics while still permitting accurate sensing of line voltage and line current.

The *zero sequence* CT is a special current transformer encircling all three motor phase conductors, providing indication of a ground fault within the motor. The fact that this CT measures the instantaneous algebraic sum of currents in and out of the motor means that in ordinary operation it will output absolutely zero signal, since Kirchhoff's Current Law states that the algebraic sum of currents into and out of a node (the motor here is considered a node) must be zero. If, however,

<sup>28</sup>Potential transformers are also known as *voltage transformers*, abbreviated *VT*.

a ground fault develops within the motor where some AC current “leaks” from a stator winding to earth ground to return to the 4160 VAC power source’s neutral connection, that imbalance of phase currents will be sensed by the zero sequence CT, since that ground fault current represents a fourth path for current not accounted for by the three power conductors passing through to the motor.

This next photograph shows the front panel display of a General Electric (“Multilin”) model 369 protective relay for an electric motor:

### 10.4.4 Motor control circuit wiring

A simple three-phase, 480 volt AC motor-control circuit is shown here, both in pictorial and schematic form. This entire assembly consisting of contactor, overload block, control power transformer, power fuses (or alternatively, a circuit breaker) and associated components is informally referred to as a *bucket*:

To 3- $\phi$ , 480 volt power source

Note how a *control power transformer* steps down the 480 volt AC to provide 120 volt AC power for the contactor coil to operate on. Furthermore, note how the overload (“OL”) contact is wired in series with the contactor coil so that a thermal overload event forces the contactor to de-energize and thus interrupt power to the motor even if the control switch is still in the “on” position. The overload heaters appear in the schematic diagram as pairs of back-to-back “hook” shapes, connected in series with the three “T” lines of the motor. Remember that these “OL” heater elements do not directly interrupt power to the motor in the event of an overload, but rather signal the “OL” contact to open up and de-energize the contactor.

In an automatic control system, the toggle switch would be replaced by another relay contact (that relay controlled by the status of a process), a process switch, or perhaps the discrete output channel of a programmable logic controller (PLC).

It should be noted that a toggling-style of switch is necessary in order for the motor to continue to run after a human operator actuates the switch. The motor runs when the switch is in the closed state, and stops when the switch opens. An alternative to this design is to build a *latching* circuit allowing the use of momentary contact switches (one to start, and one to stop). A simple latching motor control circuit is shown here:

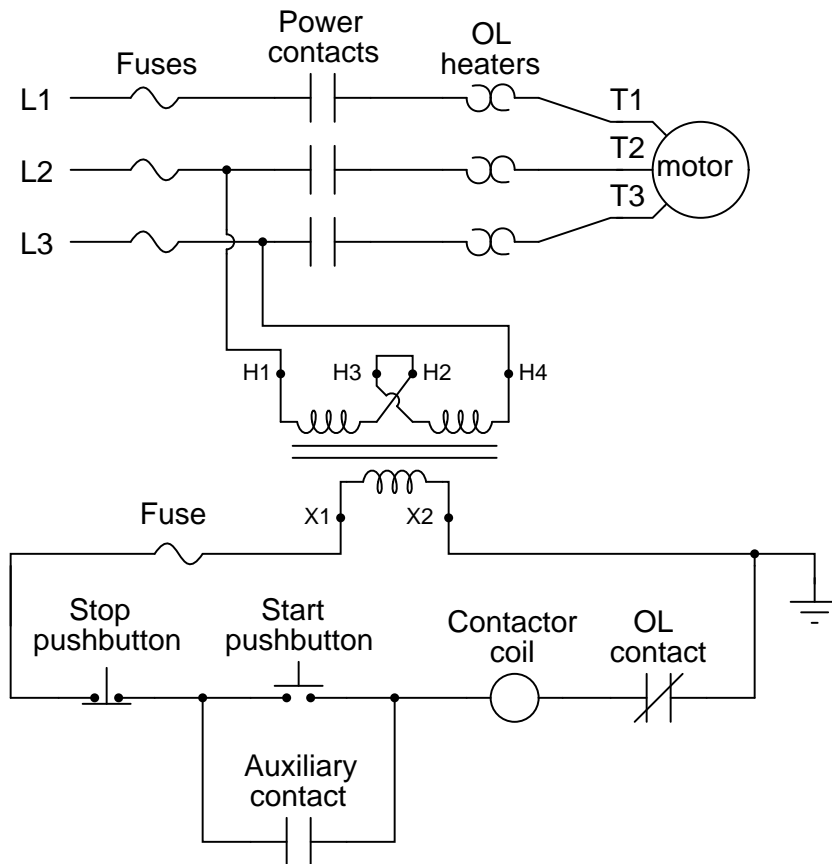

In this circuit, an *auxiliary contact* actuated by the motor contactor is wired in parallel with the “Start” pushbutton switch, so that the motor contactor continues to receive power after the operator releases the switch. This parallel contact – sometimes called a *seal-in contact* – latches the motor in an “on” state after a momentary closure of the “Start” pushbutton switch.

A normally-closed “Stop” switch provides a means to “un-latch” the motor circuit. Pressing this pushbutton switch opens the control circuit, forcing current to halt through the coil of the contactor, which then opens the three motor power contacts as well as the auxiliary contact used to maintain the contactor’s energized state.

A simple *ladder diagram* showing the interconnections of all components in this motor control circuit makes this system easier to understand:

Most on/off motor control circuits in the United States are some variation on this wiring theme, if not identical to it. Once again, this system could be automated by replacing the “Start” and “Stop” pushbutton switches with process switches (e.g. pressure switches for an air compressor control system) to make a system that starts and stops automatically. A programmable logic controller (PLC) may also be used to provide the latching function rather than an auxiliary contact on the contactor. Once a PLC is included in the motor control circuit, a great many automatic control features may be added to enhance the system’s capabilities. Examples include timing functions, motor cycle count functions, and even remote start/stop capability via a digital network connecting to operator interface displays or other computers.

In applications where reversing motor control is desired, a pair of contactors may be wired together as shown here:

Note how motor reversal is accomplished by swapping phases L1 and L3: in the forward direction, power line conductor L1 connects to motor terminal T1, L2 connects to T2, and L3 connects to T3. In the reverse direction L2 still connects to T2, but L1 now connects to T3 and L3 now connects to T1. Recall the principle that swapping *any two phases* in a three-phase power system reverses the phase rotation, which in this case make the electric motor spin the other direction.

With two contactors, the control circuit now contains two coils to actuate those contactors: one marked “forward” and the other marked “reverse”. Separate “forward” and “reverse” pushbutton switches send power to those coils, and separate seal-in auxiliary contacts connected in parallel with their respective pushbuttons latch each one.

An important feature of this reversing starter circuit is the inclusion of *interlocking* contacts in each rung of the circuit. In the forward-control circuit, a normally-closed auxiliary contact actuated by the “reverse” contactor is wired in series, and vice-versa in the reverse-control circuit. The purpose of an “interlock” is to prevent incompatible events from happening, in this case preventing the actuation of the “reverse” contactor when the “forward” contactor is already actuated, and vice-versa. If both contactors were to be simultaneously actuated, it would result in a direct phase-to-phase fault (short-circuit) between L1 and L3!

Some reversing motor starters provide a feature called *mechanical interlocking*, where the motion of the armature in each contactor is restrained in such a way that both cannot actuate simultaneously. This usually takes the form of a “rocking beam” lever preventing one contactor armature from being pulled in while the other contactor’s armature is pulled in, similar to a “see-saw” playground toy where only one end can be down at any given time. It is not uncommon for both electrical and mechanical interlocking to be used in the same reversing starter, as a measure of extra protection.

A modern trend in motor control is the use of digital networks to both command the contactor as well as monitor the motor's operating status remotely. This next photograph<sup>29</sup> shows a digitally monitored and controlled “bucket,” using DeviceNet as the control network:

Using a digital network standard such as Ethernet, DeviceNet, Modbus, Profibus, or any number of others to monitor and control a motor brings a host of benefits for maintenance and operations. Control wiring is vastly simplified with digital networks, as a single network cable is able to address multiple motor buckets. The “smart” network interface module installed in the bucket may be designed to monitor such parameters as line voltage, line current, phase imbalance, and power factor to report these values to the host control system via the network.

---

<sup>29</sup>This bucket was still under construction at the time the photograph was taken. As such, none of the motor leads have been connected, which is why there are no power conductors exiting the bottom of the bucket. Instead, all you see are three terminals ready to accept heavy-gauge motor leads.

It is common for the network interface module inside the bucket to have its own digital display for local indication of these parameters as well. A close-up photograph of a Square-D “Motor Logic Plus” unit shows some of its locally-accessible features:

The PLC connected to the network is able to access all these values as well, reporting them to operations and/or maintenance personnel as desired. Instead of individual wires running between the PLC and the motor starter to command each motor to run and stop, the PLC simply transmits “start” and “stop” commands over the network to individually addressed digital starter modules. The network wiring may simply be paralleled (“daisy-chained”) between units, such that several buckets reside on the same physical network, each one programmed with a unique address. A PLC connected to this same network is thus able to access and control all parameters for all motors on that network.

## 10.5 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader's view of this chapter's concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **“Normal” switch status:** the “normal” status of a switch contact as defined by the manufacturer is its *resting* condition (minimum stimulus).
- **“Seal-in” circuit:** when an electrical relay uses one of its own switch contacts to continue its own coil energization after the initial triggering event has passed. Relevant to motor starter circuits.
- **Lenz’s Law:** any magnetic field arising from electromagnetic induction opposes the inducing field. Relevant to the operation of induction AC motors.
- **Rotating magnetic field:** this is necessary to cause an AC induction motor to spin in a particular direction, and is generated by polyphase field poles (i.e. multiple magnetic fields that are out-of-phase with each other). All AC induction motors require such a polyphase magnetic field to start up in a particular direction, although a single-phase magnetic field is sufficient to maintain rotation once started.

## Chapter 11

# Relay control systems

The word “discrete” means *individual* or *distinct*. In engineering, a “discrete” variable or measurement refers to a true-or-false condition. Thus, a discrete control system is one designed to operate on Boolean (“on” or “off”) signals supplied by discrete sensors such as process switches.

A form of discrete control taught in every introductory course on digital electronics involves the use of circuits called *logic gates*. These circuits input one or more Boolean signals, and output a Boolean signal according to a simple rule such as “AND” or “OR”:

**AND**

A	B	Output
0	0	0
0	1	0
1	0	0
1	1	1

**OR**

A	B	Output
0	0	0
0	1	1
1	0	1
1	1	1

**XOR**

A	B	Output
0	0	0
0	1	1
1	0	1
1	1	0

**NAND**

A	B	Output
0	0	1
0	1	1
1	0	1
1	1	0

**NOR**

A	B	Output
0	0	1
0	1	0
1	0	0
1	1	0

**XNOR**

A	B	Output
0	0	1
0	1	0
1	0	0
1	1	1

Industrial control systems rarely utilize logic gates in a direct fashion for discrete control systems, although the fundamental *concepts* of “AND,” “OR,” and other gate types are universally applied. Instead, control functions are either implemented using electromechanical relays and/or

with programmable digital devices such as PLCs (Programmable Logic Controllers). This chapter focuses on the practical use of both technologies for industrial discrete control.

An “AND” function is equivalent to *series-connected* normally-open contacts in a relay control circuit, because the lamp will energize only if switch A *and* switch B are actuated:

An “OR” function is equivalent to *parallel-connected* normally-open contacts in a relay control circuit, because the lamp will energize if switch A *or* switch B is actuated:

The “NOT” function is equivalent to a single normally-closed contact in a relay control circuit, because the lamp will energize only if the switch is *not* actuated:

## 11.1 Control relays

An *electromechanical relay* is an electrical switch actuated by an electromagnet coil. As switching devices, they exhibit simple “on” and “off” behavior with no intermediate states. Relays are very useful devices, as they allow a single discrete (on/off) electrical signal to *control* much greater levels of electrical power, and/or multiple power or control signals that are otherwise isolated from each other. For example, a relay may be controlled by a low-voltage, low-current signal that passes through a delicate switch of some sort (e.g. limit switch, proximity switch, optical sensor), and then the switching contacts of that relay may be used to control a much higher-voltage, higher-current circuit, and even multiple circuits given multiple sets of switching contacts.

The electronic schematic symbol for a simple single-pole, single-throw (SPST) relay is shown here:

SPST relay  
(NO contact)

A coil of wire wrapped around a laminated ferrous core provides the magnetic field necessary to actuate the switch mechanism. This electromagnet coil's actuating influence on the relay's contact(s) is represented by the dashed line. This particular relay is equipped with *normally open* (NO) switch contacts, which means the switch will be in the open (off) state when the relay coil is de-energized. Recall from section 9.1 that the “normal” status of a switch is the resting condition of *no stimulation*. A relay switch contact will be in its “normal” status when its coil is not energized. A single-pole, single-throw relay with a normally-closed (NC) switch contact would be represented in an electronic schematic like this:

SPST relay  
(NC contact)

In the electrical control world, the labels “Form-A” and “Form-B” are synonymous with “normally open” and “normally closed” contacts, respectively. Thus, we could have labeled the SPST relay contacts as “Form-A” and “Form-B,” respectively:

An extension of this theme is the single-pole, double-throw (SPDT) relay contact, otherwise known as a “Form-C” contact. This design of switch provides both a normally-open and normally-closed contact set in one unit, actuated by the electromagnet coil:

A further extension on this theme is the double-pole, double-throw (DPDT) relay contact. This design of switch provides two sets of Form-C contacts in one unit, simultaneously actuated by the electromagnet coil:

DPDT relays are some of the most common found in industry, due to their versatility. Each Form-C contact set offers a choice of either normally-open or normally-closed contacts, and the two

sets (two “poles”) are electrically isolated from each other so they may be used in different circuits.

A common package for industrial relays is the so-called *ice cube relay*, named for its clear plastic case allowing inspection of the working elements. These relays plug into multi-pin base sockets for easy removal and replacement in case of failure. A DPDT “ice cube” relay is shown in the following photographs, ready to be plugged into its base (left) and with the plastic cover removed to expose both sets of Form-C contacts (right):

These relays connect to the socket with eight pins: three for each of the two Form-C contact set, plus two more pins for the coil connections. Due to the pin count (8), this style of relay base is often referred to as an *octal* base.

A closer view of one Form-C contact shows how the moving metal “leaf” contacts one of two stationary points, the actual point of contact being made by a silver-coated “button” at the end of the leaf. The following photographs show one Form-C contact in both positions:

Industrial control relays usually have connection diagrams drawn somewhere on the outer shell to indicate which pins connect to which elements inside the relay. The style of these diagrams may vary somewhat, even between relays of identical function. Take for instance the diagrams shown here, photographed on three different brands of DPDT relay:

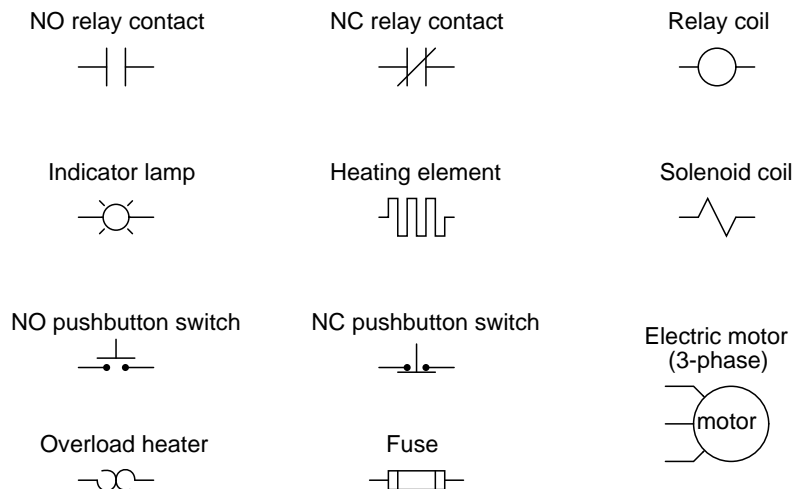

Bear in mind that these three relays are *identical* in their essential function (DPDT switching), despite differences in physical size and contact ratings (voltage and current capacities). Only two of the three diagrams shown use the same symbols to represent contacts, and all three use unique symbols to represent the coil.

## 11.2 Relay circuits

Electromechanical relays may be connected together to perform logic and control functions, acting as logic elements much like digital gates (AND, OR, etc.). A very common form of schematic diagram showing the interconnection of relays to perform these functions is called a *ladder diagram*. In a “ladder” diagram, the two poles of the power source are drawn as vertical rails of a ladder, with horizontal “rungs” showing the switch contacts, relay contacts, relay coils, and final control elements (lamps, solenoid coils, motors) drawn in between the power rails.

Ladder diagrams differ from regular schematic diagrams of the sort common to electronics technicians primarily in the strict orientation of the wiring: vertical power “rails” and horizontal control “rungs.” Symbols also differ a bit from common electronics notation: relay coils are drawn as circles, with relay contacts drawn in a way resembling capacitors:

*Ladder diagram symbols*

Unlike schematic diagrams where the association between relay coils and relay contacts is represented by dashed lines, ladder diagrams associate coils and contacts *by label*. Sometimes you will find relay contacts labeled identically to the coil (e.g. coil labeled CR5 and all contacts for that relay also labeled CR5) while other times you will find suffix numbers used to distinguish individual contacts within each relay from each other (e.g. coil labeled CR5 and its three contacts labeled CR5-1, CR5-2, and CR5-3).

Another notable convention in relay circuits and their ladder diagrams is that each and every wire in the circuit is labeled with a number corresponding to common connection points. That is, wires connected together always bear the same number: the common number designates a condition of electrical commonality (all points bearing the same number are *equipotential* to each other). Wire numbers only change when the connection passes through a switch or other device capable of dropping voltage.

An actual ladder diagram of a relay-based motor control system is shown here, complete with *red-line* edits showing modifications to the circuit made by an industrial electrician:

Perhaps the most confusing aspect of relay control circuits for students to grasp is the meaning of *normal* as it applies to the status of relay contacts. As discussed previously, the word “normal” in this context – whether it be the status of hand switches, process switches, or the switch contacts inside control relays – means “in a condition of rest” or no stimulation. In other words, a “normally-open” relay contact is open *when the relay coil is unpowered* and closed when the relay coil is powered. Likewise, a “normally-closed” relay contact is closed *when the relay coil is unpowered* and open when the relay coil is powered.

To illustrate this concept, let us examine a relay control circuit where a pressure switch activates an alarm light:

Here, both the pressure switch and the relay contact (CR1-1) are drawn as normally-closed switch contacts. This means the pressure switch contact will be closed when the applied pressure is less than its trip point (50 PSI), and the relay switch contact will be closed when the relay coil is de-energized.

When analyzing the operation of a relay control system, it is helpful to have some way to temporarily denote the conductive status of switch contacts and the energization status of relay coils (i.e. a notation we might sketch using pencil on a diagram to help us follow the operation of the circuit). A symbology I recommend is the use of arrow and “X” symbols to represent power flow and no power flow (respectively). These symbols clearly denote component status while avoiding confusion with the symbols used to denote *normal* status of switch contacts<sup>1</sup>.

In this next diagram, we assume the applied pressure is less than 50 PSI, leaving the pressure switch in its “normal” (closed) state:

Since the pressure is insufficient to actuate the pressure switch, its contact remains in the “normal” state (closed). This sends power to relay coil CR1, thus actuating contact CR1-1 and holding it in the *open* state. With CR1-1 contact open, the alarm lamp receives no power. In this example we see the pressure switch in its “normal” state but the relay in the *actuated* state.

<sup>1</sup>An unfortunately common tendency among novices is to sketch slash marks through relay contact symbols in order to show when they happen to be closed. This is a very bad habit, and should be discouraged at all times! Diagonal lines drawn through a contact symbol are supposed to denote the contact to be *normally-closed*, not *closed*: it shows that a switch contact will be in the closed (conducting) state *when it is at rest*. What we actually need is a different kind of symbol to show when a contact is closed during any arbitrary condition we may imagine. When someone uses this same symbology to denote a contact that happens to be closed during some condition, it needlessly confuses the concepts of *closed* versus *normally-closed*.

Using arrow and “X” symbols again to represent the presence or absence of power in this circuit, we will now analyze its status with an applied switch pressure greater than 50 PSI:

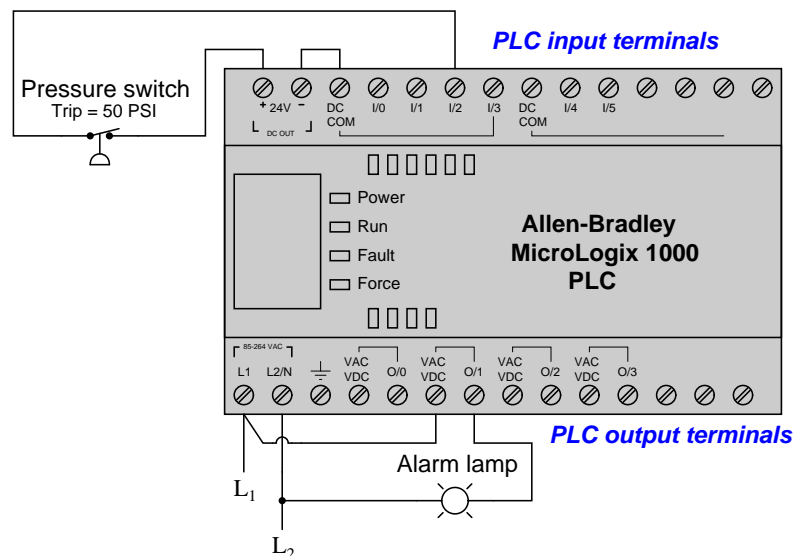

Now that there is sufficient fluid pressure applied to the switch to actuate it, its contact is forced into the actuated state which for this “normally-closed” switch is open. This open condition de-energizes relay coil CR1, allowing relay contact CR1-1 to spring-return to its normal status (closed), thus sending power to the alarm lamp. From this analysis we see that the lamp fulfills the function of a *high pressure alarm*, energizing when the applied pressure exceeds the trip point.

Where students typically find themselves confused is assuming the switch contact will be in the same state it is drawn in. This is not necessarily true. The way switch contacts are drawn merely reflects their *normal* status as defined by the switch manufacturer, which means the status of the switch when there is no (or insufficient) actuating stimulus present. Whether or not the switch will actually be in its normal state at any given time is a question of whether or not a sufficient stimulus is present to actuate that switch. Just because a switch is drawn normally-closed does not necessarily mean it *will* be closed when you go to analyze it. All it means is that the switch will be closed *when nothing actuates it*.

This exact same principle applies to relay ladder-logic programming in electronic control systems called PLCs (Programmable Logic Controllers). In a PLC, a digital microprocessor performs the logic functions traditionally provided by electromechanical relays, with the programming for this microprocessor taking the form of a relay diagram (also called a “ladder-logic” diagram).

Here, we will emulate the exact same high-pressure alarm circuit using an Allen-Bradley MicroLogix 1000 PLC instead of a relay coil:

**Wiring diagram:**

**Ladder-logic program:**

Suppose a fluid pressure of 36 PSI is applied to the pressure switch. This is less than the switch's trip setting of 50 PSI, leaving the switch in its "normal" (closed) state. This sends power to input I:0/2 of the PLC. The contact labeled I:0/2 drawn in the ladder-logic program of the PLC acts like a relay contact driven by a coil energized by input terminal I:0/2. Thus, the closed pressure switch

contact energizes input terminal I:0/2, which in turn “closes” the normally-open contact symbol I:0/2 drawn in the ladder-logic program. This “virtual” contact sends virtual power to a virtual coil labeled B3:0/0, which is nothing more than a single bit of data in the PLC’s microprocessor memory. “Energizing” this virtual coil has the effect of “actuating” any contact drawn in the program bearing the same label. This means the normally-closed contact B3:0/0 will now be “actuated” and thus in the open state, not sending virtual power to the output coil 0:0/1. With virtual coil 0:0/1 “unpowered,” the real-life output 0:0/1 on the PLC will be electrically open, and the alarm lamp will be unpowered (off).

If we apply a fluid pressure of 61 PSI to the pressure switch, the normally-closed pressure switch contact will be actuated (forced) into the open state. This will have the effect of de-energizing PLC input I:0/2, thus “opening” the normally-open virtual contact in the PLC program bearing the same label. This “open” virtual contact interrupts virtual power to the virtual coil B3:0/0, causing the normally-closed virtual contact B3:0/0 to “close,” sending virtual power to virtual coil 0:0/1. When this virtual output coil “energizes,” the real-life output channel of the PLC activates, sending real power to the alarm light to turn it on, signaling a high-pressure alarm condition.

We may simplify this PLC program further by eliminating the virtual control relay B3:0/0 and simply having input I:0/2 activate output 0:0/1 through a “normally-closed” virtual contact:

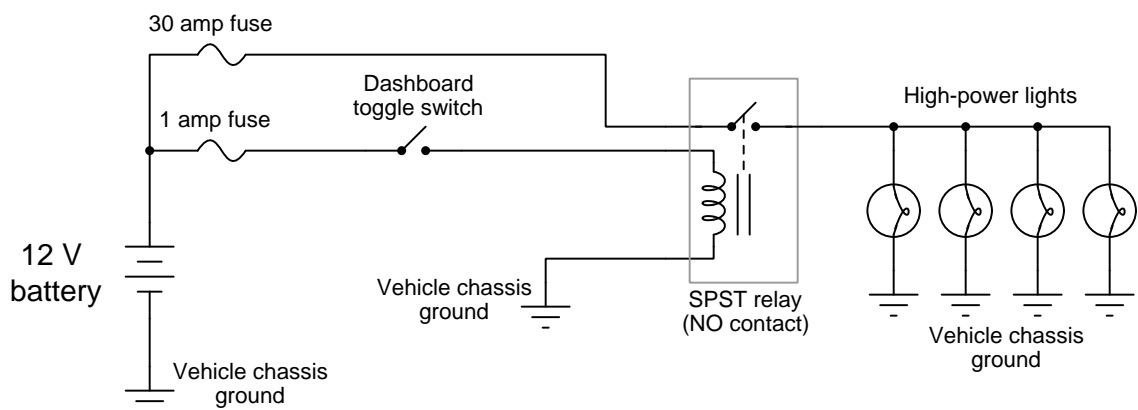

The effect is the same: the PLC output 0:0/1 will activate whenever input I:0/2 de-energizes (whenever the pressure switch is opened by a high pressure), turning on the alarm lamp in a high-pressure condition. In a low-pressure condition, the energized input I:0/2 forces the virtual normally-closed contact I:0/2 to open, thus de-energizing the PLC’s output 0:0/1 and turning the alarm lamp off.

Programmable Logic Controllers have not only greatly simplified the wiring of industrial logic controls by replacing multitudes of electromechanical relays with a microprocessor, but they have also added advanced capabilities such as counters, timers, sequencers, mathematical functions, communications, and of course the ability to easily modify the control logic through programming rather than by re-wiring relays. The beauty of ladder-logic programming is that it translates the technician’s understanding of traditional relay control circuits into a virtual form where contacts and coils interact to perform practical control functions. A key concept to master, however, is the association of real-life conditions to switch status based on the “normal” representation of those switch contacts, whether the switches be real (relay) or virtual (PLC). Once this vital concept is

mastered, both hard-wired relay control circuits and PLC programs become possible to understand. Without mastering this vital concept, neither relay control circuits nor PLC programs may be understood.

### 11.3 Interposing relays

In addition to directly performing logic functions, electromechanical relays may also be used as *interposing* devices between mismatched sensors, controllers, and/or control devices. A very simple example of a relay used to interpose between mismatched devices is shown in the following circuit diagram, where a delicate toggle switch is used to control a bank of high-power lights for an off-road vehicle:

In this circuit the relay performs no logic function whatsoever. Rather, it merely “amplifies” the signal sent by the dashboard toggle switch to send or halt power to the bank of high-power lights. Without the relay, a much heavier-duty toggle switch would have to be installed in the dashboard of this vehicle to safely and reliably make and break the light circuit.

Another example of an interposing relay found in automotive applications is the use of a “solenoid” in the electric starting motor circuit for an internal combustion engine. The “start” control switch is typically actuated by the driver turning a key, that switch mounted on the steering column or dashboard of the vehicle. The starting motor, meanwhile, typically draws *hundreds of amps* of current as it labors to start up the engine. A keyswitch capable of making and breaking hundreds of amps of current would be enormous, and in fact dangerous to locate in the cab of the vehicle. The “solenoid” relay connected between the keyswitch and the starting motor relocates that danger, and allows a relatively delicate keyswitch to safely activate the high-power motor.

An industrial example of an interposing relay between mismatched devices is shown here, where a DC output proximity switch must trigger an input channel to a Programmable Logic Controller (PLC) rated for 120 volts AC:

Again, the relay in this system performs no logic function, but merely allows the proximity switch to drive one of the PLC input channels. Directly connecting the proximity switch to one of the input channels of the PLC is not a practical option, because this particular PLC input requires 120 volts AC to activate, and our proximity switch operates on 24 volts DC. The mismatch between switch voltage and PLC input voltage requires us to use the relay to “interpose” between the switch and PLC. When the proximity switch senses an object nearby, its output activates, which in turn energizes the relay coil. When the relay contact magnetically closes, it completes a circuit for 120 volts AC to reach input channel 0 on the PLC, thereby energizing it.

An important detail in this relay circuit is the inclusion of a *commutating diode* in parallel with the relay coil, the purpose being to dissipate the coil’s stored energy upon de-energization when the proximity switch turns off. Without this diode in place, the coil’s “kickback” voltage (which may reach hundreds of volts in potential) will destroy the proximity switch’s output transistor.

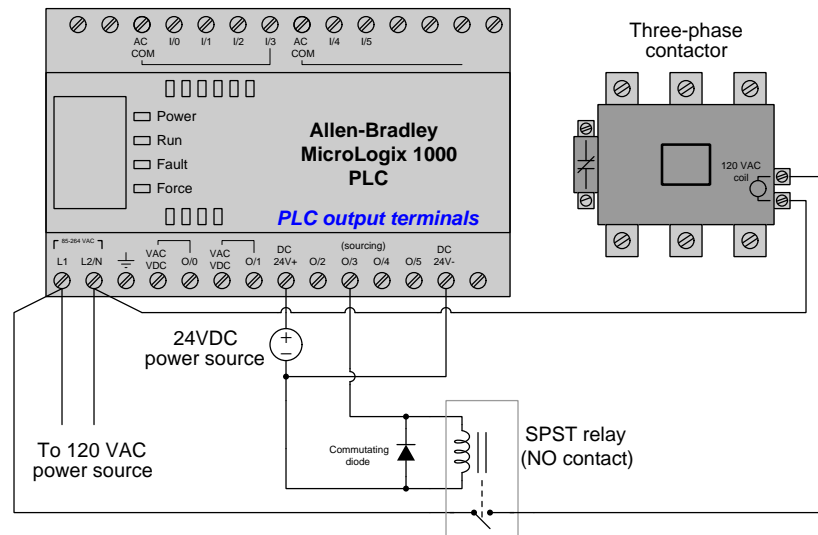

Note how this commutating diode appears to be connected “backwards” with regard to the polarity of the 24 volt DC power source: cathode toward the source’s positive pole and anode toward the source’s negative pole. This is intentional, as we do *not* wish to have the diode conduct when power is applied to the relay coil through the proximity switch<sup>2</sup>. The diode only turns on when the polarity reverses, which is what happens when the proximity switch turns off and the relay coil’s magnetic field collapses (now acting as a source rather than as a load). As the relay coil

<sup>2</sup>If the diode were connected the other way, it would pass current whenever the proximity switch turned on, shorting past the relay coil and most likely damaging the proximity switch in doing so!

temporarily outputs a “reverse” voltage, the diode gives that coil a continuous path for its current while dropping a low voltage (about 0.7 volts DC), dissipating the coil’s stored energy in the form of heat at the diode.

Interposing relays are also used to connected mismatched PLC outputs and control devices. In this application, the mismatch may be in terms of voltage ratings and/or current ratings. As with the input interposing circuit shown previously, the task of the relay in an output interposing circuit is to be controlled by the PLC’s output channel, and in turn direct power to a field device that is itself incompatible with the PLC’s output.

The following diagram shows an example of an interposing relay connected to a PLC output channel:

In this circuit the PLC’s transistor outputs can only handle 24 volts DC, and at fairly low current. The three-phase contactor<sup>3</sup> coil requires 120 volts AC at modest current levels to function, and so the relay interposes between the PLC’s low-voltage and low-current output channel and the relatively high-voltage and high-current demands of the contactor’s coil. Once again we see the use of a commutating diode to dissipate the relay coil’s stored energy whenever the PLC de-energizes it, so that the resulting “kickback” voltage does not damage the fragile transistor output circuitry within the PLC.

<sup>3</sup>A “contactor” is nothing more than a very large electromechanical relay, and itself is a form of interposing device. Its purpose is to make and break three-phase AC power to a heavy load (e.g. an electric motor) at the command of a much smaller electrical signal, in this case a 120 volt AC signal sent to the coil of the contactor.

## 11.4 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader's view of this chapter's concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **Amplification:** the control of a relatively large signal by a relatively small signal. Relevant to the role of relays as interposing devices.
- **Interposing:** the use of a relay as an intermediary between electrically incompatible devices.
- **“Normal” switch status:** the “normal” status of a switch contact as defined by the manufacturer is its *resting* condition (minimum stimulus).
- **“Seal-in” circuit:** when an electrical relay uses one of its own switch contacts to continue its own coil energization after the initial triggering event has passed. Relevant to all manner of relay control circuits.

## Chapter 12

# Programmable Logic Controllers

Every control system may be divided into three general sections: *input* devices (sensors), *controllers*, and *output* devices (actuators). The input devices sense what is happening in the process, the controller decides what to do about it, and the output devices manipulate the process to achieve the desired result.

A *programmable logic controller* or *PLC* is a general-purpose controller, applicable to many different types of process control applications. The word “programmable” in its name reveals just why PLCs are so useful: the end-user is able to program, or instruct, the PLC to do virtually any control function imaginable. Unlike PID loop controllers, which are special-purpose devices intended to perform a single type of control function, a PLC may be instructed to do almost anything with the signals it receives from input devices.

PLCs were introduced to industry as electronic replacements for electromechanical relay controls. In applications where relays typically control the starting and stopping of electric motors and other discrete output devices, the reliability of an electronic PLC meant fewer system failures and longer operating life. The re-programmability of a PLC also meant changes could be implemented to the control system strategy must easier than with relay circuits, where re-wiring was the only way to alter the system’s function. Additionally, the computer-based nature of a PLC meant that process control data could now be communicated by the PLC over *networks*, allowing process conditions to be monitored in distant locations, and by multiple operator stations.

The legacy of PLCs as relay-replacements is probably most evident in their traditional programming language: a graphical convention known as a *Ladder Diagram*. Ladder Diagram PLC programs resemble ladder-style electrical schematics, where vertical power “rails” convey control power to a set of parallel “rung” circuits containing switch contacts and relay coils. A human being programming a PLC literally draws the diagram on the screen, using relay-contact symbols to represent instructions to read data bits in the PLC’s memory, and relay-coil symbols to represent instructions writing data bits to the PLC’s memory. This style of programming was developed to make it easier for industrial electricians to adapt to the new technology of PLCs. While Ladder Diagram programming definitely has limitations compared to other computer programming languages, it is relatively easy to learn and diagnose, which is why it remains popular as a PLC programming language today.

Typical devices connecting to a PLC’s inputs include hand switches, process switches, sensors, analog transmitters (4-20 mA), thermocouples, thermistors, and strain gauges. Typical devices

connecting to a PLC's outputs include electric lamps, solenoids, relay coils, motor contactors, analog final control elements (e.g. throttling control valves, variable-speed motor drives), and audible buzzers. While PLCs were originally designed for discrete (on/off) control applications such as conveyor belt management, batch sequencing, and assembly line controls, modern PLCs are equally capable of inputting and outputting analog signals as well. Thus, it is just as likely now to find a PLC performing PID loop control as it is to find a PLC turning discrete devices on and off.

## 12.1 PLC examples

Programmable logic controllers are essentially nothing more than special-purpose, industrial computers. As such, they are built far more ruggedly than an ordinary personal computer (PC), and designed to run extremely reliable operating system software<sup>1</sup>. PLCs as a rule do not contain disk drives, cooling fans, or any other moving parts. This is an intentional design decision, intended to maximize the reliability of the hardware in harsh industrial environments where the PLC chassis may be subjected to temperature extremes, vibration, humidity, and airborne particulates (dust, fibers, and/or fumes).

Large PLC systems consist of a rack into which circuit “cards” are plugged. These cards include processors, input and output (I/O) points, communications ports, and other functions necessary to the operation of a complete PLC system. Such “modular” PLCs may be configured differently according to the specific needs of the application. Individual card failures are also easier to repair in a modular system, since only the failed card need be replaced, not all the cards or the whole card rack.

Small PLC systems consist of a monolithic “brick” containing all processor, I/O, and communication functions. These PLCs are typically far less expensive than their modular cousins, but are also more limited in I/O capability and must be replaced as a whole in the event of failure.

The following photographs show several examples of real PLC systems, some modular and some monolithic. These selections are not comprehensive by any means, as there are many more manufacturers and models of PLC than those I have photographed. They do, however, represent some of the more common brands and models in current (2010) industrial use.

---

<sup>1</sup>There are such things as *soft PLCs*, which consist of special-purpose software running on an ordinary personal computer (PC) with some common operating system. Soft PLCs enjoy the high speed and immense memory capacity of modern personal computers, but do not possess the same ruggedness either in hardware construction or in operating system design. Their applications should be limited to non-critical controls where neither main process production nor safety would be jeopardized by a control system failure.

The first photograph is of a Siemens (Texas Instruments) 505 series PLC, installed in a control panel of a municipal wastewater treatment plant. This is an example of a modular PLC, with individual processor, I/O, and communication cards plugged into a rack. Three racks appear in this photograph (two completely filled with cards, and the third only partially filled):

The power supply and processor card for each rack is located on the left-hand end, with I/O cards plugged into slots in the rest of the rack. Input devices such as switches and sensors connect by wire to terminals on *input* cards, while output devices such as lamps, solenoids, and motor contactor coils connect by wire to terminals on *output* cards.

One of the benefits of modular PLC construction is that I/O cards may be changed out as desired, altering the I/O configuration of the PLC as needed. If, for example, the PLC needs to be configured to monitor a greater number of sensors, more input cards may be plugged into the rack and subsequently wired to those sensors. Or, if the *type* of sensor needs to be changed – perhaps from a 24 volt DC sensor to one operating on 120 volts AC – a different type of input card may be substituted to match the new sensor(s).

In this particular application, the PLC is used to sequence the operation of self-cleaning “trash racks” used to screen large debris such as rags, sticks, and other non-degradable items from municipal wastewater prior to treatment. These trash racks are actuated by electric motors, the captured debris scraped off and transported to a solid waste handling system. The motion of the trash racks, the sensing of wastewater levels and pressures, and the monitoring of any human-operated override controls are all managed by these PLCs. The programming of these PLCs involves timers, counters, sequencers, and other functions to properly manage the continuous operation of the trash racks.

The next photograph shows an Allen-Bradley (Rockwell) PLC-5 system, used to monitor and control the operation of a large natural gas compressor. Two racks appear in this first photograph, with different types of I/O cards plugged into each rack:

Like the Siemens 505 PLC seen previously, this Allen-Bradley PLC-5 system is fully modular and configurable. The types and locations of the I/O cards inserted into the rack may be altered by appropriately skilled technicians to suit any desired application. The programming of the PLC's processor card may also be altered if a change in the control strategy is desired for any reason.

In this particular application, the PLC is tasked with monitoring certain variables on the gas compressor unit, and taking corrective action if needed to keep the machine productive and safe. The automatic control afforded by the PLC ensures safe and efficient start-ups, shut-downs, and handling of emergency events. The networking and data-logging capability of the PLC ensures that critical data on the compressor unit may be viewed by the appropriate personnel. For this particular compressor station, the data gets communicated from Washington state where the compressor is located all the way to Utah state where the main operations center is located. Human operators in Utah are able to monitor the compressor's operating conditions and issue commands to the compressor over digital networks.

Both the Siemens (formerly Texas Instruments) 505 and Allen-Bradley (Rockwell) PLC-5 systems are considered "legacy" PLC systems by modern standards, the two systems in the previous photographs being about 20 years old each. It is not uncommon to find "obsolete" PLCs still in operation, though. Given their extremely rugged construction and reliable design, these control systems may continue to operate without significant trouble for decades.

A newer model of PLC manufactured by Allen-Bradley is the SLC 500 series (often verbally referred to as the “Slick 500”), which is also modular in design like the older PLC-5 system, although the racks and modules of the SLC 500 design are more compact. The SLC 500 rack shown in the next photograph has 7 “slots” for processor and I/O cards to plug in to, numbered 0 through 6 (left to right):

The first three slots of this particular SLC 500 rack (0, 1, and 2) are occupied by the processor card, an analog input card, and a discrete input card, respectively. The slots 3 and 4 are empty (revealing the backplane circuit board and connectors for accepting new cards). The slots 5 and 6 hold discrete output and analog output cards, respectively.

A feature visible on all cards in this system are numerous LED indicators, designed to show the status of each card. The processor card has LED indicators for “Run” mode, “Fault” conditions, “Force” conditions (when either input or output bits have been forced into certain states by the human programmer for testing purposes), and communication network indicators. Each discrete I/O card has indicator LEDs showing the on/off status of each I/O bit, and the analog card has a single LED showing that the card is powered.

A nine-slot SLC 500 system is shown in the next photograph, controlling a high-purity water treatment system for a biopharmaceuticals manufacturing facility. As you can see in this photograph, not all slots in this particular rack are occupied by I/O cards either:

Some of the inputs to this PLC include water level switches, pressure switches, water flow meters, and conductivity meters (to measure the purity of the water, greater electrical conductivity indicating the presence of more dissolved minerals, which is undesirable in this particular process application). In turn, the PLC controls the starting and stopping of water pumps and the switching of water valves to manage the water purification and storage processes.

A modern PLC manufactured by Siemens appears in this next photograph, an S7-300, which is a different design of modular PLC. Instead of individual cards plugging into a rack, this modular PLC design uses individual modules plugging into each other on their sides to form a wider unit:

A modern PLC manufactured by Allen-Bradley (Rockwell) is this ControlLogix 5000 system, shown in this photograph used to control a cereal manufacturing process. The modular design of the ControlLogix 5000 system follows the more traditional scheme of individual cards plugged into a rack of fixed size:

While the Siemens S7 and Rockwell ControlLogix PLC platforms represent large-scale, modular PLC systems, there exist much smaller PLCs available for a fraction of the cost. Perhaps the least expensive PLC on the market at this time of writing is the Koyo “CLICK” PLC series, the processor module (with eight discrete input and six discrete output channels built in) shown in my hand (sold for 69 US dollars in the year 2010, and with free programming software!):

This is a semi-modular PLC design, with a minimum of input/output (I/O) channels built into the processor module, but having the capacity to accept multiple I/O modules plugged in to the side, much like the Siemens S7-300 PLC.

Other semi-modular PLCs expand using I/O cards that plug in to the base unit not unlike traditional rack-based PLC systems. The Koyo DirectLogic DL06 is a good example of this type of semi-modular PLC, the following photograph showing a model DL06 accepting a thermocouple input card in one of its four available card slots:

This photograph shows the PLC base unit with 20 discrete input channels and 16 discrete output channels, accepting an analog input card (this particular card is designed to input signals from thermocouples to measure up to four channels of temperature).

Some low-end PLCs are strictly monolithic, with no ability to accept additional I/O modules. This General Electric Series One PLC (used to monitor a small-scale hydroelectric power generating station) is an example of a purely monolithic design, having no “expansion” slots to accept I/O cards:

A disadvantage of monolithic PLC construction is that damaged I/O cannot be independently replaced. If an I/O channel on one of these PLCs becomes damaged, the entire PLC must be replaced to fix the problem. In a modular system, the damaged I/O card may simply be unplugged from the rack and replaced with a new I/O card. Another disadvantage of monolithic PLCs is the inherently fixed nature of the I/O: the end-user cannot customize the I/O configuration to match the application. For these reasons, monolithic PLCs are usually found on small-scale processes with few I/O channels and limited potential for expansion.

## 12.2 Input/Output (I/O) capabilities

Every programmable logic controller must have some means of receiving and interpreting signals from real-world sensors such as switches, and encoders, and also be able to effect control over real-world control elements such as solenoids, valves, and motors. This is generally known as *input/output*, or *I/O*, capability. Monolithic (“brick”) PLCs have a fixed amount of I/O capability built into the unit, while modular (“rack”) PLCs use individual circuit board “cards” to provide customized I/O capability.

The advantages of using replaceable I/O cards instead of a monolithic PLC design are numerous. First, and most obvious, is the fact that individual I/O cards may be easily replaced in the event of failure without having to replace the entire PLC. Specific I/O cards may be chosen for custom applications, biasing toward discrete cards for applications using many on/off inputs and outputs, or biasing toward analog cards for applications using many 4-20 mA and similar signals. Some PLCs even offer the feature of *hot-swappable* cards, meaning each card may be removed and a new one inserted without de-energizing power to the PLC processor and rack. Please note that one should not assume any system has hot-swappable cards, because if you attempt to change out a card “live” in a system without this feature, you run the risk of damaging the card and/or the rest of the unit it is plugged in to!

Some PLCs have the ability to connect to processor-less remote racks filled with additional I/O cards or modules, thus providing a way to increase the number of I/O channels beyond the capacity of the base unit. The connection from host PLC to remote I/O racks usually takes the form of a special digital network, which may span a great physical distance:

An alternative scheme for system expansion is to network multiple PLCs together, where each PLC has its own dedicated rack and processor. Through the use of communication instructions, one PLC may be programmed to read data from and/or write data to another PLC, effectively using the other PLC as an extension of its own I/O. Although this method is more expensive than remote I/O (where the remote racks lack their own dedicated processors), it provides the capability of stand-alone control in the event the network connection between PLC processors becomes severed.

Input/output capability for programmable logic controllers comes in three basic varieties: *discrete*, *analog*, and *network*; each type discussed in a following subsection.

### 12.2.1 Discrete I/O

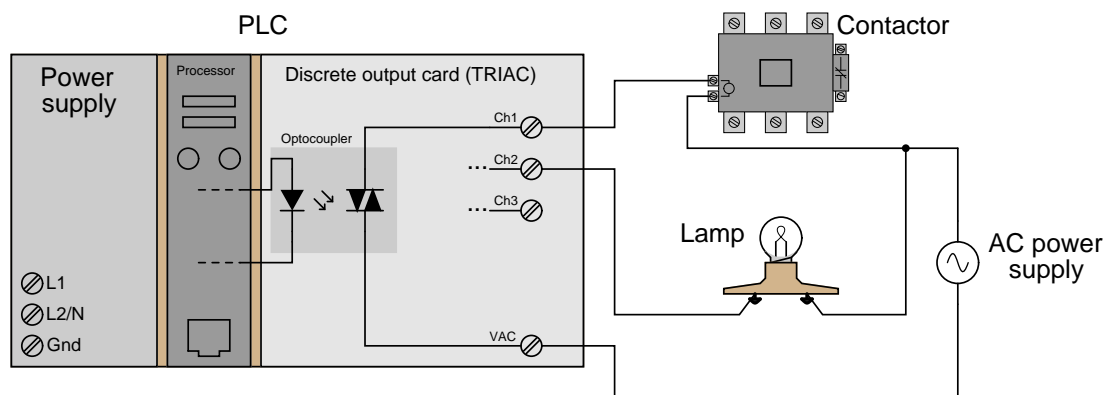

A “discrete” data point is one with only two states *on* and *off*. Process switches, pushbutton switches, limit switches, and proximity switches are all examples of discrete sensing devices. In order for a PLC to be aware of a discrete sensor’s state, it must receive a signal from the sensor through a *discrete input* channel. Inside each discrete input module is (typically) a set of light-emitting diodes (LEDs) which will be energized when the corresponding sensing device turns on. Light from each LED shines on a photo-sensitive device such as a phototransistor inside the module, which in turn activates a *bit* (a single element of digital data) inside the PLC’s memory. This opto-coupled arrangement makes each input channel of a PLC rather rugged, capable of isolating the sensitive computer circuitry of the PLC from transient voltage “spikes” and other electrical phenomena capable of causing damage:

*Energizing an input channel lights the LED inside the optocoupler, turning on the phototransistor, sending a "high" signal to the PLC's microprocessor, setting (1) that bit in the PLC's input register.*

The internal schematic diagram for a discrete input module (“card”) shown above reveals the componentry typical for a single input channel on that card. Each input channel has its own optocoupler, writing to its own unique memory register bit inside the PLC’s memory. Discrete input cards for PLCs typically have 4, 8, 16, or 32 channels.

Indicator lamps, solenoid valves, and motor starters (assemblies consisting of contactors and overload protection devices) are all examples of discrete control devices. In a manner similar to discrete inputs, a PLC connects to any number of different discrete final control devices through a *discrete output channel*<sup>2</sup>. Discrete output modules typically use the same form of opto-isolation to allow the PLC's computer circuitry to send electrical power to loads: the internal PLC circuitry driving an LED which then activates some form of photosensitive switching device. Alternatively, small electromechanical relays may be used in lieu of opto-isolating semiconductor switching elements such as transistors (DC) or TRIACs (AC):

*Setting a bit (1) in the PLC's output register sends a "high" signal to the LED inside the optocoupler, turning on the photo-TRIAC, sending AC power to the output channel to energize the load.*

As with the schematic diagram for a discrete input module shown previously, the schematic diagram shown here for a discrete output module reveals the componentry typical for a single channel on that card. Each output channel has its own optocoupler, driven by its own unique memory register bit inside the PLC's memory. Discrete output cards for PLCs also typically have 4, 8, 16, or 32 channels.

An important concept to master when working with DC discrete I/O is the distinction between *current-sourcing* and *current-sinking* devices. The terms "sourcing" and "sinking" refer to the direction of current (as denoted by conventional flow notation) into or out of a device's control wire<sup>3</sup>. A device sending (conventional flow) current out of its control terminal to some other device(s) is said to be *sourcing* current, while a device accepting (conventional flow) current into its control terminal is said to be *sinking* current.

<sup>2</sup>I/O "channels" are often referred to as "points" in industry lingo. Thus, a "32-point input card" refers to an input circuit with 32 separate channels through which to receive signals from on/off switches and sensors.

<sup>3</sup>By "control wire," I mean the single conductor connecting the I/O card channel to the field device, as opposed to conductors directly common with either the positive or negative lead of the voltage source. If you focus your attention on this one wire, noting the direction of conventional-flow current through it, the task of determining whether a device is sourcing or sinking current becomes much simpler.

To illustrate, the following illustration shows a PLC output channel is *sourcing* current to an indicator lamp, which is *sinking* current to ground:

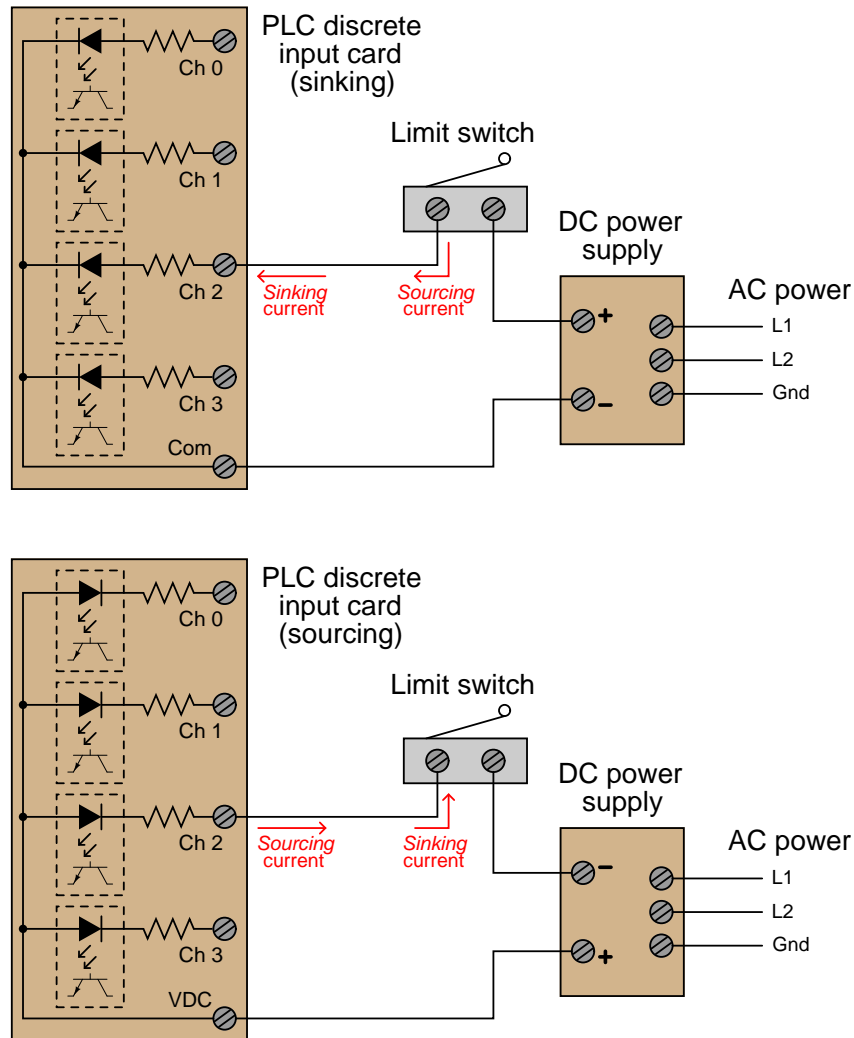

These terms really only make sense when electric current is viewed from the perspective of conventional flow, where the positive terminal of the DC power supply is envisioned to be the “source” of the current, with current finding its way “down” to ground (the negative terminal of the DC power supply). In every circuit formed by the output channel of a PLC driving a discrete control device, or by a discrete sensing device driving an input channel on a PLC, one element in the circuit must be sourcing current while the other is sinking current.

An engineering colleague of mine has a charming way to describe sourcing and sinking: *blowing* and *sucking*. A device that sources current to another “blows” current toward the other device. A device that sinks current “sucks” current from the other device. Many students seem to find these terms helpful in first mastering the distinction between sourcing and sinking despite (or perhaps because of!) their informal nature.

If the discrete device connecting to the PLC is not polarity-sensitive, either type of PLC I/O module will suffice. For example, the following diagrams show a mechanical limit switch connecting to a sinking PLC input and to a sourcing PLC input:

Note the differences in polarity and labeling between the sinking card's common terminal and the sourcing card's common terminal. On the "sinking" card, the input channel terminal is positive while the common ("Com") terminal is negative. On the "sourcing" card, the input channel terminal is negative while the common ("VDC") terminal is positive.

Some discrete sensing devices *are* polarity-sensitive, such as electronic proximity sensors containing transistor outputs. A “sourcing” proximity switch can only interface with a “sinking” PLC input channel, and vice-versa:

In all cases, the “sourcing” device sends current *out of* its signal terminal while the “sinking” device takes current *into* its signal terminal.

Two photographs of a DC (sinking) discrete input module for an Allen-Bradley model SLC 500 PLC are shown here: one with the plastic cover closed over the connection terminals, and the other with the plastic cover opened up for viewing the terminals. A legend on the inside of the cover shows the purpose of each screw terminal: eight input channels (numbered 0 through 7) and two redundant “DC Com” terminals for the negative pole of the DC power supply to connect:

A standard feature found on practically every PLC discrete I/O module is a set of LED indicators visually indicating the status of each bit (discrete channel). On the SLC 500 module, the LEDs appear as a cluster of eight numbered squares near the top of the module.

A photograph of discrete output terminals on another brand of PLC (a Koyo model DL06) shows somewhat different labeling:

Here, each output channel terminal is designated with a letter/number code beginning with the letter “Y”. Several “common” terminals labeled with “C” codes service clusters of output channels. In this particular case, each “common” terminal is common only to four output channels. With sixteen total output channels on this PLC, this means there are four different “common” terminals. While this may seem somewhat strange (why not just have one “common” terminal for all sixteen output channels?), it more readily permits different DC power supplies to service different sets of output channels.

Electrical polarity is not an issue with AC discrete I/O, since the polarity of AC reverses periodically anyway. However, there is still the matter of whether the “common” terminal on a discrete PLC module will connect to the *neutral* (grounded) or *hot* (ungrounded) AC power conductor.

The next photograph shows a discrete AC output module for an Allen-Bradley SLC 500 PLC, using TRIACs as power switching devices rather than transistors as is customary with DC discrete output modules:

This particular eight-channel module provides two sets of TRIACs for switching power to AC loads, each set of four TRIACs receiving AC power from a “hot” terminal (VAC 1 or VAC 2), the other side of the load device being connected to the “neutral” (grounded) conductor of the AC power source.

Fortunately, the hardware reference manual supplied by the manufacturer of every PLC shows diagrams illustrating how to connect discrete input and output channels to field devices. One should always consult these diagrams before connecting devices to the I/O points of a PLC!

### 12.2.2 Analog I/O

In the early days of programmable logic controllers, processor speed and memory were too limited to support anything but discrete (on/off) control functions. Consequently, the only I/O capability found on early PLCs were discrete in nature<sup>4</sup>. Modern PLC technology, though, is powerful enough to support the measurement, processing, and output of analog (continuously variable) signals.

All PLCs are digital devices at heart. Thus, in order to interface with an analog sensor or control device, some “translation” is necessary between the analog and digital worlds. Inside every analog input module is an *ADC*, or *Analog-to-Digital Converter*, circuit designed to convert an analog electrical signal into a multi-bit binary word. Conversely, every analog output module contains a *DAC*, or *Digital-to-Analog Converter*, circuit to convert the PLC’s digital command words into analog electrical quantities.

Analog I/O is commonly available for modular PLCs for many different analog signal types, including:

- Voltage (0 to 10 volt, 0 to 5 volt)
- Current (0 to 20 mA, 4 to 20 mA)
- Thermocouple (millivoltage)
- RTD (millivoltage)
- Strain gauge (millivoltage)

---

<sup>4</sup>Some modern PLCs such as the Koyo “CLICK” are also discrete-only. Analog I/O and processing is significantly more complex to engineer and more expensive to manufacture than discrete control, and so low-end PLCs are more likely to lack analog capability.

The following photographs show two analog I/O cards for an Allen-Bradley SLC 500 modular PLC system, an analog input card and an analog output card. Labels on the terminal cover doors indicate screw terminal assignments:

### 12.2.3 Network I/O

Many different digital network standards exist for PLCs to communicate with, from PLC to PLC and between PLCs and field devices. One of the earliest digital protocols developed for PLC communication was *Modbus*, originally for the Modicon brand of PLC. Modbus was adopted by other PLC and industrial device manufacturers as a *de facto* standard<sup>5</sup>, and remains perhaps the most universal digital protocol available for industrial digital devices today.

Another digital network standard developed by a particular manufacturer and later adopted as a *de facto* standard is *Profibus*, originally developed by Siemens.

For more information on networking standards used in PLC systems, refer to the “Digital electronic instrumentation” chapter, specifically sections on specific network standards such as Modbus and Profibus.

---

<sup>5</sup>A “de facto” standard is one arising naturally out of legacy rather than by an premeditated agreement between parties. Modbus and Profibus networks are considered “de facto” standards because those networks were designed, built, and marketed by pioneering firms prior to their acceptance as standards for others to conform to. In Latin, *de facto* means “from the fact,” which in this case refers to the fact of pre-existence: a standard agreed upon to conform to something already in popular use. By contrast, a standard intentionally agreed upon before its physical realization is a *de jure* standard (Latin for “from the law”). FOUNDATION Fieldbus is an example of a *de jure* standard, where a committee arrives at a consensus for a network design and specifications prior to that network being built and marketed by any firm.

## 12.3 Logic programming

Although it seems each model of PLC has its own idiosyncratic standard for programming, there does exist an international standard for controller programming that most PLC manufacturers at least attempt to conform to. This is the IEC 61131-3 standard, which will be the standard presented in this chapter.

One should take solace in the fact that despite differences in the details of PLC programming from one manufacturer to another and from one model to another, the basic principles are largely the same. There exist much greater disparities between different general-purpose programming languages (e.g. C/C++, BASIC, FORTRAN, Pascal, Java, Ada, etc.) than between the programming languages supported by different PLCs, and this fact does not prevent computer programmers from being “multilingual.” I have personally written and/or analyzed programs for over a half-dozen different manufacturers of PLCs (Allen-Bradley, Siemens, Square D, Koyo, Fanuc, Moore Products APACS and QUADLOG, and Modicon), with multiple PLC models within most of those brands, and I can tell you the differences in programming conventions are largely insignificant. After learning how to program one model of PLC, it is quite easy to adapt to programming other makes and models of PLC. If you are learning to program a particular PLC that does not exactly conform to the IEC 61131-3 standard, you will still be able to apply every single principle discussed in this chapter – the fundamental concepts are truly that universal.

The IEC 61131-3 standard specifies five distinct forms of programming language for industrial controllers:

- Ladder Diagram (LD)
- Structured Text (ST)
- Instruction List (IL)
- Function Block Diagram (FBD)
- Sequential Function Chart (SFC)

Not all programmable logic controllers support all five language types, but nearly all of them support Ladder Diagram (LD), which will be the primary focus of this book.

Programming languages for many industrial devices are limited by design. One reason for this is *simplicity*: any programming language simple enough in structure for someone with no formal computer programming knowledge to understand is going to be limited in its capabilities. Another reason for programming limitations is *safety*: the more flexible and unbounded a programming language is, the more potential there will be to unintentionally create complicated “run-time” errors when programming. The ISA safety standard number 84 classifies industrial programming languages as either *Fixed Programming Languages* (FPL), *Limited Variability Languages* (LVL), or *Full Variability Languages* (FVL). Ladder Diagram and Function Block Diagram programming are both considered to be “limited variability” languages, whereas Instruction List (and traditional computer programming languages such as C/C++, FORTRAN, BASIC, etc.) are considered “full variability” languages with all the attendant potential for complex errors.

### 12.3.1 Relating I/O status to virtual elements

Perhaps the most important yet elusive concept to grasp when learning to program PLCs is the relationship between the electrical status of the PLC's I/O points and the status of variables and other “elements” in its programming. This is especially true for Ladder Diagram (LD) programming, where the program itself resembles an electrical diagram. Making the mental connection between the “real” world of the switches, contactors, and other electrical devices connected to the PLC and the “imaginary” world of the PLC's program consisting of virtual contacts and relay “coils” is most fundamental.

The first fundamental rule one should keep in mind when examining a Ladder Diagram PLC program is that **each virtual contact shown in the program *actuates* whenever it reads a “1” state in its respective bit and will be *at rest* whenever it reads a “0” state in its respective bit** (in the PLC's memory). If the contact is a normally-open (NO) type, it will open when its bit is 0 and close when its bit is 1. If the contact is a normally-closed (NC) type, it will close when its bit is 0 and open when its bit is 1. A 0 bit state causes the contact to be in its “normal” (resting) condition, while a 1 bit state *actuates* the contact, forcing it into its non-normal (actuated) state.

Another rule to remember when examining a Ladder Diagram PLC program is that the programming software offers *color highlighting*<sup>6</sup> to display the virtual status of each program element: **a colored contact is *closed*, while an un-colored contact is *open***. While the presence or absence of a “slash” symbol marks the *normal* status of a contact, its live color highlighting shown by PLC programming software reveals the “conductive” status of the elements *in real time*.

The following table shows how the two types of contacts in a PLC's Ladder Diagram program respond to bit states, using red coloring to signify each contact's virtual conductivity:

		<i>Contact type</i>		
				
		Normally-open	Normally-closed	
<i>Bit state</i>	0	 (open)	 (closed)	(Normal)
	1	 (closed)	 (open)	(Actuated)

Just as a pressure switch's contacts are actuated by a high pressure condition, and a level switch's contacts are actuated by a high level condition, and a temperature switch's contacts are actuated by a high temperature condition, so a PLC's virtual contact is actuated by a high *bit* condition (1). In the context of any switch, an *actuated* condition is the opposite of its *normal* (resting) condition.

<sup>6</sup>It should be noted that in some situations the programming software will fail to color the contacts properly, especially if their status changes too quickly for the software communication link to keep up, and/or if the bit(s) change state multiple times within one scan of the program. However, for simple programs and situations, this rule holds true and is a great help to beginning programmers as they learn the relationship between real-world conditions and conditions within the PLC's “virtual” world.

The following simplified<sup>7</sup> illustration shows a small PLC with two of its discrete input channels electrically energized, causing those two bits to have “1” statuses. The color-highlighted contacts in the programming editor software’s display shows a collection of contacts addressed to those input bits in various states (colored = closed ; un-colored = open). As you can see, every contact addressed to a “set” bit (1) is in its actuated state, while every contact addressed to a “cleared” bit (0) is in its normal state:

(Displayed on the editing software)

Remember that a *colored* contact is a *closed* contact. The contacts appearing as colored are either normally-closed contacts with “0” bit states, or normally-open contacts with “1” bit states. It is the combination of bit state and contact type (NO vs. NC) that determines whether the virtual contact will be open (un-colored) or closed (colored) at any given time. Correspondingly, it is a combination of colored highlighting and virtual contact type that indicates the real-world energization status of a particular PLC input at any given time.

<sup>7</sup>The electrical wiring shown in this diagram is incomplete, with the “Common” terminal shown unconnected for simplicity’s sake.

In my teaching experience, the main problem students have comprehending PLC Ladder Diagram programs is that they over-simplify and try to directly associate real-world switches connected to the PLC with their respective contact instructions inside the PLC program. Students mistakenly think the real-world switch connecting to the PLC and the respective virtual switch contact inside the PLC program are one and the same, when this is not the case at all. Rather, the real-world switch sends power to the PLC input, *which in turn controls the state of the virtual contact(s) programmed into the PLC*. Specifically, I see students routinely fall into the following mis-conceptions:

- Students mistakenly think the contact instruction type (NO vs. NC) needs to match that of its associated real-world switch
- Students mistakenly think color highlighting of a contact instruction is equivalent to the electrical status of its associated real-world PLC input
- Students mistakenly think a closed real-world switch must result in a closed contact instruction in the live PLC program

To clarify, here are the fundamental rules one should keep in mind when interpreting contact instructions in Ladder Diagram PLC programs:

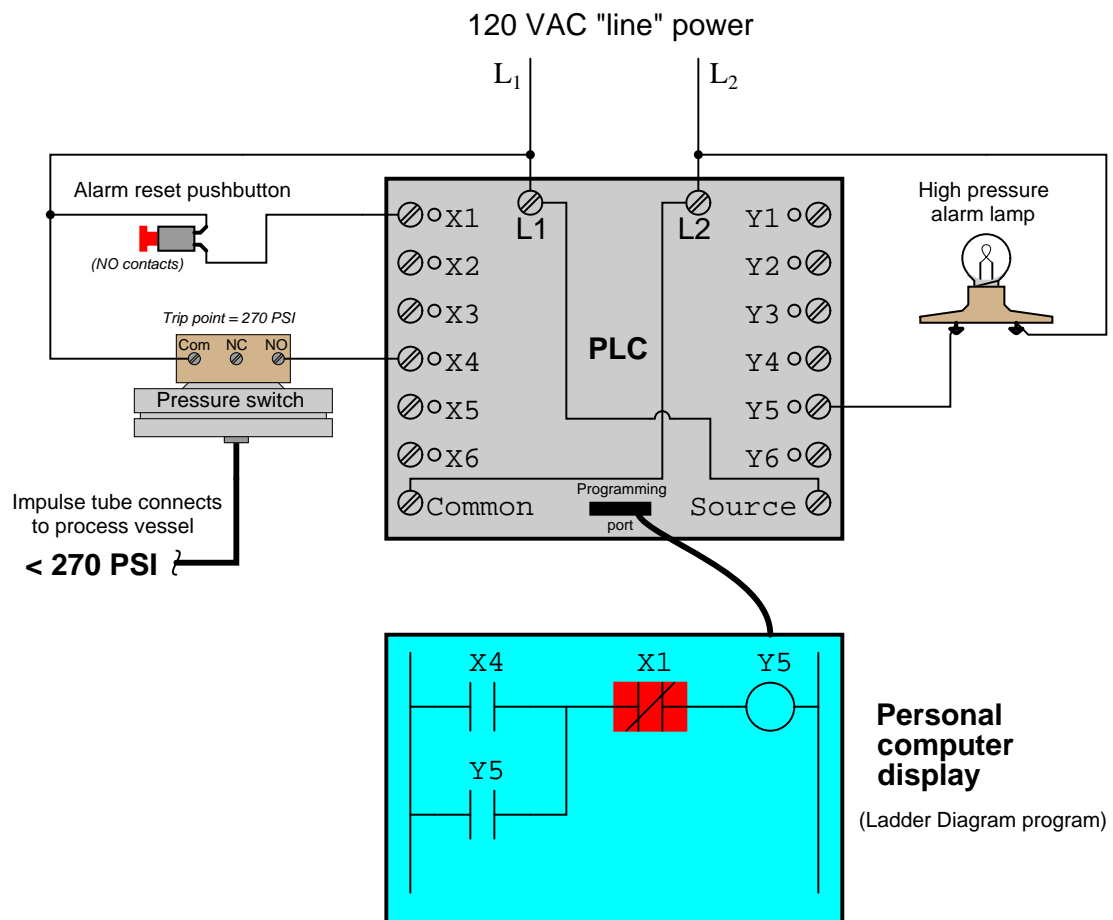

- **Each input bit in the PLC's memory will be a "1" when its input channel is powered, and will be a "0" when its input channel is unpowered**
- **Each virtual contact shown in the program *actuates* whenever it reads a "1" state in its respective bit, and will be *at rest* whenever it reads a "0" state in its respective bit**
- **A colored contact is *closed* (passes virtual power in the PLC program), while an un-colored contact is *open* (blocks virtual power in the PLC program)**

In trying to understand PLC Ladder Diagram programs, the importance of these rules cannot be overemphasized. The truth of the matter is a causal chain – rather than a direct equivalence – between the real-world switch and the contact instruction status. The real-world switch controls whether or not electrical power reaches the PLC input channel, which in turn controls whether the input register bit will be a "1" or a "0", which in turn controls whether the contact instruction will actuated or at rest. Virtual contacts inside the PLC program are thus *controlled* by their corresponding real-world switches, rather than simply being *identical* to their real-world counterparts as novices tend to assume. Following these rules, we see that normally-open (NO) contact instructions will mimic what their real-world switches are doing, while normally-closed (NC) contact instructions will act opposite of their real-world counterparts.

The color highlighting of *coil* instructions in a Ladder Diagram PLC program follows similar rules. A coil will be "on" (colored) when all contact instructions prior to it are closed (colored). A colored coil writes a "1" to its respective bit in memory, while an un-colored coil instruction writes a "0" to its respective bit in memory. If these bits are associated with real-world discrete output channels on the PLC, their states will control the real-world energization of devices electrically connected to those channels.

To further illuminate these fundamental concepts, we will examine the operation of a simple PLC system designed to energize a warning lamp in the event that a process vessel experiences a high fluid pressure. The PLC's task is to energize a warning lamp if the process vessel pressure ever exceeds 270 PSI, and keep that warning lamp energized even if the pressure falls below the trip point of 270 PSI. This way, operators will be alerted to both *past* and *present* process vessel overpressure events.

120 volt AC "line" power (L1 and L2) provides electrical energy for the PLC to operate, as well as signal potential for the input switches and power for the warning lamp. Two switches connect to the input of this PLC: one normally-open pushbutton switch acting as the alarm reset (pressing this switch "unlatches" the alarm lamp) and one normally-open pressure switch acting as the sensing element for high process vessel pressure:

The reset pushbutton connects to discrete input X1 of the PLC, while the pressure switch connects to discrete input X4. The warning lamp connects to discrete output Y5. Red indicator LEDs next to each I/O terminal visually indicate the electrical status of the I/O points, while red-shaded

highlighting shows the *virtual power*<sup>8</sup> status of the “contacts” and “coils” in the PLC’s program, displayed on the screen of a personal computer connected to the PLC through a programming cable.

With no one pressing the reset pushbutton, that switch will be in its normal status, which for a “normally-open” switch is open. Likewise with the pressure switch: with process pressure less than the trip point of 270 PSI, the pressure switch will also be in its normal status, which for a “normally-open” switch is open. Since neither switch is conducting electricity right now, neither discrete input **X1** nor **X4** will be energized. This means the “virtual” contacts inside the PLC program will likewise be in their own normal states. Thus, any virtual contact drawn as a normally-open will be open (not passing virtual power), and any virtual contact drawn as a normally-closed (a diagonal slash mark through the contact symbol) will be closed. This is why the two normally-open virtual contacts **X4** and **Y5** have no highlighting, but the normally-closed virtual contact **X1** does – the colored highlighting representing the ability to pass virtual power.

---

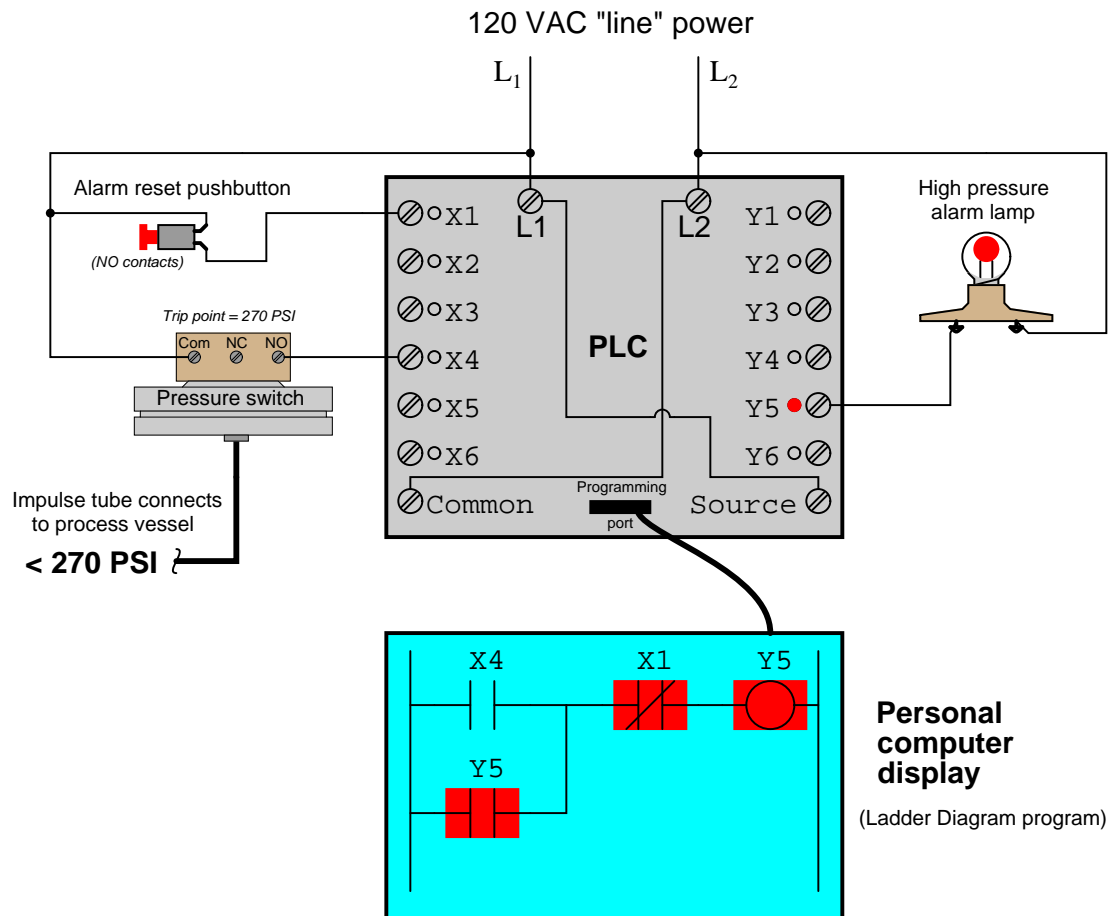

<sup>8</sup>For a PLC program contact, the shading represents virtual “conductivity.” For a PLC program coil, the shading represents a set (1) bit.

If the process vessel experiences a high pressure ( $> 270$  PSI), the pressure switch will actuate, closing its normally-open contact. This will energize input  $X4$  on the PLC, which will “close” the virtual contact  $X4$  in the ladder program. This sends virtual power to the virtual “coil”  $Y5$ , which in turn latches itself on through virtual contact  $Y5$ <sup>9</sup> and also energizes the real discrete output  $Y5$  to energize the warning lamp:

<sup>9</sup>It is worth noting the legitimacy of referencing virtual contacts to output bits (e.g. contact  $Y5$ ), and not just to input bits. A “virtual contact” inside a PLC program is nothing more than an instruction to the PLC’s processor to *read* the status of a bit in memory. It matters not whether that bit is associated with a physical input channel, a physical output channel, or some abstract bit in the PLC’s memory. It would, however, be wrong to associate a virtual coil with an input bit, as coil instructions *write* bit values to memory, and input bits are supposed to be controlled solely by the energization states of their physical input channels.

If now the process pressure falls below 270 PSI, the pressure switch will return to its normal state (open), thus de-energizing discrete input X4 on the PLC. Because of the latching contact Y5 in the PLC's program, however, output Y5 remains on to keep the warning lamp in its energized state:

Thus, the Y5 contact performs a *seal-in* function to keep the Y5 bit set (1) even after the high-pressure condition clears. This is precisely the same concept as the "seal-in" auxiliary contact on a hard-wired motor starter circuit, where the electromechanical contactor keeps itself energized after the "Start" pushbutton switch has been released.

The only way for a human operator to re-set the warning lamp is to press the pushbutton. This will have the effect of energizing input X1 on the PLC, thus opening virtual contact X1 (normally-closed) in the program, thus interrupting virtual power to the virtual coil Y5, thus powering down the warning lamp and un-latching virtual power in the program:

### 12.3.2 Memory maps and I/O addressing

A wise PLC programmer once told me that the first thing any aspiring programmer should learn about the PLC they intend to program is how the digital memory of that PLC is organized. This is sage advice for any programmer, especially on systems where memory is limited, and/or where I/O has a fixed association with certain locations in the system's memory. Virtually every microprocessor-based control system comes with a published *memory map* showing the organization of its limited memory: how much is available for certain functions, which addresses are linked to which I/O points, how different locations in memory are to be referenced by the programmer.

Discrete input and output channels on a PLC correspond to individual *bits* in the PLC's memory array. Similarly, analog input and output channels on a PLC correspond to multi-bit *words* (contiguous blocks of bits) in the PLC's memory. The association between I/O points and memory locations is by no means standardized between different PLC manufacturers, or even between different PLC models designed by the same manufacturer. This makes it difficult to write a general tutorial on PLC addressing, and so my ultimate advice is to consult the engineering references for the PLC system you intend to program.

The most common brand of PLC in use in the United States at the time of this writing (2010) is Allen-Bradley (Rockwell), which happens to use a unique form of I/O addressing<sup>10</sup> students tend to find confusing. For these two reasons (popularity and confusion), I will focus on Allen-Bradley addressing conventions for the bulk of this section.

---

<sup>10</sup>The most modern Allen-Bradley PLCs have all but done away with fixed-location I/O addressing, opting instead for *tag name* based I/O addressing. However, enough legacy Allen-Bradley PLC systems still exist in industry to warrant coverage of these addressing conventions.

The following table shows a partial memory map for an Allen-Bradley SLC 500 PLC<sup>11</sup>:

File number	File type	Logical address range
0	Output image	O:0 to O:30
1	Input image	I:0 to I:30
2	Status	S:0 to S: <i>n</i>
3	Binary	B3:0 to B3:255
4	Timers	T4:0 to T4:255
5	Counters	C5:0 to C5:255
6	Control	R6:0 to R6:255
7	Integer	N7:0 to N7:255
8	Floating-point	F8:0 to F8:255
9	Network	x9:0 to x9:255
10 through 255	User defined	x10:0 to x255:255

Note that Allen-Bradley's use of the word "file" differs from personal computer parlance. In the SLC 500 controller, a "file" is a block of random-access memory used to store a particular type of data. By contrast, a "file" in a personal computer is a contiguous collection of data bits with collective meaning (e.g. a word processing file or a spreadsheet file), usually stored on the computer's hard disk drive. Within each of the Allen-Bradley PLC's "files" are multiple "elements," each element consisting of a set of bits (8, 16, 24, or 32) representing data. Elements are addressed by number following the colon after the file designator, and individual bits within each element addressed by a number following a slash mark. For example, the first bit (bit 0) of the second element in file 3 (Binary) would be addressed as B3:2/0.

In Allen-Bradley PLCs such as the SLC 500 and PLC-5 models, files 0, 1, and 2 are exclusively reserved for discrete outputs, discrete inputs, and status bits, respectively. Thus, the letter designators O, I, and S (file types) are redundant to the numbers 0, 1, and 2 (file numbers). Other file types such as B (binary), T (timers), C (counters), and others have their own default file numbers (3, 4, and 5, respectively), but may also be used in some of the user-defined file numbers (10 and above). For example, file 7 in an Allen-Bradley controller is reserved for data of the "integer" type (N), but integer data may also be stored in any file numbered 10 or greater at the user's discretion. Thus, file numbers and file type letters for data types other than output (O), input (I), and status (S) always appear together. You would not typically see an integer word addressed as N:30 (integer word 30 in the PLC's memory) for example, but rather as N7:30 (integer word 30 *in file 7* of the PLC's memory) to distinguish it from other integer word 30's that may exist in other files of the PLC's memory.

---

<sup>11</sup>Also called the *data table*, this map shows the addressing of memory areas reserved for programs entered by the user. Other areas of memory exist within the SLC 500 processor, but these other areas are inaccessible to the technician writing PLC programs.

This file-based addressing notation bears further explanation. When an address appears in a PLC program, special characters are used to separate (or “delimit”) different fields from each other. The general scheme for Allen-Bradley SLC 500 PLCs is shown here:

Not all file types need to distinguish individual words and bits. Integer files (N), for example, consist of one 16-bit word for each element. For instance, N7:5 would be the 16-bit integer word number five held in file seven. A discrete input file type (I), though, needs to be addressed as individual bits because each separate I/O point refers to a single bit. Thus, I:3/7 would be bit number seven residing in input element three. The “slash” symbol is necessary when addressing discrete I/O bits because we do not wish to refer to all sixteen bits in a word when we just mean a single input or output point on the PLC. Integer numbers, by contrast, are collections of 16 bits each in the SLC 500 memory map, and so are usually addressed as entire words rather than bit-by-bit<sup>12</sup>.

Certain file types such as timers are more complex. Each timer “element”<sup>13</sup> consists of *two* different 16-bit words (one for the timer’s accumulated value, the other for the timer’s target value) in addition to no less than *three* bits declaring the status of the timer (an “Enabled” bit, a “Timing” bit, and a “Done” bit). Thus, we must make use of both the decimal-point and slash separator symbols when referring to data within a timer. Suppose we declared a timer in our PLC program with the address T4:2, which would be timer number two contained in timer file four. If we wished to address that timer’s current value, we would do so as T4:2.ACC (the “Accumulator” word of timer number two in file four). The “Done” bit of that same timer would be addressed as T4:2/DN (the “Done” bit of timer number two in file four)<sup>14</sup>.

<sup>12</sup>This is not to say one *cannot* specify a particular bit in an otherwise whole word. In fact, this is one of the powerful advantages of Allen-Bradley’s addressing scheme: it gives you the ability to precisely specify portions of data, even if that data is not generally intended to be portioned into smaller pieces!

<sup>13</sup>Programmers familiar with languages such as C and C++ might refer to an Allen-Bradley “element” as a *data structure*, each type with a set configuration of words and/or bits.

<sup>14</sup>Referencing the Allen-Bradley engineering literature, we see that the accumulator word may alternatively be addressed by number rather than by mnemonic, T4:2.2 (word 2 being the accumulator word in the timer data structure), and that the “done” bit may be alternatively addressed as T4:2.0/13 (bit number 13 in word 0 of the timer’s data structure). The mnemonics provided by Allen-Bradley are certainly less confusing than referencing word and bit numbers for particular aspects of a timer’s function!

A hallmark of the SLC 500's addressing scheme common to many legacy PLC systems is that the address labels for input and output bits explicitly reference the physical locations of the I/O channels. For instance, if an 8-channel discrete input card were plugged into slot 4 of an Allen-Bradley SLC 500 PLC, and you wished to specify the second bit (bit 1 out of a 0 to 7 range), you would address it with the following label: **I:4/1**. Addressing the seventh bit (bit number 6) on a discrete output card plugged into slot 3 would require the label **O:3/6**. In either case, the numerical structure of that label tells you exactly where the real-world input signal connects to the PLC.

To illustrate the relationship between physical I/O and bits in the PLC's memory, consider this example of an Allen-Bradley SLC 500 PLC, showing one of its discrete input channels energized (the switch being used as a "Start" switch for an electric motor):

A close-up photograph of a 32-bit DC input card for an Allen-Bradley SLC 500 PLC system shows this multi-word addressing:

The first sixteen input points on this card (the left-hand LED group numbered 0 through 15) are addressed  $I:X.0/0$  through  $I:X.0/15$ , with “X” referring to the slot number the card is plugged into. The next sixteen input points (the right-hand LED group numbered 16 through 31) are addressed  $I:X.1/0$  through  $I:X.1/15$ .

Legacy PLC systems typically reference each one of the I/O channels by labels such as “I:1/3” (or equivalent<sup>15</sup>) indicating the actual location of the input channel terminal on the PLC unit. The IEC 61131-3 programming standard refers to this channel-based addressing of I/O data points as *direct addressing*. A synonym for direct addressing is *absolute addressing*.

Addressing I/O bits directly by their card, slot, and/or terminal labels may seem simple and elegant, but it becomes very cumbersome for large PLC systems and complex programs. Every time a technician or programmer views the program, they must “translate” each of these I/O labels to some real-world device (e.g. “Input I:1/3 is actually the *Start* pushbutton for the middle tank mixer motor”) in order to understand the function of that bit. A later effort to enhance the clarity of PLC programming was the concept of addressing variables in a PLC’s memory by arbitrary names rather than fixed codes. The IEC 61131-3 programming standard refers to this as *symbolic addressing* in contrast to “direct” (channel-based) addressing, allowing programmers arbitrarily

<sup>15</sup>Some systems such as the Texas Instruments 505 series used “X” labels to indicate discrete input channels and “Y” labels to indicate discrete output channels (e.g. input X9 and output Y14). This same labeling convention is still used by Koyo in its DirectLogic and “CLICK” PLC models. Siemens continues a similar tradition of I/O addressing by using the letter “I” to indicate discrete inputs and the letter “Q” to indicate discrete outputs (e.g. input channel I0.5 and output Q4.1).

name I/O channels in ways that are meaningful to the system as a whole. To use our simple motor “Start” switch example, it is now possible for the programmer to designate input `I:1/3` (an example of a *direct address*) as “`Motor_start_switch`” (an example of a *symbolic address*) within the program, thus greatly enhancing the readability of the PLC program. Initial implementations of this concept maintained direct addresses for I/O data points, with symbolic names appearing as supplements to the absolute addresses.

The modern trend in PLC addressing is to avoid the use of direct addresses such as `I:1/3` altogether, so they do not appear anywhere in the programming code. The Allen-Bradley “Logix” series of programmable logic controllers is the most prominent example of this new convention at the time of this writing. Each I/O point, regardless of type or physical location, is assigned a *tag name* which is meaningful in a real-world sense, and these tag names (or *symbols* as they are alternatively called) are referenced to absolute I/O channel locations by a database file. An important requirement of tag names is that they contain no space characters between words (e.g. instead of “`Motor start switch`”, a tag name should use hyphens or underscore marks as spacing characters: “`Motor_start_switch`”), since spaces are generally assumed by computer programming languages to be delimiters (separators between different variables).

Having introduced Allen-Bradley’s addressing notation for SLC 500 model PLCs, I will now abandon it in favor of the modern convention of symbolic addressing throughout the rest of this chapter, so as to avoid making the programming examples brand- or model-specific. Each data point within my PLC programs will bear its own tag name rather than a direct (channel-based) address label.

## 12.4 Ladder Diagram (LD) programming

In the United States, the most common language used to program PLCs is *Ladder Diagram* (LD), also known as *Relay Ladder Logic* (RLL). This is a graphical language showing the logical relationships between inputs and outputs as though they were contacts and coils in a hard-wired electromechanical relay circuit. This language was invented for the express purpose of making PLC programming feel “natural” to electricians familiar with relay-based logic and control circuits. While Ladder Diagram programming has many shortcomings, it remains extremely popular and so will be the primary focus of this chapter.

Every Ladder Diagram program is arranged to resemble an electrical diagram, making this a graphical (rather than text-based) programming language. Ladder diagrams are to be thought of as *virtual circuits*, where virtual “power” flows through virtual “contacts” (when closed) to energize virtual “relay coils” to perform logical functions. None of the contacts or coils seen in a Ladder Diagram PLC program are real; rather, they act on bits in the PLC’s memory, the logical inter-relationships between those bits expressed in the form of a diagram *resembling* a circuit.

The following computer screenshot shows a typical Ladder Diagram program<sup>16</sup> being edited on a personal computer:

Contacts appear just as they would in an electrical relay logic diagram – as short vertical line segments separated by a horizontal space. Normally-open contacts are empty within the space between the line segments, while normally-closed contacts have a diagonal line crossing through that space. Coils are somewhat different, appearing as either circles or pairs of parentheses. Other instructions appear as rectangular boxes.

Each horizontal line is referred to as a *rung*, just as each horizontal step on a stepladder is called a “rung.” A common feature among Ladder Diagram program editors, as seen on this screenshot, is

<sup>16</sup>This particular program and editor is for the Koyo “CLICK” series of micro-PLCs.

the ability to color-highlight those virtual “components” in the virtual “circuit” ready to “conduct” virtual “power.” In this particular editor, the color used to indicate “conduction” is light blue. Another form of status indication seen in this PLC program is the values of certain variables in the PLC’s memory, shown in red text.

For example, you can see coil T2 energized at the upper-right corner of the screen (filled with light blue coloring), while coil T3 is not. Correspondingly, each normally-open T2 contact appears colored, indicating its “closed” status, while each normally-closed T2 contact is uncolored. By contrast, each normally-open T3 contact is uncolored (since coil T3 is unpowered) while each normally-closed T3 contact is shown colored to indicate its conductive status. Likewise, the current count values of timers T2 and T3 are shown as 193 and 0, respectively. The output value of the math instruction box happens to be 2400, also shown in red text.

Color-highlighting of Ladder Diagram components only works, of course, when the computer running the program editing software is connected to the PLC and the PLC is in the “run” mode (and the “show status” feature of the editing software is enabled). Otherwise, the Ladder Diagram is nothing more than black symbols on a white background. Not only is status highlighting very useful in de-bugging PLC programs, but it also serves an invaluable diagnostic purpose when a technician analyzes a PLC program to check the status of real-world input and output devices connected to the PLC. This is especially true when the program’s status is viewed remotely over a computer network, allowing maintenance staff to investigate system problems without even being near the PLC!

### 12.4.1 Contacts and coils

The most elementary objects in Ladder Diagram programming are *contacts* and *coils*, intended to mimic the contacts and coils of electromechanical relays. Contacts and coils are *discrete* programming elements, dealing with Boolean (1 and 0; on and off; true and false) variable states. Each contact in a Ladder Diagram PLC program represents the *reading* of a single bit in memory, while each coil represents the *writing* of a single bit in memory.

Discrete input signals to the PLC from real-world switches are read by a Ladder Diagram program by contacts referenced to those input channels. In legacy PLC systems, each discrete input channel has a specific address which must be applied to the contact(s) within that program. In modern PLC systems, each discrete input channel has a tag name created by the programmer which is applied to the contact(s) within the program. Similarly, discrete output channels – referenced by coil symbols in the Ladder Diagram – must also bear some form of address or tag name label.

To illustrate, we will imagine the construction and programming of a redundant flame-sensing system to monitor the status of a burner flame using three sensors. The purpose of this system will be to indicate a “lit” burner if at least two out of the three sensors indicate flame. If only one sensor indicates flame (or if no sensors indicate flame), the system will declare the burner to be un-lit. The burner’s status will be visibly indicated by a lamp that human operators can readily see inside the control room area.

Our system's wiring is shown in the following diagram:

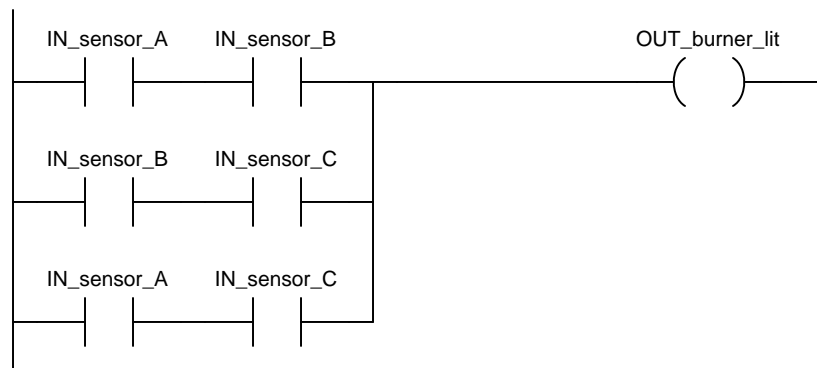

Each flame sensor outputs a DC voltage signal indicating the detection of flame at the burner, either on (24 volts DC) or off (0 volts DC). These three discrete DC voltage signals are sensed by the first three channels of the PLC's discrete input card. The indicator lamp is a 120 volt light bulb, and so must be powered by an AC discrete output card, shown here in the PLC's last slot.

To make the ladder program more readable, we will assign tag names (symbolic addresses) to each input and output bit in the PLC, describing its real-world device in an easily-interpreted format<sup>17</sup>. We will tag the first three discrete input channels as `IN_sensor_A`, `IN_sensor_B`, and `IN_sensor_C`, and the output as `OUT_burner_lit`.

<sup>17</sup>If this were a legacy Allen-Bradley PLC system using absolute addressing, we would be forced to address the three sensor inputs as `I:1/0`, `I:1/1`, and `I:1/2` (slot 1, channels 0 through 2), and the indicator lamp output as `O:2/0` (slot 2, channel 0). If this were a newer Logix5000 Allen-Bradley PLC, the default tag names would be `Local:1:I.Data.0`, `Local:1:I.Data.1`, and `Local:1:I.Data.2` for the three inputs, and `Local:2:O.Data.0` for the output. However, in either system we have the ability to assign symbolic addresses so we have a way to reference the I/O channels without having to rely on these cumbersome labels. The programs showing in this book exclusively use tag names rather than absolute addresses, since this is the more modern programming convention.

A ladder program to determine if at least two out of the three sensors detect flame is shown here, with the tag names referencing each contact and coil:

Series-connected contacts in a Ladder Diagram perform the logical **AND** function, while parallel contacts perform the logical **OR** function. Thus, this two-out-of-three flame-sensing program could be verbally described as:

“Burner is lit if either *A and B*, or either *B and C*, or either *A and C*”

An alternate way to express this is to use the notation of *Boolean algebra*, where multiplication represents the **AND** function and addition represents the **OR** function:

$$\text{Burner\_lit} = AB + BC + AC$$

Yet another way to represent this logical relationship is to use logic gate symbols:

To illustrate how this program would work, we will consider a case where flame sensors B and C detect flame, but sensor A does not<sup>18</sup>. This represents a two-out-of-three-good condition, and so we would expect the PLC to turn on the “Burner lit” indicator light as programmed. From the perspective of the PLC’s rack, we would see the indicator LEDs for sensors B and C lit up on the discrete input card, as well as the indicator LED for the lamp’s output channel:

Those two energized input channels “set” bits (1 status) in the PLC’s memory representing the status of flame sensors B and C. Flame sensor A’s bit will be “clear” (0 status) because its corresponding input channel is de-energized. The fact that the output channel LED is energized (and the “Burner lit” indicator lamp is energized) tells us the PLC program has “set” that corresponding bit in the PLC’s output memory register to a “1” state.

<sup>18</sup>The most likely reason why one out of two flame sensors might not detect the presence of a flame is some form of misalignment or fouling of the flame sensor. In fact, this is a good reason for using a 2-out-of-3 flame detection system rather than a simplex (1-out-of-1) detector scheme: to make the system more tolerant of occasional sensor problems without compromising burner safety.

A display of input and output register bits shows the “set” and “reset” states for the PLC at this moment in time:

Input register								Output register							
0	0	0	0	0	1	1	0	0	0	0	0	0	0	0	1
I7	I6	I5	I4	I3	I2	I1	I0	OUT7	OUT6	OUT5	OUT4	OUT3	OUT2	OUT1	OUT0

Examining the Ladder Diagram program with status indication enabled, we see how only the middle contact pair is passing “virtual power” to the output coil:

Recall that the purpose of a contact in a PLC program is to *read* the status of a bit in the PLC's memory. These six “virtual contacts” read the three input bits corresponding to the three flame sensors. Each normally-open “contact” will “close” when its corresponding bit has a value of 1, and will “open” (go to its normal state) when its corresponding bit has a value of 0. Thus, we see here that the two contacts corresponding to sensor A appear without highlighting (representing no “conductivity” in the virtual relay circuit) because the bit for that input is reset (0). The two contacts corresponding to sensor B and the two contacts corresponding to sensor C all appear highlighted (representing “conductivity” in the virtual circuit) because their bits are both set (1).

Recall also that the purpose of a coil in a PLC program is to *write* the status of a bit in the PLC's memory. Here, the “energized” coil sets the bit for the PLC output 0 to a “1” state, thus activating the real-world output and sending electrical power to the “Burner lit” lamp.

Note that the color highlighting does *not* indicate a virtual contact is *conducting* virtual power, but merely that it is *able* to conduct power. Color highlighting around a virtual coil, however, *does* indicate the presence of virtual “power” at that coil.

Contacts and relays are not just useful for implementing simple logic functions, but they may also perform *latching* functions as well. A very common application of this in industrial PLC systems is a latching start/stop program for controlling electric motors by means of momentary-contact pushbutton switches. As before, this functionality will be illustrated by means of an hypothetical example circuit and program:

In this system, two pushbutton switches are connected to discrete inputs on a PLC, and the PLC in turn energizes the coil of a motor contactor relay by means of one of its discrete outputs<sup>19</sup>.

<sup>19</sup>The particular input and output channels chosen for this example are completely arbitrary. There is no particular

An overload contact is wired directly in series with the contactor coil to provide motor overcurrent protection, even in the event of a PLC failure where the discrete output channel remains energized<sup>20</sup>.

The ladder program for this motor control system would look like this:

Pressing the “Start” pushbutton energizes discrete input channel 6 on the PLC, which “closes” the virtual contact in the PLC program labeled `IN_switch_Start`. The normally-closed virtual contact for input channel 7 (the “Stop” pushbutton) is already closed by default when the “Stop” button is not being pressed, and so the virtual coil will receive “power” when the “Start” pushbutton is pressed and the “Stop” pushbutton is not.

Note the *seal-in* contact bearing the exact same label as the coil: `OUT_contactor`. At first it may seem strange to have both a contact and a coil in a PLC program labeled identically<sup>21</sup>, since contacts are most commonly associated with inputs and coils with outputs, but this makes perfect sense if you realize the true meaning of contacts and coils in a PLC program: as *read* and *write* operations on bits in the PLC’s memory. The coil labeled `OUT_contactor` *writes* the status of that bit, while the contact labeled `OUT_contactor` *reads* the status of that same bit. The purpose of this contact, of course, is to latch the motor in the “on” state after a human operator has released his or her finger from the “Start” pushbutton.

This programming technique is known as *feedback*, where an output variable of a function (in this case, the feedback variable is `OUT_contactor`) is also an input to that same function. The path of feedback is *implicit* rather than *explicit* in Ladder Diagram programming, with the only indication of feedback being the common name shared by coil and contact. Other graphical programming languages (such as Function Block) have the ability to show feedback paths as connecting lines between function outputs and inputs, but this capacity does not exist in Ladder Diagram.

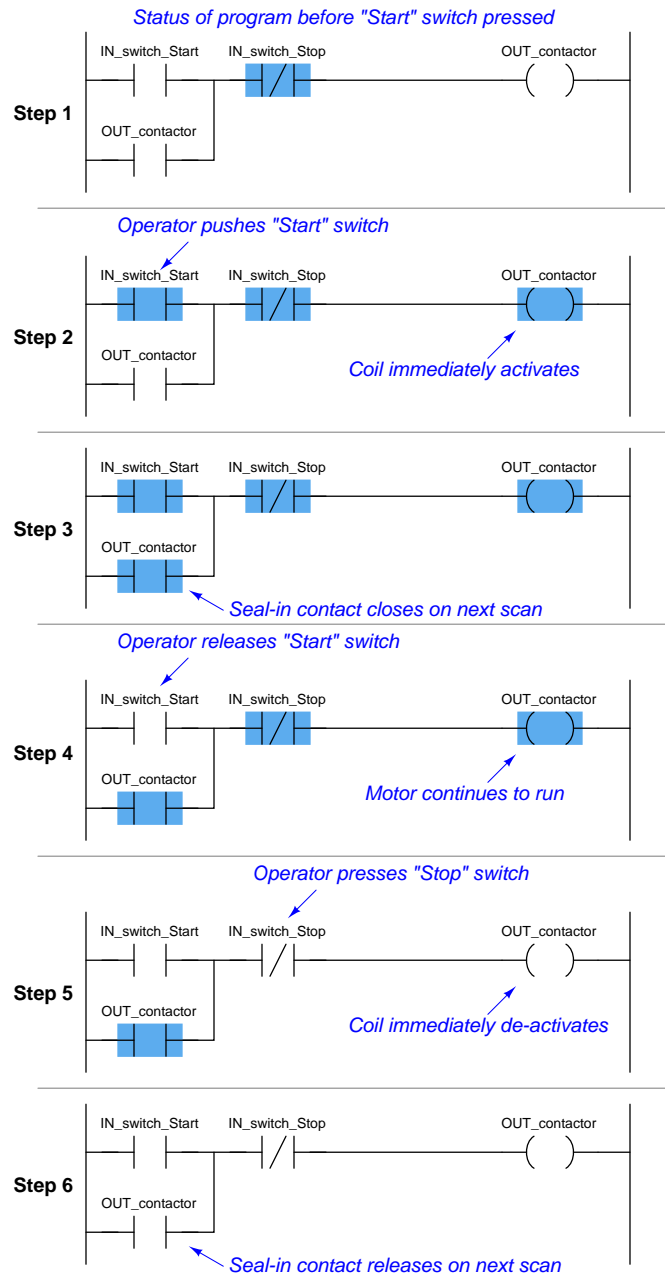

---

reason to choose input channels 6 and 7, or output channel 2, as I have shown in the wiring diagram. Any available I/O channels will suffice.

<sup>20</sup>While it is possible to wire the overload contact to one of the PLC’s discrete input channels and then program a *virtual* overload contact in series with the output coil to stop the motor in the event of a thermal overload, this strategy would rely on the PLC to perform a safety function which is probably better performed by hard-wired circuitry.

<sup>21</sup>A very common misconception among students first learning PLC Ladder Diagram programming is to always associate contacts with PLC inputs and coils with PLC outputs, thus it seems weird to have a contact bear the same label as an output. However, this is a false association. In reality, contacts and coils are *read* and *write* instructions, and thus it is possible to have the PLC read one of its own output bits as a part of some logic function. What *would* be truly strange is to label a coil with an input bit address or tag name, since the PLC is not electrically capable of setting the real-world energization status of any input channels.

A step-by-step sequence showing the operation and status of this simple program illustrates how the seal-in contact functions, through a start-up and shut-down cycle of the motor:

This sequence helps illustrate the *order of evaluation* or *scan order* of a Ladder Diagram program. The PLC reads a Ladder Diagram from left to right, top to bottom, in the same general order as

a human being reads sentences and paragraphs written in English. However, according to the IEC 61131-3 standard, a PLC program must evaluate (read) all inputs (contacts) to a function before determining the status of a function's output (coil or coils). In other words, the PLC does not make any decision on how to set the state of a coil until all contacts providing power to that coil have been read. Once a coil's status has been written to memory, any contacts bearing the same tag name will update with that status on subsequent rungs in the program.

Step 5 in the previous sequence is particularly illustrative. When the human operator presses the "Stop" pushbutton, the input channel for `IN_switch_Stop` becomes activated, which "opens" the normally-closed virtual contact `IN_switch_Stop`. Upon the next scan of this program rung, the PLC evaluates all input contacts (`IN_switch_Start`, `IN_switch_Stop`, and `OUT_contactor`) to check their status before deciding what status to write to the `OUT_contactor` coil. Seeing that the `IN_switch_Stop` contact has been forced open by the activation of its respective discrete input channel, the PLC writes a "0" (or "False") state to the `OUT_contactor` coil. However, the `OUT_contactor` feedback contact does not update until the next scan, which is why you still see it color-highlighted during step 5.

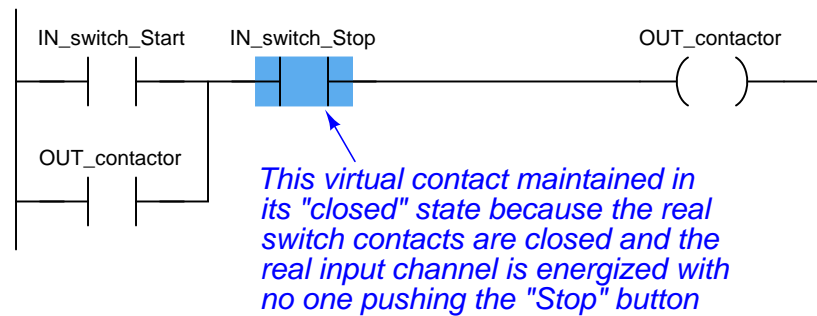

A potential problem with this system as it is designed is that the human operator loses control of the motor in the event of an "open" wiring failure in either pushbutton switch circuit. For instance, if a wire fell off a screw contact for the "Start" pushbutton switch circuit, the motor could not be started if it was already stopped. Similarly, if a wire fell off a screw contact for the "Stop" pushbutton switch circuit, the motor could not be stopped if it was already running. In either case, a broken wire connection acts the same as the pushbutton switch's "normal" status, which is to keep the motor in its present state. In some applications, this failure mode would not be a severe problem. In many applications, though, it is quite dangerous to have a running motor that cannot be stopped. For this reason, it is customary to design motor start/stop systems a bit differently from what has been shown here.

In order to build a “fail-stop” motor control system with our PLC, we must first re-wire the pushbutton switch to use its normally-closed (NC) contact:

This keeps discrete input channel 7 activated when the pushbutton is unpressed. When the operator presses the “Stop” pushbutton, the switch’s contact will be forced open, and input channel 7 will de-energize. If a wire happens to fall off a screw terminal in the “Stop” switch circuit, input channel 7 will de-energize just the same as if someone pressed the “Stop” pushbutton, which will automatically shut off the motor.

In order for the PLC program to work properly with this new switch wiring, the virtual contact for `IN_switch_Stop` must be changed from a normally-closed (NC) to a normally-open (NO):

As before, the `IN_switch_Stop` virtual contact is in the “closed” state when no one presses the “Stop” switch, enabling the motor to start any time the “Start” switch is pressed. Similarly, the `IN_switch_Stop` virtual contact will open any time someone presses the “Stop” switch, thus stopping virtual “power” from flowing to the `OUT_contactor` coil.

Although this is a very common way to build PLC-controlled motor start/stop systems – with an NC pushbutton switch and an NO “Stop” virtual contact – students new to PLC programming often find this logical reversal confusing<sup>22</sup>. Perhaps the most common reason for this confusion is a mis-understanding of the “normal” concept for switch contacts, be they real or virtual. The `IN_switch_Stop` virtual contact is programmed to be normally-open (NO), but yet it is *typically* found in the closed state. Recall that the “normal” status of any switch is its status while in a resting condition of no stimulation, *not* necessarily its status while the process is in a “normal” operating mode. The “normally-open” virtual contact `IN_switch_Stop` is typically found in the closed state because its corresponding input channel is typically found energized, owing to the normally-closed pushbutton switch contact, which passes real electrical power to the input channel while no one presses the switch. Just because a switch is configured as normally-open does not necessarily mean it will be *typically* found in the open state! The status of any switch contact, whether real or virtual, is a function of its configuration (NO versus NC) and the stimulus applied to it.

Another concern surrounding real-world wiring problems is what this system will do if the motor contactor coil circuit opens for any reason. An open circuit may develop as a result of a wire falling off a screw terminal, or it may occur because the thermal overload contact tripped open due to an over-temperature event. The problem with our motor start/stop system as designed is that it is not “aware” of the contactor’s real status. In other words, the PLC “thinks” the contactor will be

<sup>22</sup>In an effort to alleviate this confusion, the Allen-Bradley corporation (Rockwell) uses the terms *examine if closed* (XIC) and *examine if open* (XIO) to describe “normally open” and “normally closed” virtual contacts, respectively, in their Ladder Diagram programming. The idea here is that a virtual contact drawn as a normally-open symbol will be “examined” (declared “true”) by the PLC’s processor if its corresponding input channel is energized (powered by a real-life contact in the *closed* state). Conversely, a virtual contact drawn as a normally-closed symbol (with a slash mark through the middle) will be “examined” by the PLC’s processor if its corresponding input channel is de-energized (if the real-life contact sending power to that terminal is in the open state). In my experience, I have found this nomenclature to be even more confusing to students than simply calling these virtual contacts “normally open” and “normally closed” like other PLC manufacturers do. The foundational concept for students to grasp here is that *the virtual contact is not a direct representation of the real-life electrical switch contact – rather, it is a read instruction for the bit set by power coming from the real-life electrical switch contact.*

energized any time discrete output channel 2 is energized, but that may not actually be the case if there is an open fault in the contactor's coil circuit.

This may lead to a dangerous condition if the open fault in the contactor's coil circuit is later cleared. Imagine an operator pressing the "Start" switch but noticing the motor does not actually start. Wondering why this may be, he or she goes to look at the overload relay to see if it is tripped. If it is tripped, and the operator presses the "Reset" button on the overload assembly, the motor will immediately start because the PLC's discrete output has remained energized all the time following the pressing of the "Start" switch. Having the motor start up as soon as the thermal overload is reset may come as a surprise to operations personnel, and this could be quite dangerous if anyone happens to be near the motor-powered machinery when it starts.

What would be safer is a motor control system that refuses to "latch" on unless the contactor actually energizes when the "Start" switch is pressed. For this to be possible, the PLC must have some way of sensing the contactor's status.

In order to make the PLC “aware” of the contactor’s real status, we may connect the auxiliary switch contact to one of the unused discrete input channels on the PLC, like this:

Now, the PLC is able to sense the real-time status of the contactor via input channel 5.

We may modify the PLC program to recognize this status by assigning a new tag name to this input (`IN_contactor_aux`) and using a normally-open virtual contact of this name as the seal-in contact instead of the `OUT_contactor` bit:

Now, if the contactor fails to energize for any reason when the operator presses the “Start” switch, the PLC’s output will fail to latch when the “Start” switch is released. When the open fault in the contactor’s coil circuit is cleared, the motor will *not* immediately start up, but rather wait until the operator presses the “Start” switch again, which is a much safer operating characteristic than before.

A special class of virtual “coil” used in PLC ladder programming that bears mentioning is the “latching” coil. These usually come in two forms: a *set* coil and a *reset* coil. Unlike a regular “output” coil that positively writes to a bit in the PLC’s memory with every scan of the program, “set” and “reset” coils only write to a bit in memory when energized by virtual power. Otherwise, the bit is allowed to retain its last value.

A very simple motor start/stop program could be written with just two input contacts and two of these latching coils (both bearing the same tag name, writing to the same bit in memory):

### Real-world I/O wiring

### PLC program

Note the use of a normally-open (NO) pushbutton switch contact (again!), with no auxiliary contact providing status indication of the contactor to the PLC. This is a very minimal program, shown for the strict purpose of illustrating the use of “set” and “reset” latching coils in Ladder Diagram PLC programming.

“Set” and “Reset” coils<sup>23</sup> are examples of what is known in the world of PLC programming as *retentive instructions*. A “retentive” instruction *retains* its value after being virtually “de-energized” in the Ladder Diagram “circuit.” A standard output coil is *non-retentive*, which means it does not “latch” when de-energized. The concept of retentive and non-retentive instructions will appear again as we explore PLC programming, especially in the area of *timers*.

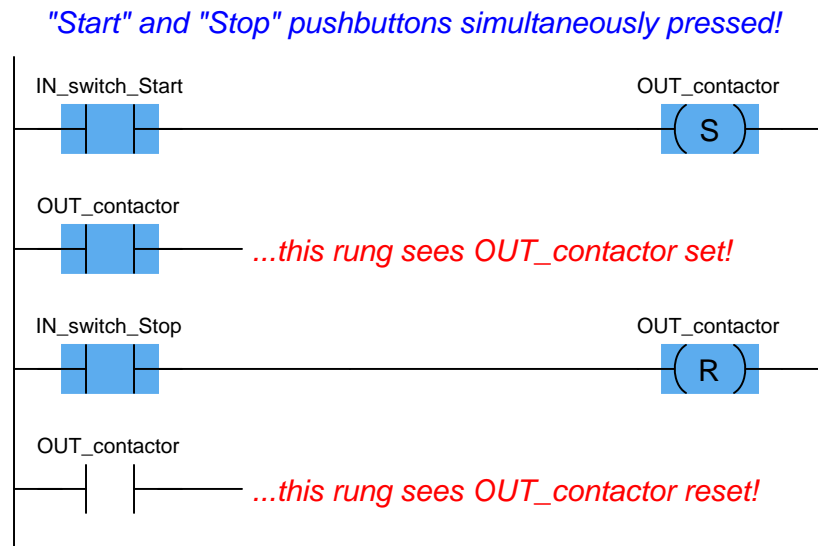

Ordinarily, we try to avoid multiple coils bearing the same label in a PLC Ladder Diagram program. With each coil representing a “write” instruction, multiple coils bearing the same name represents multiple “write” operations to the same bit in the PLC’s memory. Here, with latching coils, there is no conflict because each of the coils only writes to the `OUT_contactor` bit when its

<sup>23</sup>Referred to as “Latch” and “Unlatch” coils by Allen-Bradley.

respective contact is energized. So long as only one of the pushbutton switches is actuated at a time, there is no conflict between the identically-named coils.

This raises the question: what would happen if *both* pushbutton switches were simultaneously pressed? What would happen if *both* “Set” and “Reset” coils were “energized” at the same time? The result is that the `OUT_contactor` bit would first be “set” (written to a value of 1) then “reset” (written to a value of 0) in that order as the two rungs of the program were scanned from top to bottom. PLCs typically do not typically update their discrete I/O registers while scanning the Ladder Diagram program (this operation takes place either before or after each program scan), so the real discrete output channel status will be whatever the *last* write operation told it to be, in this case “reset” (0, or off).

Even if the discrete output is not “confused” due to the conflicting write operations of the “Set” and “Reset” coils, other rungs of the program written between the “Set” and “Reset” rungs might be. Consider for example a case where there were other program rungs following the “Set” and “Reset” rungs reading the status of the `OUT_contactor` bit for some purpose. Those other rungs *would* indeed become “confused” because they would see the `OUT_contactor` bit in the “set” state while the actual discrete output of the PLC (and any rungs following the “Reset” rung) would see the `OUT_contactor` bit in the “reset” state:

Multiple (non-retentive) output coils with the same memory address are almost always a programming *faux pax* for this reason, but even retentive coils which are designed to be used in matched pairs can cause trouble if the implications of simultaneous energization are not anticipated. Multiple *contacts* with identical addresses are no problem whatsoever, because multiple “read” operations to the same bit in memory will never cause a conflict.

The IEC 61131-3 PLC programming standard specifies *transition-sensing* contacts as well as the more customary “static” contacts. A transition-sensing contact will “actuate” only for a duration of one program scan, even if its corresponding bit remains active. Two types of transition-sensing Ladder Diagram contacts are defined in the IEC standard: one for *positive* transitions and another

for *negative* transitions. The following example shows a wiring diagram, Ladder Diagram program, and a timing diagram demonstrating how each type of transition-sensing contact functions when stimulated by a real (electrical) input signal to a discrete channel:

### Real-world I/O wiring

### PLC program

### Timing diagram

When the pushbutton switch is pressed and the discrete input energized, the first test lamp will blink “on” for exactly one scan of the PLC’s program, then return to its off state. The positive-transition contact (with the letter “P” inside) activates the coil `OUT_test1` only during the scan it sees the status of `IN_test` transition from “false” to “true,” even though the input remains energized for many scans after that transition. Conversely, when the pushbutton switch is released and the discrete input de-energizes, the second test lamp will blink “on” for exactly one scan of the PLC’s

program then return to its off state. The negative-transition contact (with the letter “N” inside) activates the coil `OUT_test2` only during the scan it sees the status of `IN_test` transition from “true” to “false,” even though the input remains de-energized for many scans after that transition:

It should be noted that the duration of a single PLC program scan is typically very short: measured in milliseconds. If this program were actually tested in a real PLC, you would probably not be able to see either test lamp light up, since each pulse is so short-lived. Transitional contacts are typically used any time it is desired to execute an instruction just one time following a “triggering” event, as opposed to executing that instruction over and over again so long as the event status is maintained “true.”

Contacts and coils represent only the most basic of instructions in the Ladder Diagram PLC programming language. Many other instructions exist, which will be discussed in the following subsections.

### 12.4.2 Counters

A *counter* is a PLC instruction that either increments (counts up) or decrements (counts down) an integer number value when prompted by the transition of a bit from 0 to 1 (“false” to “true”). Counter instructions come in three basic types: *up* counters, *down* counters, and *up/down* counters. Both “up” and “down” counter instructions have single inputs for triggering counts, whereas “up/down” counters have two trigger inputs: one to make the counter increment and one to make the counter decrement.

To illustrate the use of a counter instruction, we will analyze a PLC-based system designed to count objects as they pass down a conveyor belt:

In this system, a continuous (unbroken) light beam causes the light sensor to close its output contact, energizing discrete channel IN4. When an object on the conveyor belt interrupts the light beam from source to sensor, the sensor's contact opens, interrupting power to input IN4. A pushbutton switch connected to activate discrete input IN5 when pressed will serve as a manual “reset” of the count value. An indicator lamp connected to one of the discrete output channels will serve as an indicator of when the object count value has exceeded some pre-set limit.

We will now analyze a simple Ladder Diagram program designed to increment a counter instruction each time the light beam breaks:

This particular counter instruction (CTU) is an incrementing counter, which means it counts “up” with each off-to-on transition input to its “CU” input. The normally-closed virtual contact (IN\_sensor\_object) is typically held in the “open” state when the light beam is continuous, by virtue of the fact the sensor holds that discrete input channel energized while the beam is continuous. When the beam is broken by a passing object on the conveyor belt, the input channel de-energizes, causing the virtual contact IN\_sensor\_object to “close” and send virtual power to the “CU” input of the counter instruction. This increments the counter just as the leading edge of the object breaks the beam. The second input of the counter instruction box (“R”) is the *reset* input, receiving virtual power from the contact IN\_switch\_reset whenever the reset pushbutton is pressed. If this input is activated, the counter immediately resets its current value (CV) to zero.

Status indication is shown in this Ladder Diagram program, with the counter’s preset value (PV) of 25 and the counter’s current value (CV) of 0 shown highlighted in blue. The preset value is something programmed into the counter instruction before the system put into service, and it serves as a threshold for activating the counter’s output (Q), which in this case turns on the count indicator lamp (the OUT\_counts\_reached coil). According to the IEC 61131-3 programming standard, this counter output should activate whenever the current value is equal to or greater than the preset value (Q is active if  $CV \geq PV$ ).

This is the status of the same program after thirty objects have passed by the sensor on the conveyor belt. As you can see, the current value of the counter has increased to 30, exceeding the preset value and activating the discrete output:

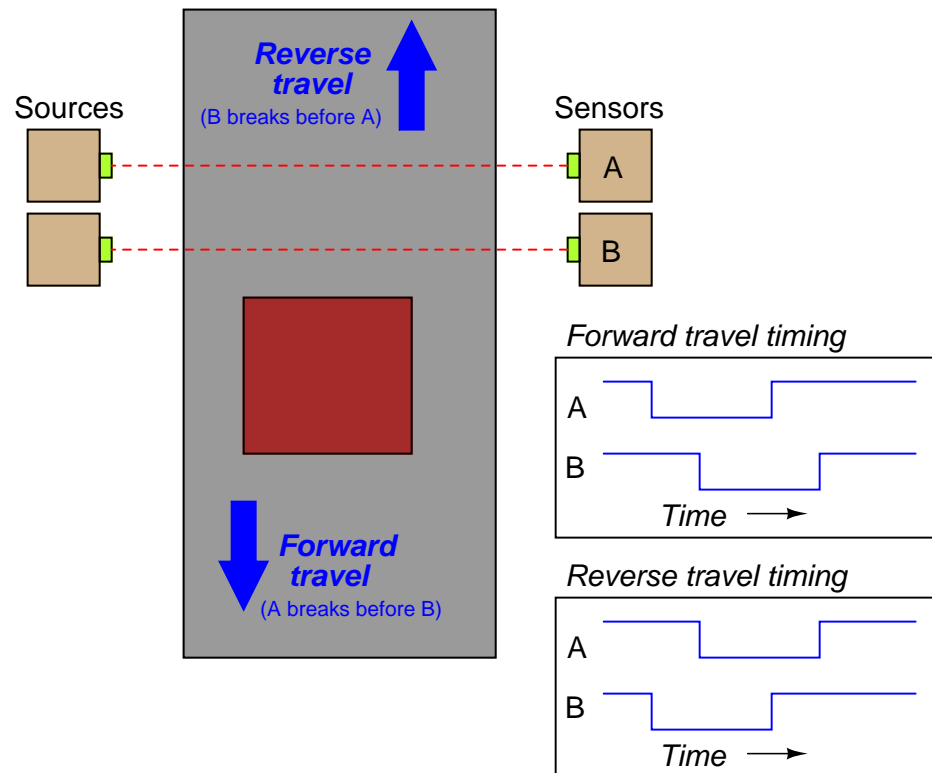

If all we did not care about maintaining an accurate total count of objects past 25 – but merely wished the program to indicate when 25 objects had passed by – we could also use a *down* counter instruction preset to a value of 25, which turns on an output coil when the count reaches zero:

Here, a “load” input causes the counter’s current value to equal the preset value (25) when activated. With each sensor pulse received, the counter instruction decrements. When it reaches zero, the Q output activates.

A potential problem in either version of this object-counting system is that the PLC cannot discriminate between forward and reverse motion on the conveyor belt. If, for instance, the conveyor belt were ever reversed in direction, the sensor would continue to count objects that had already passed by before (in the forward direction) as those objects retreated on the belt. This would be a problem because the system would “think” more objects had passed along the belt (indicating greater production) than actually did.

One solution to this problem is to use an up/down counter, capable of both incrementing (counting up) and decrementing (counting down), and equip this counter with two light-beam sensors capable of determining direction of travel. If two light beams are oriented parallel to each other, closer than the width of the narrowest object passing along the conveyor belt, we will have enough information to determine direction of object travel:

This is called *quadrature* signal timing, because the two pulse waveforms are approximately  $90^\circ$  (one-quarter of a period) apart in phase. We can use these two phase-shifted signals to increment or decrement an up/down counter instruction, depending on which pulse leads and which pulse lags.

A Ladder Diagram PLC program designed to interpret the quadrature pulse signals is shown here, making use of negative-transition contacts as well as standard contacts:

The counter will increment (count up) when sensor B de-energizes only if sensor A is already in the de-energized state (i.e. light beam A breaks before B). The counter will decrement (count down) when sensor A de-energizes only if sensor B is already in the de-energized state (i.e. light beam B breaks before A).

Note that the up/down counter has both a “reset” (R) input and a “load” input (“LD”) to force the current value. Activating the reset input forces the counter’s current value (CV) to zero, just as we saw with the “up” counter instruction. Activating the load input forces the counter’s current value to the preset value (PV), just as we saw with the “down” counter instruction. In the case of an up/down counter, there are two Q outputs: a QU (output up) to indicate when the current value is equal to or greater than the preset value, and a QD (output down) to indicate when the current value is equal to or less than zero.

Note how the current value (CV) of each counter shown is associated with a tag name of its own, in this case `parts_counted`. The integer number of a counter’s current value (CV) is a variable in the PLC’s memory just like boolean values such as `IN_sensor_A` and `IN_switch_reset`, and may be associated with a tag name or symbolic address just the same<sup>24</sup>. This allows other instructions in a PLC program to read (and sometimes write!) values from and to that memory location.

<sup>24</sup>This represents the IEC 61131-3 standard, where each variable within an instruction may be “connected” to its own arbitrary tag name. Other programming conventions may differ somewhat. The Allen-Bradley Logix5000 series of controllers is one of those that differs, following a convention reminiscent of structure element addressing in the C programming language: each counter is given a tag name, and variables in each counter are addressed as elements within that structure. For example, a Logix5000 counter instruction might be named `parts_count`, with the accumulated count value (equivalent to the IEC’s “current value”) addressed as `parts_count.ACC` (each element within the counter specified as a suffix to the counter’s tag name).

### 12.4.3 Timers

A *timer* is a PLC instruction measuring the amount of time elapsed following an event. Timer instructions come in two basic types: *on-delay* timers and *off-delay* timers. Both “on-delay” and “off-delay” timer instructions have single inputs triggering the timed function.

An “on-delay” timer activates an output only when the input has been active for a minimum amount of time. Take for instance this PLC program, designed to sound an audio alarm siren prior to starting a conveyor belt. To start the conveyor belt motor, the operator must press and hold the “Start” pushbutton for 10 seconds, during which time the siren sounds, warning people to clear away from the conveyor belt that is about to start. Only after this 10-second start delay does the motor actually start (and latch “on”):

*Real-world I/O wiring*

*PLC program*

Similar to an “up” counter, the on-delay timer’s elapsed time (ET) value increments once per second until the preset time (PT) is reached, at which time its output (Q) activates. In this program, the preset time value is 10 seconds, which means the Q output will not activate until the “Start” switch has been depressed for 10 seconds. The alarm siren output, which is not activated by the timer, energizes immediately when the “Start” pushbutton is pressed.

An important detail regarding this particular timer’s operation is that it be *non-retentive*. This means the timer instruction should *not* retain its elapsed time value when the input is de-activated. Instead, the elapsed time value should reset back to zero every time the input de-activates. This ensures the timer resets itself when the operator releases the “Start” pushbutton. A *retentive* on-delay timer, by contrast, maintains its elapsed time value even when the input is de-activated. This makes it useful for keeping “running total” times for some event.

Most PLCs provide retentive and non-retentive versions of on-delay timer instructions, such that the programmer may choose the proper form of on-delay timer for any particular application. The IEC 61131-3 programming standard, however, addresses the issue of retentive versus non-retentive timers a bit differently. According to the IEC 61131-3 standard, a timer instruction may be specified with an additional *enable* input (EN) that causes the timer instruction to behave non-retentively when activated, and retentively when de-activated. The general concept of the enable (EN) input is that the instruction behaves “normally” so long as the enable input is active (in this case, non-retentive timing action is considered “normal” according to the IEC 61131-3 standard), but the instruction “freezes” all execution whenever the enable input de-activates. This “freezing” of operation has the effect of retaining the current time (CT) value even if the input signal de-activates.

For example, if we wished to add a retentive timer to our conveyor control system to record total run time for the conveyor motor, we could do so using an “enabled” IEC 61131-3 timer instruction like this:

When the motor’s contactor bit (`OUT_contactor`) is active, the timer is enabled and allowed to time. However, when that bit de-activates (becomes “false”), the timer instruction as a whole is disabled, causing it to “freeze” and retain its current time (CT) value<sup>25</sup>. This allows the motor to be started and stopped, with the timer maintaining a tally of total motor run time.

If we wished to give the operator the ability to manually reset the total run time value to zero, we could hard-wire an additional switch to the PLC’s discrete input card and add “reset” contacts to the program like this:

Whenever the “Reset” switch is pressed, the timer is enabled (EN) but the timing input (IN) is disabled, forcing the timer to (non-retentively) reset its current time (CT) value to zero.

<sup>25</sup>The “enable out” (ENO) signal on the timer instruction serves to indicate the instruction’s status: it activates when the enable input (EN) activates and de-activates when either the enable input de-activates or the instruction generates an error condition (as determined by the PLC manufacturer’s internal programming). The ENO output signal serves no useful purpose in this particular program, but it is available if there were any need for other rungs of the program to be “aware” of the run-time timer’s status.

The other major type of PLC timer instruction is the *off-delay* timer. This timer instruction differs from the on-delay type in that the timing function begins as soon as the instruction is de-activated, not when it is activated. An application for an off-delay timer is a cooling fan motor control for a large industrial engine. In this system, the PLC starts an electric cooling fan as soon as the engine is detected as rotating, and keeps that fan running for two minutes following the engine's shut-down to dissipate residual heat:

### Real-world I/O wiring

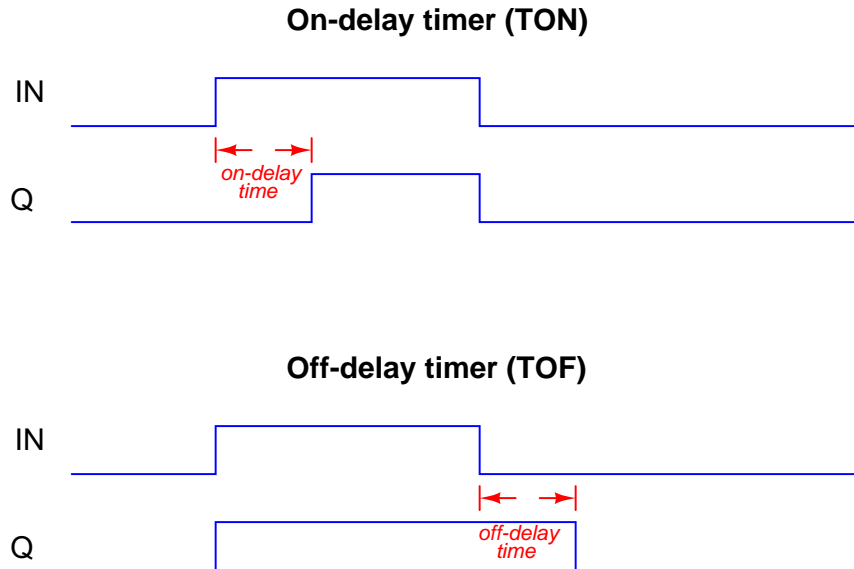

### PLC program

When the input (IN) to this timer instruction is activated, the output (Q) immediately activates (with no time delay at all) to turn on the cooling fan motor contactor. This provides the engine with cooling as soon as it begins to rotate (as detected by the speed switch connected to the PLC's discrete input). When the engine stops rotating, the speed switch returns to its normally-open position, de-activating the timer's input signal which starts the timing sequence. The Q output remains active while the timer counts from 0 seconds to 120 seconds. As soon as it reaches 120 seconds, the output de-activates (shutting off the cooling fan motor) and the elapsed time value remains at 120 seconds until the input re-activates, at which time it resets back to zero.

The following timing diagrams compare and contrast on-delay with off-delay timers:

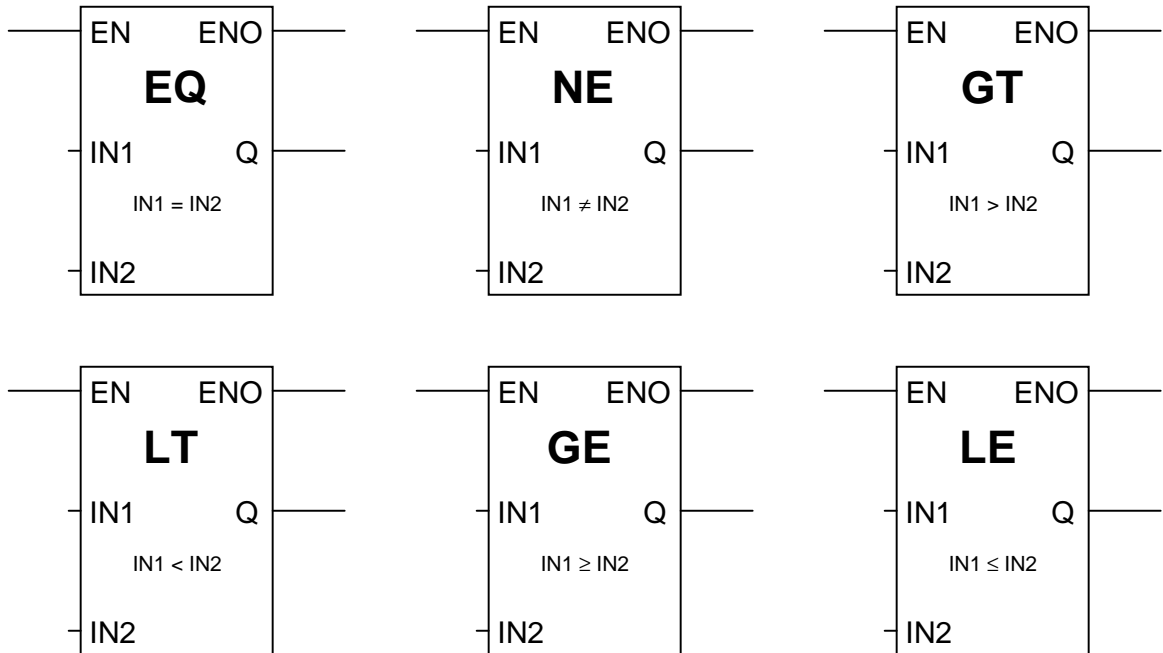

While it is common to find on-delay PLC instructions offered in both retentive and non-retentive forms within the instruction sets of nearly every PLC manufacturer and model, it is almost unheard of to find retentive off-delay timer instructions. Typically, off-delay timers are non-retentive only<sup>26</sup>.

<sup>26</sup>The enable (EN) input signals specified in the IEC 61131-3 programming standard make retentive off-delay timers possible (by de-activating the enable input while maintaining the “IN” input in an inactive state), but bear in mind that most PLC implementations of timers do not have separate EN and IN inputs. This means (for most PLC timer instructions) the only input available to activate the timer is the “IN” input, in which case it is *impossible* to create a retentive off-delay timer (since such a timer’s elapsed time value would be immediately re-set to zero each time the input re-activates).

### 12.4.4 Data comparison instructions

As we have seen with counter and timers, some PLC instructions generate digital values other than simple Boolean (on/off) signals. Counters have current value (CV) registers and timers have elapsed time (ET) registers, both of which are typically integer number values. Many other PLC instructions are designed to receive and manipulate non-Boolean values such as these to perform useful control functions.

The IEC 61131-3 standard specifies a variety of *data comparison* instructions for comparing two non-Boolean values, and generating Boolean outputs. The basic comparative operations of “less than” ( $<$ ), “greater than” ( $>$ ), “less than or equal to” ( $\leq$ ), “greater than or equal to” ( $\geq$ ), “equal to” ( $=$ ), and “not equal to” ( $\neq$ ) may be found as a series of “box” instructions in the IEC standard:

The Q output for each instruction “box” activates whenever the evaluated comparison function is “true” and the enable input (EN) is active. If the enable input remains active but the comparison function is false, the Q output de-activates. If the enable input de-de-activates, the Q output retains its last state.

A practical application for a comparative function is something called *alternating motor control*, where the run-times of two redundant electric motors<sup>27</sup> are monitored, with the PLC determining which motor to turn on next based on which motor has run the least:

Real-world I/O wiring

PLC program

In this program, two retentive on-delay timers keep track of each electric motor's total run time, storing the run time values in two registers in the PLC's memory: `Motor_A_runtime` and

<sup>27</sup>Perhaps two pumps performing the same pumping function, one serving as a backup to the other. Alternating motor control ensures the two motors' run times are matched as closely as possible.

**Motor\_B\_runtime.** These two integer values are input to the “greater than” instruction box for comparison. If motor A has run longer than motor B, motor B will be the one enabled to start up next time the “start” switch is pressed. If motor A has run less time or the same amount of time as motor B (the scenario shown by the blue-highlighted status indications), motor A will be the one enabled to start. The two series-connected virtual contacts `OUT_motor_A` and `OUT_motor_B` ensure the comparison between motor run times is not made until both motors are stopped. If the comparison were continually made, a situation might arise where *both* motors would start if someone happened to press the Start pushbutton with one motor is already running.

### 12.4.5 Math instructions

The IEC 61131-3 standard specifies several dedicated ladder instructions for performing arithmetic calculations. Some of them are shown here:

As with the data comparison instructions, each of these math instructions must be enabled by an “energized” signal to the enable (EN) input. Input and output values are linked to each math instruction by tag name.

An example showing the use of such instructions is shown here, converting a temperature measurement in units of degrees Fahrenheit to units of degrees Celsius. In this particular case, the program inputs a temperature measurement of 138 °F and calculates the equivalent temperature of 58.89 °C:

*PLC program*

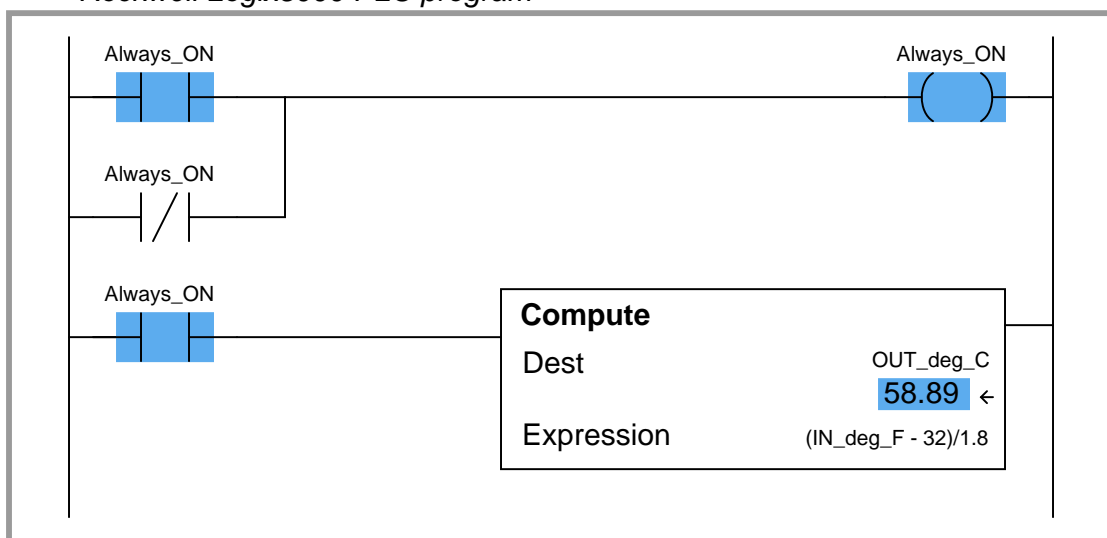

Note how two separate math instructions were required to perform this simple calculation, as well as a dedicated variable (X) used to store the intermediate calculation between the subtraction and the division “boxes.”

Although not specified in the IEC 61131-3 standard, many programmable logic controllers support Ladder Diagram math instructions allowing the direct entry of arbitrary equations. Rockwell

(Allen-Bradley) Logix5000 programming, for example, has the “Compute” (CPT) function, which allows any typed expression to be computed in a single instruction as opposed to using several dedicated math instructions such as “Add,” “Subtract,” etc. General-purpose math instructions dramatically shorten the length of a ladder program compared to the use of dedicated math instructions for any applications requiring non-trivial calculations.

For example, the same Fahrenheit-to-Celsius temperature conversion program implemented in Logix5000 programming only requires a single math instruction and no declarations of intermediate variables:

*Rockwell Logix5000 PLC program*

### 12.4.6 Sequencers

Many industrial processes require control actions to take place in certain, predefined sequences. Batch processes are perhaps the most striking example of this, where materials for making a batch must be loaded into the process vessels, parameters such as temperature and pressure controlled during the batch processing, and then discharge of the product monitored and controlled. Before the advent of reliable programmable logic devices, this form of sequenced control was usually managed by an electromechanical device known as a *drum sequencer*. This device worked on the principle of a rotating cylinder (drum) equipped with tabs to actuate switches as the drum rotated into certain positions. If the drum rotated at a constant speed (turned by a clock motor), those switches would actuate according to a timed schedule<sup>28</sup>.

The following photograph shows a drum sequencer with 30 switches. Numbered tabs on the circumference of the drum mark the drum's rotary position in one of 24 increments. With this number of switches and tabs, the drum can control up to thirty discrete (on/off) devices over a series of twenty-four sequenced steps:

---

<sup>28</sup>The operation of the drum is not unlike that of an old *player piano*, where a strip of paper punched with holes caused hammers in the piano to automatically strike their respective strings as the strip was moved along at a set speed, thus playing a pre-programmed song.

A typical application for a sequencer is to control a *Clean In Place (CIP)* system for a food processing vessel, where a process vessel must undergo a cleaning cycle to purge it of any biological matter between food processing cycles. The steps required to clean the vessel are well-defined and must always occur in the same sequence in order to ensure hygienic conditions. An example timing chart is shown here:

In this example, there are nine discrete outputs – one for each of the nine final control elements (pumps and valves) – and seventeen steps to the sequence, each one of them timed. In this particular sequence, the only input is the discrete signal to commence the CIP cycle. From the initiation of the CIP to its conclusion two and a half hours (150 minutes) later, the sequencer simply steps through the programmed routine.

Another practical application for a sequencer is to implement a *Burner Management System* (BMS), also called a *flame safety system*. Here, the sequencer manages the safe start-up of a combustion burner: beginning by “purging” the combustion chamber with fresh air to sweep out any residual fuel vapors, waiting for the command to light the fire, energizing a spark ignition system on command, and then continuously monitoring for presence of good flame and proper fuel supply pressure once the burner is lit.

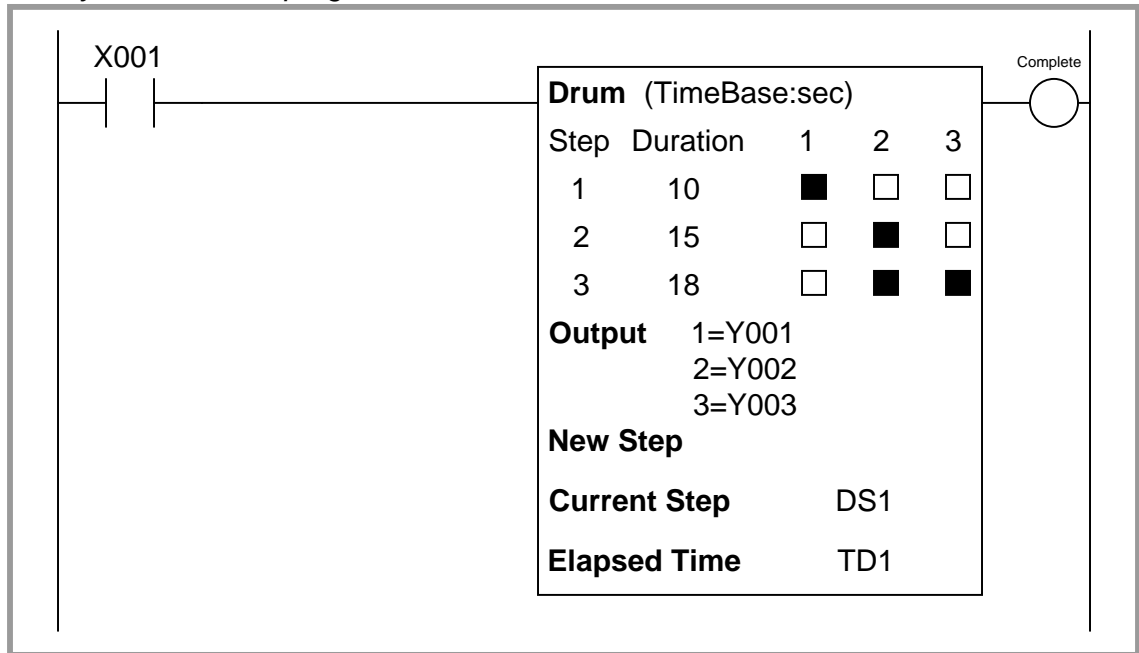

In a general sense, the operation of a drum sequencer is that of a *state machine*: the output of the system depends on the condition of the machine’s internal state (the drum position), not just the conditions of the input signals. Digital computers are very adept at implementing state functions, and so the general function of a drum sequencer should be (and is) easy to implement in a PLC. Other PLC functions we have seen (“latches” and timers in particular) are similar, in that the PLC’s output at any given time is a function of both its present input condition(s) and its past input condition(s). Sequencing functions expand upon this concept to define a much larger number of possible states (“positions” of a “drum”), some of which may even be timed.

Unfortunately, despite the utility of drum sequence functions and their ease of implementation in digital form, there seems to be very little standardization between PLC manufacturers regarding sequencing instructions. Sadly, the IEC 61131-3 standard (at least at the time of this writing, in 2009) does not specifically define a sequencing function suitable for Ladder Diagram programming. PLC manufacturers are left to invent sequencing instructions of their own design. What follows here is an exploration of some different sequencer instructions offered by PLC manufacturers.

### Koyo “drum” instructions

The *drum* instruction offered in Koyo PLCs is a model of simplicity itself. This instruction is practically self-explanatory, as shown in the following example:

*Koyo CLICK PLC program*

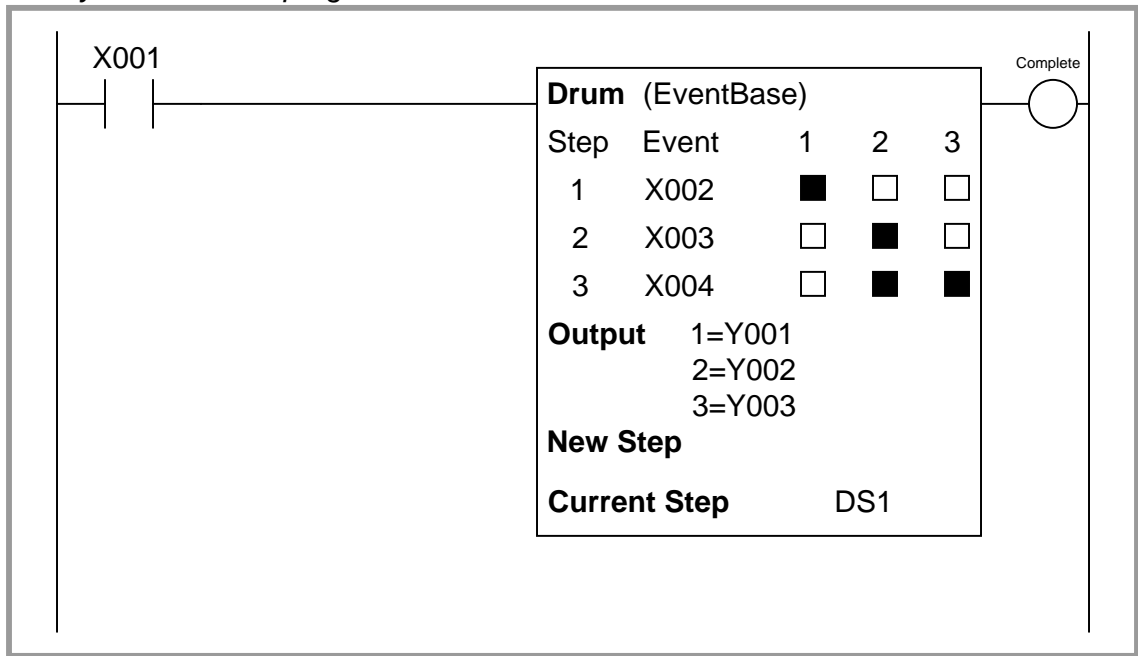

The three-by-three grid of squares represent steps in the sequence and bit states for each step. Rows represent steps, while columns represent output bits written by the drum instruction. In this particular example, a three-step sequence proceeds at the command of a single input (X001), and the drum instruction's advance from one step to the next proceeds strictly on the basis of elapsed time (a *time base* orientation). When the input is active, the drum proceeds through its timed sequence. When the input is inactive, the drum halts wherever it left off, and resumes timing as soon as the input becomes active again.

Being based on time, each step in the drum instruction has a set time duration for completion. The first step in this particular example has a duration of 10 seconds, the second step 15 seconds, and the third step 18 seconds. At the first step, only output bit Y001 is set. In the second step, only output bit Y002 is set. In the third step, output bits Y002 and Y003 are set (1), while bit Y001 is reset (0). The colored versus uncolored boxes reveal which output bits are set and reset with each step. The current step number is held in memory register DS1, while the elapsed time (in seconds) is stored in timer register TD1. A “complete” bit is set at the conclusion of the three-step sequence.

Koyo drum instructions may be expanded to include more than three steps and more than three output bits, with each of those step times independently adjustable and each of the output bits arbitrarily assigned to any writable bit addresses in the PLC's memory.

This next example of a Koyo drum instruction shows how it may be set up to trigger on *events* rather than on elapsed times. This orientation is called an *event base*:

**Koyo CLICK PLC program**

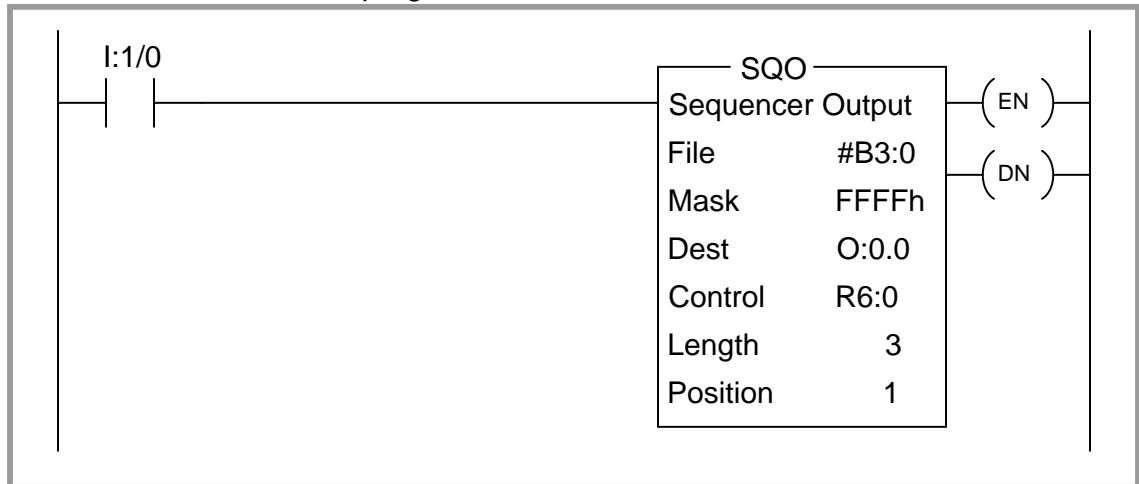

Here, a three-step sequence proceeds when enabled by a single input (X001), with the drum instruction's advance from one step to the next proceeding only as the different event condition bits become set. When the input is active, the drum proceeds through its sequence when each event condition is met. When the input is inactive, the drum halts wherever it left off regardless of the event bit states.

For example, during the first step (when only output bit Y001 is set), the drum instruction waits for the first condition input bit X002 to become set (1) before proceeding to step 2, with time being irrelevant. When this happens, the drum immediately advances to step 2 and waits for input bit X003 to be set, and so forth. If all three event conditions were met simultaneously (X002, X003, and X004 all set to 1), the drum would skip through all steps as fast as it could (one step per PLC program scan) with no appreciable time elapsed for each step. Conversely, the drum instruction will wait as long as it must for the right condition to be met before advancing, whether that event takes place in milliseconds or in days.

### Allen-Bradley sequencer instructions

Rockwell (Allen-Bradley) PLCs use a more sophisticated set of instructions to implement sequences. The closest equivalent to Koyo's *drum* instruction is the Allen-Bradley *SQO* (Sequencer Output) instruction, shown here:

*Rockwell SLC 500 PLC program*

You will notice there are no colored squares inside the SQO instruction box to specify when certain bits are set or reset throughout the sequence, in contrast to the simplicity of the Koyo PLC's drum instruction. Instead, the Allen-Bradley SQO instruction is told to read a set of 16-bit words beginning at a location in the PLC's memory arbitrarily specified by the programmer, one word at a time. It steps to the next word in that set of words with each new position (step) value. This means Allen-Bradley sequencer instructions rely on the programmer already having pre-loaded an area of the PLC's memory with the necessary 1's and 0's defining the sequence. This makes the Allen-Bradley sequencer instruction more challenging for a human programmer to interpret because the bit states are not explicitly shown inside the SQO instruction box, but it also makes the sequencer far more flexible in that these bits are not fixed parameters of the SQO instruction and therefore may be dynamically altered as the PLC runs. With the Koyo drum instruction, the assigned output states are part of the instruction itself, and are therefore fixed once the program is downloaded to the PLC (i.e. they cannot be altered without editing and re-loading the PLC's program). With the Allen-Bradley, the on-or-off bit states for the sequence may be freely altered<sup>29</sup> during run-time. This is a very useful feature in recipe-control applications, where the recipe is subject to change at the whim of production personnel, and they would rather not have to rely on a technician or an engineer to re-program the PLC for each new recipe.

The "Length" parameter tells the SQO instruction how many words will be read (i.e. how many steps are in the entire sequence). The sequencer advances to each new position when its

<sup>29</sup>Perhaps the most practical way to give production personnel access to these bits without having them learn and use PLC programming software is to program an HMI panel to write to those memory areas of the PLC. This way, the operators may edit the sequence at any time simply by pressing "buttons" on the screen of the HMI panel, and the PLC need not have its program altered in any "hard" way by a technician or engineer.

enabling input transitions from inactive to active (from “false” to “true”), just like a count-up (CTU) instruction increments its accumulator value with each new false-to-true transition of the input. Here we see another important difference between the Allen-Bradley SQO instruction and the Koyo drum instruction: the Allen-Bradley instruction is fundamentally *event-driven*, and does not proceed on its own like the Koyo drum instruction is able to when configured for a *time* base.

Sequencer instructions in Allen-Bradley PLCs use a notation called *indexed addressing* to specify the locations in memory for the set of 16-bit words it will read. In the example shown above, we see the “File” parameter specified as **#B3:0**. The “#” symbol tells the instruction that this is a *starting* location in memory for the first 16-bit word, when the instruction’s position value is zero. As the position value increments, the SQO instruction reads 16-bit words from successive addresses in the PLC’s memory. If **B3:0** is the word referenced at position 0, then **B3:1** will be the memory address read at position 1, **B3:2** will be the memory address read at position 2, etc. Thus, the “position” value causes the SQO instruction to “point” or “index” to successive memory locations.

The bits read from each indexed word in the sequence are compared against a static mask<sup>30</sup> specifying which bits in the indexed word are relevant. At each position, only these bits are written to the destination address.

As with most other Allen-Bradley instructions, the sequencer requires the human programmer to declare a special area in memory reserved for the instruction’s internal use. The “R6” file exists just for this purpose, each element in that file holding bit and integer values associated with a sequencer instruction (e.g. the “enable” and “done” bits, the array length, the current position, etc.).

---

<sup>30</sup>In this particular example, the mask value is FFFF hexadecimal, which means all 1’s in a 16-bit field. This mask value tells the sequencer instruction to regard *all* bits of each **B3** word that is read. To contrast, if the mask were set to a value of 000F hexadecimal instead, the sequencer would only pay attention to the four least-significant bits of each **B3** word that is read, while ignoring the 12 more-significant bits of each 16-bit word. The mask allows the SQO instruction to only write to selected bits of the destination word, rather than always writing all 16 bits of the indexed word to the destination word.

To illustrate, let us examine a set of bits held in the B3 file of an Allen-Bradley SLC 500 PLC, showing how each row (element) of this data file would be read by an SQO instruction as it stepped through its positions:

### Data File B3 (bin) -- BINARY

B3:0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	<i>If File = #B3:0, then . . .</i>
B3:1	0	1	1	1	1	0	0	0	0	0	0	0	0	0	0	1	<i>← Read at position = 1</i>
B3:2	1	0	0	0	0	0	1	1	0	0	0	0	0	0	1	0	<i>← Read at position = 2</i>
B3:3	0	0	0	1	0	0	0	0	0	1	0	1	0	1	1	0	<i>← Read at position = 3</i>
	Bit 15	Bit 14	Bit 13	Bit 12	Bit 11	Bit 10	Bit 9	Bit 8	Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0	

The sequencer's position number is added to the file reference address as an *offset*. Thus, if the data file is specified in the SQO instruction box as #B3:0, then B3:1 will be the row of bits read when the sequencer's position value is 1, B3:2 will be the row of bits read when the position value is 2, and so on.

The *mask* value specified in the SQO instruction tells the instruction which bits out of each row will be copied to the destination address. A mask value of FFFFh (FFFF in *hexadecimal* format) means all 16 bits of each B3 word will be read and written to the destination. A mask value of 0001h means only the first (least-significant) bit will be read and written, with the rest being ignored.

Let's see what would happen with an SQO instruction having a mask value of 000Fh, starting from file index #B3:0, and writing to a destination that is output register 0:0.0, given the bit array values in file B3 shown above:

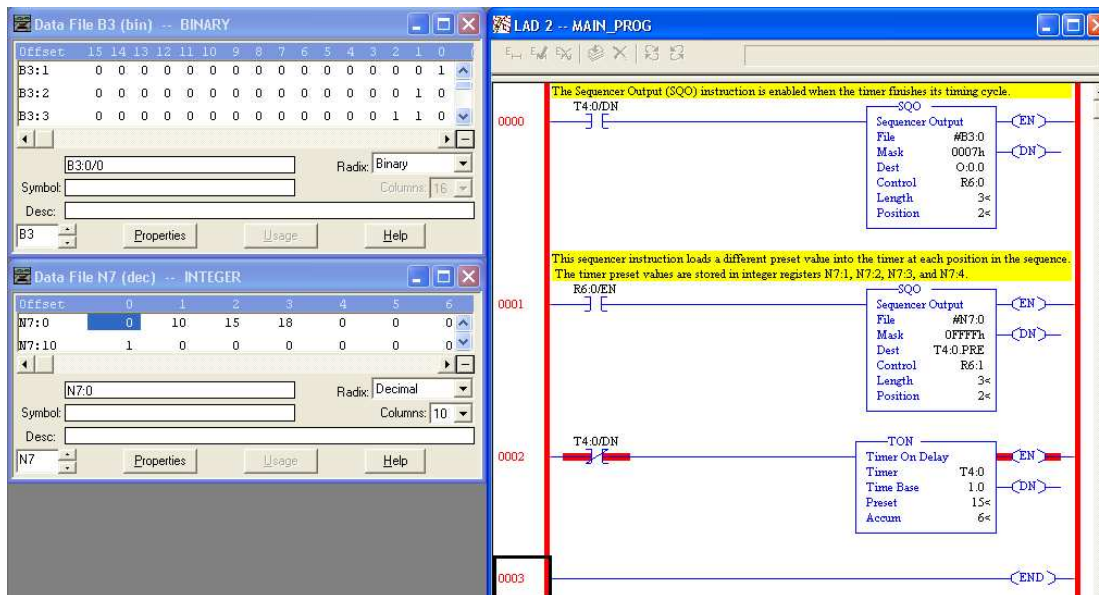

B3:0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	
B3:1	0	1	1	1	1	0	0	0	0	0	0	0	0	0	0	1	
B3:2	1	0	0	0	0	0	1	1	0	0	0	0	0	0	1	0	<i>← Read at position = 2</i>
B3:3	0	0	0	1	0	0	0	0	0	1	0	1	0	1	1	0	
	Bit 15	Bit 14	Bit 13	Bit 12	Bit 11	Bit 10	Bit 9	Bit 8	Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0	

Mask	0	0	0	0	0	0	0	0	0	0	0	0	1	1	1	1	<i>000Fh</i>
------	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	--------------

O:0.0	X	X	X	X	X	X	X	X	X	X	X	X	X	0	0	1	0	<i>Output register as written at sequencer position = 2</i>
-------	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---

When this SQO instruction is at position 2, it reads the bit values 0010 from B3:2 and writes only those four bits to 0:0.0. The "X" symbols shown in the illustration mean that all the other bits in that output register are untouched – the SQO instruction does not write to those bits because they are "masked off" from being written. You may think of the mask's zero bits inhibiting source bits from being written to the destination word in the same sense that *masking tape* prevents paint from being applied to a surface.

The following Allen-Bradley SLC 500 PLC program shows how a pair of SQO instructions plus an on-delay timer instruction may be used to duplicate the exact same functionality as the “time base” Koyo drum instruction presented earlier:

The first SQO instruction reads bits in the B3 file array, sending only the three least-significant of them to the output register 0:0.0 (as specified by the 0007h mask value). The second SQO instruction reads integer number values from elements of the N7 integer file and places them into the “preset” register of timer T4:0, so as to dynamically update the timer’s preset value with each step of the sequence. The timer, in turn, counts off each of the time delays and then enables both sequencers to advance to the next position when the specified time has elapsed. Here we see a tremendous benefit of the SQO instruction’s indexed memory addressing: the fact that the SQO instruction reads its bits from arbitrarily-specified memory addresses means we may use SQO instructions to sequence *any type of data existing in the PLC’s memory!* We are not limited to turning on and off individual bits as we are with the Koyo drum instruction, but rather are free to index whole integer numbers, ASCII characters, or any other forms of binary data resident in the PLC’s memory.

Data file windows appear on the computer screen showing the bit array held in the B3 file as well as the timer values held in the N7 file. In this live screenshot, we see both sequencer instructions at position 2, with the second SQO instruction having loaded a value of 15 seconds from register N7:2 to the timer’s preset register T4:0.PRE.

Note how the enabling contact address for the second SQO instruction is the “enable” bit of the first instruction, ensuring both instructions are enabled simultaneously. This keeps the two separate sequencers synchronized (on the same step).

Event-based transitions may be implemented in Allen-Bradley PLCs using a complementary sequencing instruction called SQC (Sequencer Compare). The SQC instruction is set up very similar to the SQO instruction, with an indexed file reference address to read from, a reserved memory structure for internal use, a set length, and a position value. The purpose of the SQC instruction is to read a data register and compare it against another data register, setting a “found” (FD) bit if the two match. Thus, the SQC instruction is ideally suited for detecting when certain conditions have been met, and thus may be used to enable an SQO instruction to proceed to the next step in its sequence.

The following program example shows an Allen-Bradley MicroLogix 1100 PLC programmed with both an SQO and an SQC instruction:

The three-position SQO (Sequencer Output) instruction reads data from B3:1, B3:2, and B3:3, writing the four least-significant of those bits to output register O:0.0. The three-position SQC (Sequencer Compare) instruction reads data from B3:6, B3:7, and B3:8, comparing the four least-significant of those bits against input bits in register I:0.0. When the four input bit conditions match the selected bits in the B3 file, the SQC instruction’s FD bit is set, causing both the SQO instruction and the SQC instruction to advance to the next step.

Lastly, Allen-Bradley PLCs offer a third sequencing instruction called *Sequencer Load* (SQL), which performs the opposite function as the Sequencer Output (SQO). An SQL instruction takes data from a designated source and writes it into an indexed register according to a position count value, rather than reading data from an indexed register and sending it to a designated destination as does the SQO instruction. SQL instructions are useful for reading data from a live process and storing it in different registers within the PLC’s memory at different times, such as when a PLC is used for *datalogging* (recording process data).

## 12.9 Human-Machine Interfaces

Programmable logic controllers are built to input various signal types (discrete, analog), execute control algorithms on those signals, and then output signals in response to control processes. By itself, a PLC generally lacks the capability of displaying those signal values and algorithm variables to human operators. A technician or engineer with access to a personal computer and the requisite software for editing the PLC's program may connect to the PLC and view the program's status "online" to monitor signal values and variable states, but this is not a practical way for operations personnel to monitor what the PLC is doing on a regular basis. In order for operators to monitor and adjust parameters inside the PLC's memory, we need a different sort of interface allowing certain variables to be read and written without compromising the integrity of the PLC by exposing too much information or allowing any unqualified person to alter the program itself.

One solution to this problem is a dedicated computer display programmed to provide selective access to certain variable's in the PLC's memory, generally referred to as *Human<sup>31</sup>-Machine Interface*, or *HMI*.

HMIs may take the form of general-purpose ("personal") computers running special graphic software to interface with a PLC, or as special-purpose computers designed to be mounted in sheet metal panel fronts to perform no task but the operator-PLC interface. This first photograph shows an example of an ordinary personal computer (PC) with HMI software running on it:

The display shown here happens to be for monitoring a vacuum swing adsorption (VSA) process for purifying oxygen extracted from ambient air. Somewhere, a PLC (or collection of PLCs) is monitoring and controlling this VSA process, with the HMI software acting as a "window" into the PLC's memory to display pertinent variables in an easy-to-interpret form for operations personnel. The personal computer running this HMI software connects to the PLC(s) via digital network cables such as Ethernet.

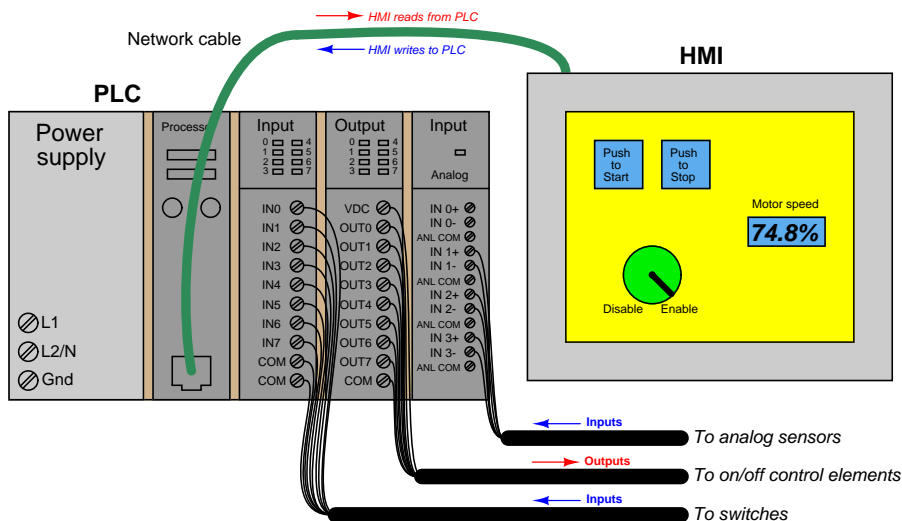

---

<sup>31</sup>An older term for an operator interface panel was the "Man-Machine Interface" or "MMI." However, this fell out of favor due to its sexist tone.

This next photograph shows an example of a special-purpose HMI panel designed and built expressly to be used in industrial operating environments:

These HMI panels are really nothing more than “hardened” personal computers built ruggedly and in a compact format to facilitate their use in industrial environments. Most industrial HMI panels come equipped with touch-sensitive screens, allowing operators to press their fingertips on displayed objects to change screens, view details on portions of the process, etc.

Technicians and/or engineers program HMI displays to read and write data via a digital network to one or more PLCs. Graphical objects arrayed on the display screen of an HMI often mimic real-world indicators and switches, in order to provide a familiar interface for operations personnel. A “pushbutton” object on the face of an HMI panel, for example, would be configured to *write* one bit of data to the PLC, in a manner similar to a real-world switch writing one bit of data to the PLC’s input register.

Modern HMI panels and software are almost exclusively tag-based, with each graphic object on the screen associated with at least one data tag name, which in turn is associated to data points (bits, or words) in the PLC by way of a tag name database file resident in the HMI. Graphic objects on the HMI screen either accept (read) data from the PLC to present useful information to the operator, send (write) data to the PLC from operator input, or both. The task of programming an HMI unit consists of building a tag name database and then drawing screens to illustrate the process to as good a level of detail as operators will need to run it.

An example screenshot of a tag name database table for a modern HMI is shown here:

The screenshot shows a window titled "Tag Name Database" with a close button (X) in the top right corner. Below the title bar, there is a "Device Name:" label followed by a dropdown menu showing "PLC\_01". To the right of this is a "Fill Down" button. Below these are two groups of checkboxes: "Display System Tags" with a "Highlight" checkbox, and "Display Internal Tags" with a "Highlight" checkbox. To the right of these is a "Highlight Unused Tags" checkbox. Below the checkboxes is a table with 7 columns: "No.", "Tag Name", "Data Type", "PLC Address", "Device Name", "Attribute", and an empty column. The table contains 8 rows of data.

No.	Tag Name	Data Type	PLC Address	Device Name	Attribute	
1	START_PUSHBUTTON	Discrete	10024	PLC_01	R	
2	STOP_PUSHBUTTON	Discrete	10031	PLC_01	R	
3	MOTOR_RUN	Discrete	00005	PLC_01	R/w	
4	MOTOR_RUN_TIMER	Unsigned int 32	40010	PLC_01	R/w	
5	START_COUNTER	Unsigned int 16	40242	PLC_01	R/w	
6	MOTOR_TEMPERATURE	Floating PT 32	30008	PLC_01	R	
7	ERROR_MESSAGE	Ascii String	40560	PLC_01	R/w	
8	MOTOR_SPEED	Floating PT 32	30017	PLC_01	R	

The tag name database is accessed and edited using the same software to create graphic images in the HMI. In this particular example you can see several tag names (e.g. `START_PUSHBUTTON`, `MOTOR_RUN_TIMER`, `ERROR_MESSAGE`, `MOTOR_SPEED`) associated with data points within the PLC's memory (in this example, the PLC addresses are shown in Modbus register format). In many cases the tag name editor will be able to display corresponding PLC memory points in the same manner as they appear in the PLC programming editor software (e.g. `I:5/10`, `SM0.4`, `C11`, etc.).

An important detail to note in this tag name database display is the read/write attributes of each tag. Note in particular how four of the tags shown are *read-only*: this means the HMI only has permission to read the values of those four tags from the PLC's memory, and not to write (alter) those values. The reason for this in the case of these four tags is that those tags refer to PLC input data points. The `START_PUSHBUTTON` tag, for instance, refers to a discrete input in the PLC energized by a real pushbutton switch. As such, this data point gets its state from the energization of the discrete input terminal. If the HMI were to be given *write* permission for this data point, there would likely be a conflict. Suppose input terminal on the PLC were energized (setting the `START_PUSHBUTTON` bit to a "1" state) and the HMI simultaneously attempted to write a "0" state to the same tag. One of these two data sources would win, and other would lose, possibly resulting in unexpected behavior from the PLC program. For this reason, data points in the PLC linked to real-world inputs should always be limited as "read-only" permission in the HMI's database, so the

HMI cannot possibly generate a conflict.

The potential for data conflict also exists for some of the other points in the database, however. A good example of this is the `MOTOR_RUN` bit, which is the bit within the PLC program telling the real-world motor to run. Presumably, this bit gets its data from a coil in the PLC's Ladder Diagram program. However, since it also appears in the HMI database with *read/write* permission, the potential exists for the HMI to over-write (i.e. conflict) that same bit in the PLC's memory. Suppose someone programmed a toggling "pushbutton" screen object in the HMI linked to this tag: pushing this virtual "button" on the HMI screen would attempt to set the bit (1), and pushing it again would attempt to reset the bit (0). If this same bit is being written to by a coil in the PLC's program, however, there exists the distinct possibility that the HMI's "pushbutton" object and the PLC's coil will conflict, one trying to tell the bit to be a "0" while the other tries to tell that bit to be a "1". This situation is quite similar to the problem experienced when multiple coils in a Ladder Diagram program are addressed to the same bit.

The general rule to follow here is *never allow more than one element to write to any data point*. In my experience teaching PLC and HMI programming, this is one of the more common errors students make when first learning to program HMIs: they will try to have both the HMI and the PLC writing to the same memory locations, with weird results.

One of the lessons you will learn when programming large, complex systems is that it is very beneficial to define all the necessary tag names *before* beginning to lay out graphics in an HMI. The same goes for PLC programming: it makes the whole project go faster with less confusion if you take the time to define all the necessary I/O points (and tag names, if the PLC programming software supports tag names in the programming environment) before you begin to create any code specifying how those inputs and outputs will relate to each other.

Maintaining a consistent convention for tag names is important, too. For example, you may wish to begin the tag name of every hard-wired I/O point as either `INPUT` or `OUTPUT` (e.g. `INPUT_PRESSURE_SWITCH_HIGH`, `OUTPUT_SHAKER_MOTOR_RUN`, etc.). The reason for maintaining a strict naming convention is not obvious at first, since the whole point of tag names is to give the programmer the freedom to assign *arbitrary names* to data points in the system. However, you will find that most tag name editors list the tags in alphabetical order, which means a naming convention organized in this way will present all the input tags contiguously (adjacent) in the list, all the output tags contiguously in the list, and so on.

Another way to leverage the alphabetical listing of tag names to your advantage is to begin each tag name with a word describing its association to a major piece of equipment. Take for instance this example of a process with several data points defined in a PLC control system and displayed in an HMI:

If we list all these tags in alphabetical order, the association is immediately obvious:

- `Exchanger_effluent_pump`
- `Exchanger_effluent_temp_out`
- `Exchanger_preheat_pump`
- `Exchanger_preheat_temp_in`
- `Exchanger_preheat_valve`
- `Reactor_bed_temp`
- `Reactor_feed_flow`
- `Reactor_feed_temp`
- `Reactor_jacket_valve`

As you can see from this tag name list, all the tags directly associated with the heat exchanger are located in one contiguous group, and all the tags directly associated with the reactor are located in the next contiguous group. In this way, judicious naming of tags serves to group them in hierarchical fashion, making them easy for the programmer to locate at any future time in the tag name database.

You will note that all the tag names shown here lack space characters between words (e.g. instead of “`Reactor bed temp`”, a tag name should use hyphens or underscore marks as spacing characters: “`Reactor_bed_temp`”), since spaces are generally assumed by computer programming languages to be delimiters (separators between different variable names).

Like programmable logic controllers themselves, the capabilities of HMIs have been steadily increasing while their price decreases. Modern HMIs support graphic trending, data archival, advanced alarming, and even web server ability allowing other computers to easily access certain data over wide-area networks. The ability of HMIs to log data over long periods of time relieves the PLC of having to do this task, which is very memory-intensive. This way, the PLC merely “serves” current data to the HMI, and the HMI is able to keep a record of current and past data using its vastly larger memory reserves<sup>32</sup>.

Some modern HMI panels even have a PLC built inside the unit, providing control and monitoring in the same device. Such panels provide terminal strip connection points for discrete and even analog I/O, allowing all control and interface functions to be located in a single panel-mount unit.

---

<sup>32</sup>If the HMI is based on a personal computer platform (e.g. Rockwell RSView, Wonderware, FIX/Intellution software), it may even be equipped with a hard disk drive for enormous amounts of historical data storage.

## 12.10 How to teach yourself PLC programming

First and foremost, you need to get your very own PLC to work with. Computer programming of any kind is not a spectator sport, and can only be learned by significant investment of time and effort at the keyboard. In many ways, learning to program is like learning a new spoken or written language: there is new vocabulary and new grammatical rules to master, and many ways to make mistakes.

Fortunately, many low-cost PLCs exist on the market for individuals to purchase. My own personal favorites are the “CLICK” PLC models manufactured by Koyo and marketed through Automation Direct, and also the Allen-Bradley MicroLogix series of PLC (especially the 1000 and 1100 models).

The first document you should read once you get your PLC is something called a *Getting Started* guide. Every PLC manufacturer publishes a document with this name (or something similar such as *Quick Start* or *Getting Results*). This manual will step you through all the basic procedures for entering a simple program into your PLC and getting it to run. It is generally *far* easier to learn programming by copying and adapting a worked example than it is to start from a “blank page” on your own, just as it is easiest to learn a spoken or written language by practicing sentences spoken in that language by other people before constructing your own sentences from scratch.

In order to work with your PLC, you will need a convenient way to simulate different input conditions coming from discrete (switch) devices. Any set of hand-operated switches will do, my recommendation being household light switches (very inexpensive and rugged). Attaching an array of these switches to a wooden board along with the PLC and interconnecting terminal blocks forms what is often called a PLC *trainer*. The following photograph shows one such trainer<sup>33</sup>, using an Allen-Bradley MicroLogix 1000 PLC:

---

<sup>33</sup>This particular trainer was partially constructed from recycled materials – the wooden platform, light switches, and power cord – to minimize cost.

Another example of a student-built PLC trainer is this unit, housed inside of an attaché case. Not only does this trainer contain an Allen-Bradley MicroLogix 1100 PLC along with input switches and output indicator lights, but it also includes an HMI touch-screen panel on a fold-down bracket:

The educational value of building your own PLC trainer is difficult to overstate when learning about PLCs. Learning how to build properly-functioning I/O circuits is every bit as important to a working technician as learning how to develop PLC programs. Additionally, the experience gained in general wiring layout and fabrication are valuable skills for any instrumentation practitioner.

Once you have learned the basic steps for entering, running, and saving a PLC program, you are ready to begin building your knowledge of the language's vocabulary and grammar. In computer programming (of all types), there are different *functions* of the language one must become familiar with in order to do useful tasks. A great way to learn how to use these functions is to create your own "demonstration" programs illustrating the use of each function.

For example, if you open up the pages of almost any computer programming book, somewhere near the beginning you will find a demonstration program called "Hello World!" The purpose of a "Hello World!" program is to do nothing more than display the words *Hello World!* on the computer screen. It is an entirely useless program to run, but it is highly useful for gaining teaching the programmer the basics of program construction and text message functionality.

By the same token, you may learn the basics of each programming function by writing simple "Hello World"-type programs illustrating each one of those functions. These demonstration programs will not serve any useful purpose (other than to help you learn), and should be kept as simple as possible in order to minimize confusion.

For example, *every* PLC provides instructions to perform the following tasks:

- Turn discrete outputs on and off
- Count discrete events
- Time events
- Control events in a specific sequence
- Compare numerical values (greater than, less than, equal, not equal)
- Perform arithmetic functions

Just as every spoken or written language has verbs, nouns, adjectives, and adverbs to describe actions and things, every PLC programming language has specific functions to perform useful tasks. The details of how to perform each function will vary somewhat between PLC manufacturers and models, but the overall functions are quite similar. The reference manuals provided for your PLC will describe in detail how to use each function. Your task is to write simple demonstration programs for each function, allowing you to directly explore how each function works, and to gain an understanding of each function by observing its behavior and also by making (inevitable) mistakes.

After writing each demonstration program, you should add a lot of comments to it, so you will be able to understand what you did later when you go back to your demonstration program for reference. These comments should cover the following points:

- Proper use of the function
- A verbal description of what the function does
- A list of possible (practical) uses for the function
- Idiosyncrasies of the function (i.e. odd or unexpected behavior, tricky points to watch out for)
- Mistakes you may have made (and thus might make again!) in using the function

Years ago when I was teaching myself how to program using the *C* language, I wrote a set of “tutorial” programs demonstrating common programming functions and techniques. The following is a partial list of these tutorial programs, which I still keep to this day:

- Program that accepts and then prints alphanumeric characters (including their equivalent numerical values)
- Program demonstrating how to use command-line arguments to the `main()` function
- Program demonstrating basic “curses” commands for plotting characters at arbitrary locations on the screen
- Program illustrating the declaration and use of *data structures*
- Program illustrating how to prototype and then call *functions* (subroutines)
- Program executing an infinite loop
- Program illustrating how to return a *pointer* from a function

Each one of these tutorial programs is heavily commented, to explain to myself in my own words how they work and what they are doing. Not only did they help me learn how to write programs in C, but they also serve as a handy reference for me any time in the future I need to refresh my knowledge. The act of writing tutorial programs is akin to *journaling* as a way to work through complex problems in life – in a way, it is like having a conversation with yourself.

## 12.11 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader’s view of this chapter’s concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **“Normal” switch status:** the “normal” status of a switch contact as defined by the manufacturer is its *resting* condition (minimum stimulus).
- **“Seal-in” circuit:** when an electrical relay uses one of its own switch contacts to continue its own coil energization after the initial triggering event has passed. Relevant to all manner of relay control circuits.
- **Sourcing versus sinking:** whether the electronic device in question is outputting (conventional flow) current or inputting current. Relevant to the proper connection of discrete DC input and output cards.

## Chapter 13

# Analog electronic instrumentation

An “analog” electronic signal is a voltage or current proportionate to the value of some physical measurement or control quantity. An instrument is often classified as being “analog” simply by virtue of using an analog signal standard to communicate information, even if the internal construction and design of the instrument may be mostly digital in nature. This is to distinguish such instruments from those making use of no analog electronic signals at all (e.g. wireless or Fieldbus instruments).

### 13.1 4 to 20 mA analog current signals

The most popular form of signal transmission used in modern industrial instrumentation systems (as of this writing) is the 4 to 20 milliamp DC standard. This is an *analog* signal standard, meaning that the electric current is used to proportionately represent measurements or command signals. Typically, a 4 milliamp current value represents 0% of scale, a 20 milliamp current value represents 100% of scale, and any current value in between 4 and 20 milliamps represents a commensurate percentage in between 0% and 100%. The following table shows the corresponding current and percentage values for each 25% increment between 0% and 100%. Every instrument technician tasked with maintaining 4-20 mA instruments commits these values to memory, because they are referenced so often:

Current value	% of scale
4 mA	0%
8 mA	25%
12 mA	50%
16 mA	75%
20 mA	100%

For example, if we were to calibrate a 4-20 mA temperature transmitter for a measurement range of 50 to 250 degrees C, we could relate the current and measured temperature values on a graph like this:

This is not unlike 3-15 pounds per square inch (PSI) pneumatic signal standard, where a varying air pressure signal proportionately represents some process variable. Both 3-15 PSI and 4-20 mA signal standards are referred to as *live zero* because their ranges begin with a non-zero value. This “live” zero provides a simple means of discriminating between a legitimate 0% signal value and a failed signal (e.g. leaking tube or severed cable)<sup>1</sup>.

<sup>1</sup>Not all industrial measurement and control signals are “live zero” like the 3-15 PSI and 4-20 mA standards. 0 to

An important concept to grasp with all analog instrumentation is that instruments sending and receiving analog signals must be compatibly ranged in order to properly represent the desired variable. To illustrate, let us consider a temperature measurement system consisting of a thermocouple<sup>2</sup>, a temperature transmitter, a 250 ohm resistor (to convert the 4-20 mA analog signal into a 1-5 volt analog signal), and a special voltmeter functioning as a temperature indicator:

Note how the output range of each sending device matches the input range of its corresponding receiving device. If we view this system as a path for information to flow from the thermocouple's tip to the transmitter to the resistor and finally to the voltmeter/indicator, we see that the analog output range of each device must correspond to the analog input range of the *next* device, or else the real-world meaning of the analog signal will be lost.

This correspondence does not happen automatically, but must be established by the instrument technician building the system. In this case, it would be the technician's responsibility to properly adjust the range of the temperature transmitter, and also to ensure the indicator's display scale was properly labeled. Both the thermocouple and the resistor are non-adjustable devices, their input/output characteristics being fixed by physical laws.

10 volts DC is a common "dead zero" signal standard, although far more common in environmental (building heating and cooling) control systems than industrial control systems. I once encountered an old analog control system using -10 volts to +10 volts as its analog signal range, which meant 0 volts represented a 50% signal! A failed signal path in such a system could have been very misleading indeed, as a 50% signal value is not suspicious in the least.

<sup>2</sup>This is a temperature sensing element consisting of two different metal wires joined together, which generate a small voltage proportional to temperature. The correspondence between junction temperature and DC millivoltage is very well established by scientific testing, and so we may use this principle to sense process temperature.

DC current signals are also used in control systems to command the positioning of a final control element, such as a control valve or a variable-speed motor drive (VSD). In these cases, the milliamp value does not directly represent a process measurement, but rather how the degree to which the final control element influences the process. Typically (but not always!), 4 milliamps commands a closed (shut) control valve or a stopped motor, while 20 milliamps commands a wide-open valve or a motor running at full speed. Final control elements often are equipped with adjustable ranges so that an accurate correspondence between the analog signal and the desired control action may be ensured.

Thus, most industrial control systems use at least *two* different 4-20 mA signals: one to represent the process variable (PV) and one to represent the command signal to the final control element (the “manipulated variable” or MV):

The relationship between these two signals depends entirely on the response of the controller. There is no reason to ever expect the PV and MV current signals to be equal to each other except by chance, for they represent entirely different variables. In fact, if the controller is reverse-acting, it is entirely normal for the two current signals to be inversely related: as the PV signal increases going to a reverse-acting controller, the output signal will decrease. If the controller is placed into “manual” mode by a human operator, the output signal will have no automatic relation to the PV signal at all, instead being entirely determined by the operator’s whim.

## 13.2 Relating 4 to 20 mA signals to instrument variables

A 4 to 20 mA current signal represents some signal along a 0 to 100 percent scale. Usually, this scale is linear as shown by this graph:

Being a linear function, we may use the standard slope-intercept linear equation to relate signal percentage to current values:

$$y = mx + b$$

Where,

$y$  = Output from instrument

$x$  = Input to instrument

$m$  = Slope

$b$  =  $y$ -intercept point (i.e. the *live zero* of the instrument's range)

Once we determine suitable values for  $m$  and  $b$ , we may then use this linear equation to predict any value for  $y$  given  $x$ , and vice-versa. This is very useful for predicting the 4-20 mA signal output of a process transmitter, or the expected stem position of a 4-20 mA controlled valve, or any other correspondence between a 4-20 mA signal and some physical variable.

Before we may use this equation for any practical purpose, we must determine the slope ( $m$ ) and intercept ( $b$ ) values appropriate for the instrument we wish to apply the equation to. Next, we will see some examples of how to do this.

For the linear function shown, we may determine the slope value ( $m$ ) by dividing the line's *rise* by its *run*. Two sets of convenient points we may use in calculating rise over run are 4 and 20 milliamps (for the rise), and 0 and 100 percent (for the run):

$$m = \frac{\text{Rise}}{\text{Run}} = \frac{(20 - 4)}{(100 - 0)} = \frac{16}{100}$$

$$y = \left( \frac{16}{100} \right) x + b$$

To calculate the y-intercept ( $b$ ), all we need to do is solve for  $b$  at some known coordinate pair of  $x$  and  $y$ . Again, we find convenient points<sup>3</sup> for this task at 0 percent and 4 milliamps:

$$4 = \left( \frac{16}{100} \right) 0 + b$$

$$4 = 0 + b$$

$$b = 4$$

<sup>3</sup>We could have just as easily chosen 100 percent for  $x$  and 20 milliamps for  $y$ , for it would have yielded the same result of  $b = 4$ .

Now we have a complete formula for converting a percentage value into a milliamp value:

$$y = \left( \frac{16}{100} \right) x + 4$$

We may now use this formula to calculate how many milliamps represent any given percentage of signal. For example, suppose we needed to convert a percentage of 34.7% into a corresponding 4-20 mA current. We would do so like this:

$$y = \left( \frac{16}{100} \right) 34.7 + 4$$

$$y = 5.552 + 4$$

$$y = 9.552$$

Thus, 34.7% is equivalent to 9.552 milliamps in a 4-20 mA signal range.

The slope-intercept formula for linear functions may be applied to *any* linear instrument, as illustrated in the following examples.

### 13.2.1 Example calculation: controller output to valve

An electronic loop controller outputs a signal of 8.55 mA to a direct-responding control valve (where 4 mA is shut and 20 mA is wide open). How far open should the control valve be at this MV signal level?

To solve for percentage of stem travel ( $x$ ) at 8.55 milliamps of signal current ( $y$ ), we may use the linear equation developed previously to predict current in milliamps ( $y$ ) from signal value in percent ( $x$ ):

$$y = \left( \frac{16}{100} \right) x + 4$$

$$8.55 = \left( \frac{16}{100} \right) x + 4$$

$$4.55 = \left( \frac{16}{100} \right) x$$

$$\left( \frac{100}{16} \right) 4.55 = x$$

$$x = 28.4$$

Therefore, we should expect the valve to be 28.4% open at an applied MV signal of 8.55 milliamps.

### 13.2.2 Example calculation: flow transmitter

*A flow transmitter is ranged 0 to 350 gallons per minute, 4-20 mA output, direct-responding. Calculate the current signal value at a flow rate of 204 GPM.*

One way we could solve for the amount of signal current is to convert the flow value of 204 GPM into a ratio of the flowmeter's full-flow value, then apply the same formula we used in the previous example relating percentage to milliamps. Converting the flow rate into a "per unit" ratio is a matter of simple division, since the flow measurement range is zero-based:

$$\frac{204 \text{ GPM}}{350 \text{ GPM}} = 0.583 \text{ per unit}$$

Converting a "per unit" ratio into percent merely requires multiplication by 100, since "percent" literally means "per 100":

$$0.583 \text{ per unit} \times 100\% = 58.3\%$$

Next, we plug this percentage value into the formula:

$$y = \left( \frac{16}{100} \right) 58.3 + 4$$

$$y = 9.33 + 4$$

$$y = 13.33$$

Therefore, the transmitter should output a PV signal of 13.3 mA at a flow rate of 204 GPM.

An alternative approach is to set up a linear equation specifically for this flowmeter given its measurement range (0 to 350 GPM) and output signal range (4 to 20 mA). We will begin this process by sketching a simple graph relating flow rate to current:

The slope ( $m$ ) for this equation is rise over run, in this case 16 milliamps of rise for 350 GPM of run:

$$y = \left( \frac{20 - 4}{350 - 0} \right) x + b = \left( \frac{16}{350} \right) x + b$$

The y-intercept for this equation is 4, since the current output will be 4 milliamps at zero flow:

$$y = \left( \frac{16}{350} \right) x + 4$$

Now that the linear equation is set up for this particular flowmeter, we may plug in the 204 GPM value for  $x$  and solve for current:

$$y = \left( \frac{16}{350} \right) 204 + 4$$

$$y = 9.33 + 4$$

$$y = 13.33$$

Just as before, we arrive at a current of 13.33 milliamps representing a flow rate of 204 GPM.

### 13.2.3 Example calculation: temperature transmitter

An electronic temperature transmitter is ranged 50 to 140 degrees Fahrenheit and has a 4-20 mA output signal. Calculate the current output by this transmitter if the measured temperature is 79 degrees Fahrenheit.

First, we will set up a linear equation describing this temperature transmitter's function:

Calculating and substituting the slope ( $m$ ) value for this equation, using the full rise-over-run of the linear function:

$$y = \left( \frac{20 - 4}{140 - 50} \right) x + b = \left( \frac{16}{90} \right) x + b$$

The y-intercept value will be different<sup>4</sup> for this example than it was for previous examples, since the measurement range is not zero-based. However, the procedure for finding this value is the same – plug any corresponding  $x$  and  $y$  values into the equation and solve for  $b$ . In this case, I will use the values of 4 mA for  $y$  and 50 °F for  $x$ :

$$4 = \left(\frac{16}{90}\right) 50 + b$$

$$4 = 8.89 + b$$

$$b = -4.89$$

Therefore, our customized linear equation for this temperature transmitter is as follows:

$$y = \left(\frac{16}{90}\right) x - 4.89$$

At a sensed temperature of 79 °F, the transmitter’s output current will be 9.16 mA:

$$y = \left(\frac{16}{90}\right) 79 - 4.89$$

$$y = 14.04 - 4.89$$

$$y = 9.16$$

---

<sup>4</sup>A common misconception for people learning to apply the slope-intercept formula to linear instrument ranges is that they tend to assume  $b$  will always be equal to the lower-range value (LRV) of the instrument’s output range. For example, given a transmitter with a 4-20 mA output range, the false assumption is that  $b = 4$ . This does happen to be true *only if the instrument possesses a “dead-zero” input range*, but it will not be true for instruments with a live-zero input range such in this case here where the temperature input range is 50 to 140 degrees.

We may apply the same alternative method of solution to this problem as we did for the flowmeter example: first converting the process variable into a simple “per unit” ratio or percentage of measurement range, then using that percentage to calculate current in milliamps. The “tricky” aspect of this example is the fact the temperature measurement range does not begin at zero.

Converting 79 °F into a percentage of a 50-to-140 °F range requires that we first subtract the live-zero value, then divide by the span:

$$\text{Per unit ratio} = \frac{79 - 50}{140 - 50} = 0.3222$$

$$\text{Percentage} = 0.3222 \text{ per unit} \times 100\% = 32.22\%$$

Next, plugging this percentage value into our standard linear equation for 4-20 mA signals:

$$y = \left( \frac{16}{100} \right) 32.22 + 4$$

$$y = 5.16 + 4$$

$$y = 9.16$$

Again, we arrive at the exact same figure for transmitter output current: 9.16 milliamps at a measured temperature of 79 °F.

The choice to calculate transmitter current by first setting up a “customized” linear equation for the transmitter in question or by converting the measured value into a percentage and using a “standard” linear equation for current is arbitrary. Either method will produce accurate results, although it could be argued that the “customized equation” approach may save time if many different current values must be calculated.

Certainly, if you are programming a computer to convert a received milliamp signal value into a measurement range (such as degrees Fahrenheit), it makes more sense to have the computer evaluate a single equation rather than perform multiple steps of calculations as we do when using percentage values as an intermediate step between the input and output value calculations. Evaluating one equation rather than two saves processing time.

### 13.2.4 Example calculation: pH transmitter

A pH transmitter has a calibrated range of 4 pH to 10 pH, with a 4-20 mA output signal. Calculate the pH sensed by the transmitter if its output signal is 11.3 mA.

First, we will set up a linear equation describing this temperature transmitter's function:

Note how we are free to set up 4-20 mA as the independent variable ( $x$  axis) and the pH as the dependent variable ( $y$  axis). We could arrange current on the  $y$  axis and the process measurement on the  $x$  axis as before, but this would force us to manipulate the linear equation to solve for  $x$ .

Calculating and substituting the slope ( $m$ ) value for this equation, using the full rise-over-run of the linear function:

$$y = \left( \frac{10 - 4}{20 - 4} \right) x + b = \left( \frac{6}{16} \right) x + b$$

Solving for the y-intercept value using the coordinate values of 4 pH and 4 mA, we see again that this is an application where  $b \neq 4$  mA. This is due to the fact that the instrument's input range (i.e. the domain of the  $y = mx + b$  function) does *not* begin at zero:

$$4 = \left(\frac{6}{16}\right) 4 + b$$

$$4 = 1.5 + b$$

$$b = 2.5$$

Therefore, our customized linear equation for this pH transmitter is as follows:

$$y = \left(\frac{6}{16}\right) x + 2.5$$

Calculating the corresponding pH value for an output current signal of 11.3 mA now becomes a very simple matter:

$$y = \left(\frac{6}{16}\right) 11.3 + 2.5$$

$$y = 4.24 + 2.5$$

$$y = 6.74$$

Therefore, the transmitter's 11.3 mA output signal reflects a measured pH value of 6.74 pH.

### 13.2.5 Example calculation: reverse-acting I/P transducer signal

A current-to-pressure transducer is used to convert a 4-20 mA electronic signal into a 3-15 PSI pneumatic signal. This particular transducer is configured for **reverse action** instead of direct, meaning that its pressure output at 4 mA should be 15 PSI and its pressure output at 20 mA should be 3 PSI. Calculate the necessary current signal value to produce an output pressure of 12.7 PSI.

Reverse-acting instruments are still linear, and therefore still follow the slope-intercept line formula  $y = mx + b$ , albeit with a negative slope:

Calculating and substituting the slope ( $m$ ) value for this equation, using the full rise-over-run of the linear function. Note how the “rise” is actually a “fall” from 20 milliamps down to 4 milliamps, yielding a negative value for  $m$ :

$$y = \left( \frac{4 - 20}{15 - 3} \right) x + b = \left( \frac{-16}{12} \right) x + b = \left( -\frac{16}{12} \right) x + b$$

Solving for the y-intercept value using the coordinate values of 3 PSI and 20 mA:

$$20 = \left( -\frac{16}{12} \right) 3 + b$$

$$20 = -4 + b$$

$$b = 24$$

Therefore, our customized linear equation for this I/P transducer is as follows:

$$y = \left( -\frac{16}{12} \right) x + 24$$

Calculating the corresponding current signal for an output pressure of 12.7 PSI:

$$y = \left( -\frac{16}{12} \right) 12.7 + 24$$

$$y = -16.93 + 24$$

$$y = 7.07$$

Therefore, a current signal of 7.07 mA is necessary to drive the output of this reverse-acting I/P transducer to a pressure of 12.7 PSI.

### 13.2.6 Example calculation: PLC analog input scaling

Allen-Bradley SLC 500 controller

An Allen-Bradley SLC500 programmable logic controller (PLC) uses a 16-bit analog-to-digital converter in its model 1746-NI4 analog input card to convert 4-20 mA signals into digital number values ranging from 3277 (at 4 mA) to 16384 (at 20 mA). However, these raw numbers from the PLC's analog card must be mathematically scaled inside the PLC to represent real-world units of measurement, in this case 0 to 700 GPM of flow. Formulate a scaling equation to program into the PLC so that 4 mA of current registers as 0 GPM, and 20 mA of current registers as 700 GPM.

We are already given the raw number values from the analog card's analog-to-digital converter (ADC) circuit for 4 mA and 20 mA: 3277 and 16384, respectively. These values define the domain of our linear graph:

Calculating and substituting the slope ( $m$ ) value for this equation, using the full rise-over-run of the linear function:

$$y = \left( \frac{700 - 0}{16384 - 3277} \right) x + b = \left( \frac{700}{13107} \right) x + b$$

Solving for the y-intercept value using the coordinate values of 0 GPM and 3277 ADC counts:

$$0 = \left( \frac{700}{13107} \right) 3277 + b$$

$$0 = 175 + b$$

$$b = -175$$

Therefore, our PLC scaling equation for this particular flowmeter is as follows:

$$y = \left( \frac{700}{13107} \right) x - 175$$

This type of scaling calculation is so common in PLC applications that Allen-Bradley has provided a special **SCL** (“scale”) instruction just for this purpose. Instead of “slope” ( $m$ ) and “intercept” ( $b$ ), the instruction prompts the human programmer to enter “rate” and “offset” values, respectively. Furthermore, the rate in Allen-Bradley’s **SCL** instruction is expressed as the numerator of a fraction where the denominator is fixed at 10000, allowing fractional (less than one) slope values to be specified using integer numbers. Aside from these details, the concept is exactly the same.

Expressing our slope of  $\frac{700}{13107}$  as a fraction with 10000 as the denominator is a simple matter of solving for the numerator using cross-multiplication and division:

$$\frac{700}{13107} = \frac{r}{10000}$$

$$r = 534$$

Thus, the **SCL** instruction would be configured as follows<sup>5</sup>

<sup>5</sup>The “Source” and “Dest” parameters shown in this instruction box refer to special addresses in the PLC’s memory where the input (ADC count) and output (scaled flowrate) values will be found. You need not concern yourself with the meanings of **I:4.2** and **N7:15**, because these addresses are unimportant to the task of deriving a scaling formula.

### 13.2.7 Graphical interpretation of signal ranges

An illustration some students find helpful in understanding analog signal ranges is to consider the signal range as a *length* expressed on a number line. For example, the common 4-20 mA analog current signal range would appear as such:

If one were to ask the percentage corresponding to a 14.4 mA signal on a 4-20 mA range, it would be as simple as determining the length of a line segment stretching from the 4 mA mark to the 14.4 mA mark:

As a percentage, this thick line is 10.4 mA long (the distance between 14.4 mA and 4 mA) over a total (possible) length of 16 mA (the total span between 20 mA and 4 mA). Thus:

$$\text{Percentage} = \left( \frac{14.4 \text{ mA} - 4 \text{ mA}}{20 \text{ mA} - 4 \text{ mA}} \right) 100\%$$

$$\text{Percentage} = \left( \frac{10.4 \text{ mA}}{16 \text{ mA}} \right) 100\%$$

$$\text{Percentage} = 65\%$$

This same “number line” approach may be used to visualize any conversion from one analog scale to another. Consider the case of an electronic pressure transmitter calibrated to a pressure range of  $-5$  to  $+25$  PSI, having an (obsolete) current signal output range of  $10$  to  $50$  mA. The appropriate current signal value for an applied pressure of  $+12$  PSI would be represented on the number line as such:

Finding the “length” of this line segment in units of milliamps is as simple as setting up a proportion between the length of the line in units of PSI over the total (span) in PSI, to the length of the line in units of mA over the total (span) in mA:

$$\frac{17 \text{ PSI}}{30 \text{ PSI}} = \frac{? \text{ mA}}{40 \text{ mA}}$$

Solving for the unknown (?) current by cross-multiplication and division yields a value of  $22.67$  mA. Of course, this value of  $22.67$  mA only tells us the length of the line segment on the number line; it does not directly tell us the current signal value. To find that, we must add the “live zero” offset of  $10$  mA, for a final result of  $32.67$  mA.

Thus, an applied pressure of  $+12$  PSI to this transmitter should result in a  $32.67$  mA output signal.

### 13.2.8 Thinking in terms of per unit quantities

Although it is possible to generate a “custom” linear equation in the form of  $y = mx + b$  for any linear-responding instrument relating input directly to output, a more general approach may be used to relate input to output values by translating all values into (and out of) *per unit* quantities. A “per unit” quantity is simply a ratio between a given quantity and its maximum value. A half-full glass of water could thus be described as having a fullness of *0.5 per unit*. The concept of percent (“per one hundred”) is very similar, the only difference between per unit and percent being the base value of comparison: half-full glass of water has a fullness of 0.5 per unit (i.e.  $\frac{1}{2}$  of the glass’s full capacity), which is the same thing as 50 percent (i.e. 50 on a scale of 100, with 100 representing complete fullness).

Let’s now apply this concept to a realistic 4-20 mA signal application. Suppose you were given a liquid level transmitter with an input measurement range of 15 to 85 inches and an output range of 4 to 20 milliamps, respectively, and you desired to know how many milliamps this transmitter should output at a measured liquid level of 32 inches. Both the measured level and the milliamp signal may be expressed in terms of *per unit* ratios, as shown by the following graphs:

So long as we choose to express process variable and analog signal values as a per unit ratios ranging from 0 to 1, we see how  $m$  (the slope of the line) is simply equal to the span of the process variable or analog signal range, and  $b$  is simply equal to the lower-range value (LRV) of the process variable or analog signal range. The advantage of thinking in terms of “per unit” is the ability to quickly and easily write linear equations for any given range. In fact, this is so easy that we don’t even have to use a calculator to compute  $m$  in most cases, and we *never* have to calculate  $b$  because the LRV is explicitly given to us. The instrument’s input equation is  $y = 70x + 15$  because the span of the 15-to-85 inch range is 70, and the LRV is 15. The instrument’s output equation is  $y = 16x + 4$  because the span of the 4-to-20 milliamp range is 16, and the LRV is 4.

If we manipulate each of the  $y = mx + b$  equations to solve for  $x$  (per unit of span), we may express the relationship between the input and output of any linear instrument as a pair of fractions with the per unit value serving as the proportional link between input and output:

The question remains, how do we apply these equations to our example problem: calculating the milliamp value corresponding to a liquid level of 32 inches for this instrument? The answer to this question is that we must perform a *two-step* calculation: first, convert 32 inches into a per unit ratio, then convert that per unit ratio into a milliamp value.

First, the conversion of inches into a per unit ratio, knowing that 32 is the value of  $y$  and we need to solve for  $x$ :

$$32 = 70x + 15$$

$$32 - 15 = 70x$$

$$\frac{32 - 15}{70} = x$$

$$x = 0.2429 \text{ per unit (i.e. 24.29\%)}$$

Next, converting this per unit ratio into a corresponding milliamp value, knowing that  $y$  will now be the current signal value using  $m$  and  $b$  constants appropriate for the 4-20 milliamp range:

$$y = 16x + 4$$

$$y = 16(0.2429) + 4$$

$$y = 3.886 + 4$$

$$y = 7.886 \text{ mA}$$

Instead of deriving a single custom  $y = mx + b$  equation directly relating input (inches) to output (milliamps) for every instrument we encounter, we may use two simple and generic linear equations to do the calculation in two steps with “per unit” being the intermediate result. Expressed in general form, our linear equation is:

$$y = mx + b$$

$$\text{Value} = (\text{Span})(\text{Per unit}) + \text{LRV}$$

$$\text{Value} = (\text{URV} - \text{LRV})(\text{Per unit}) + \text{LRV}$$

Thus, to find the per unit ratio we simply take the value given to us, subtract the LRV of its range, and divide by the span of its range. To find the corresponding value we take this per unit ratio, multiply by the span of the other range, and then add the LRV of the other range.

**Example:** Given a pressure transmitter with a measurement range of 150 to 400 PSI and a signal range of 4 to 20 milliamps, calculate the applied pressure corresponding to a signal of 10.6 milliamps.

**Solution:** Take 10.6 milliamps and subtract the LRV (4 milliamps), then divide by the span (16 milliamps) to arrive at 41.25% (0.4125 per unit). Take this number and multiply by the span of the pressure range (400 PSI – 150 PSI, or 250 PSI) and lastly add the LRV of the pressure range (150 PSI) to arrive at a final answer of 253.125 PSI.

**Example:** Given a temperature transmitter with a measurement range of –88 degrees to +145 degrees and a signal range of 4 to 20 milliamps, calculate the proper signal output at an applied temperature of +41 degrees.

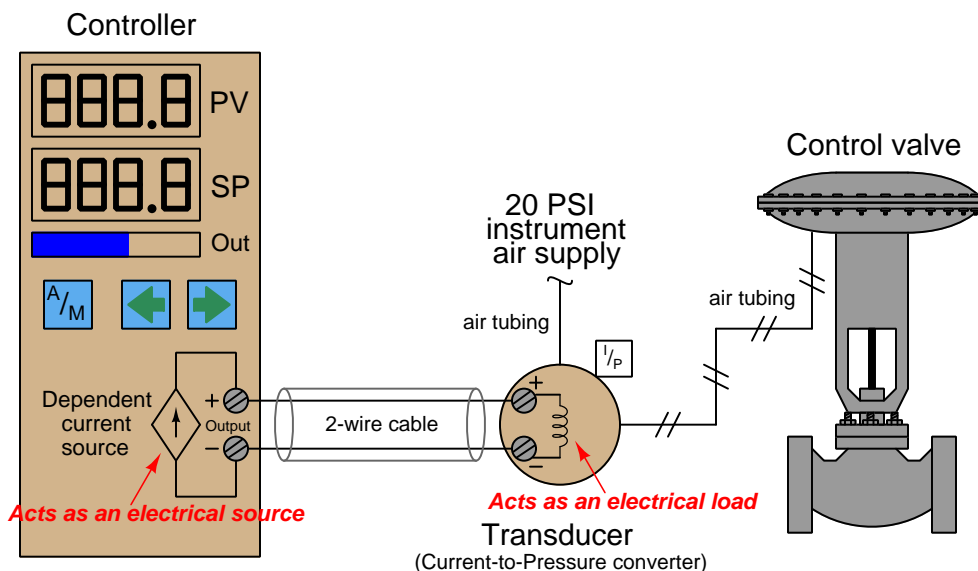

**Solution:** Take 41 degrees and subtract the LRV (–88 degrees) which is the same as *adding* 88 to 41, then divide by the span (145 degrees – (–88) degrees, or 233 degrees) to arrive at 55.36% (0.5536 per unit). Take this number and multiply by the span of the current signal range (16 milliamps) and lastly add the LRV of the current signal range (4 milliamps) to arrive at a final answer of 12.86 milliamps.

**Example:** Given a pH transmitter with a measurement range of 3 pH to 11 pH and a signal range of 4 to 20 milliamps, calculate the proper signal output at 9.32 pH.

**Solution:** Take 9.32 pH and subtract the LRV (3 pH), then divide by the span (11 pH – 3 pH, or 8 pH) to arrive at 79% (0.79 per unit). Take this number and multiply by the span of the current signal range (16 milliamps) and lastly add the LRV of the current signal range (4 milliamps) to arrive at a final answer of 16.64 milliamps.

### 13.3 Controller output current loops

The simplest form of 4-20 mA current loop is the type used to represent the output of a process controller, sending a command signal to a final control element. Here, the controller supplies both the electrical power and signal information to the final control element, which acts as an electrical load. To illustrate, consider the example of a controller sending a 4-20 mA signal to an I/P (current-to-pressure) signal converter, which then pneumatically drives a control valve:

This particular controller has two digital displays, one for process variable (PV) and one for setpoint (SP), with a bargraph for displaying the output value (Out). One pushbutton provides the operator with a way to switch between Automatic and Manual modes (A/M), while two other pushbuttons provide means to decrement and increment either the setpoint value (in Automatic mode) or the Output value (in Manual mode).

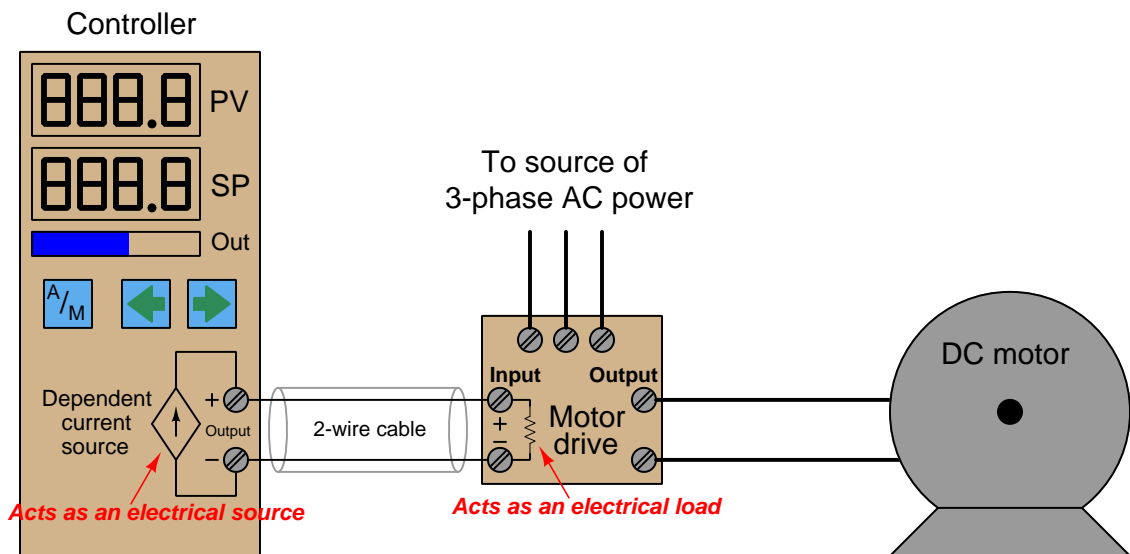

Inside the controller, a *dependent current source* provides the 4-20 mA DC current signal to the I/P transducer. Like all current sources, its purpose is to maintain current in the “loop” circuit regardless of circuit resistance or any external voltage sources. Unlike a constant current source, a “dependent” current source (represented by a diamond shape instead of a circle shape) varies its current value according to some external stimulus. In this case, either the mathematical function of the controller (Automatic mode) or the arbitrary action of the human operator (Manual mode) tells the current source how much DC current it should maintain in the circuit.

For example, if the operator happened to switch the controller into Manual mode and set the output value at 50%, the proper amount of DC current for this signal percentage would be 12 mA (exactly half-way between 4 mA and 20 mA). If everything is working properly, the current in the “loop” circuit to the I/P transducer should remain exactly at 12 mA regardless of slight changes in wire resistance, I/P coil resistance, or anything else: the current source inside the controller will “fight” as hard as it has to in order to maintain this set amount of current. This current, as it flows

through the wire coil of the I/P transducer mechanism, creates a magnetic field inside the I/P to actuate the pneumatic mechanism and produce a 9 PSI pressure signal output to the control valve (9 PSI being exactly half-way between 3 PSI and 15 PSI in the 3-15 PSI signal standard range). This should move the control valve to the half-way position.

The details of the controller's internal current source are not terribly important. Usually, it takes the form of an operational amplifier circuit driven by the voltage output of a DAC (Digital-to-Analog Converter). The DAC converts a binary number (either from the controller's automatic calculations, or from the human operator's manual setting) into a small DC voltage, which then commands the opamp circuit to regulate output current at a proportional value.

The scenario is much the same if we replace the I/P and control valve with a variable-speed motor drive. From the controller's perspective, the only difference it sees is a resistive load instead of an inductive load. The input resistance of the motor drive circuit converts the 4-20 mA signal into an analog voltage signal (typically 1-5 V, but not always). This voltage signal then commands the motor drive circuitry, telling it to modulate the power going to the electric motor in order to drive it at the desired speed:

Here, the variable-speed motor drive is a high-power electronic circuit that takes 3-phase AC power in and converts it to DC power at a variable voltage (that voltage level controlled by the 4-20 mA signal from the controller output). Another style of motor “drive” is one that takes in AC power and outputs 3-phase AC power at variable voltage and frequency to power an AC induction motor. This latter style is usually called a *variable frequency drive* or *VFD*, but it looks the same to the controller output: a fixed resistive load accepting the 4-20 mA output signal.

In some process applications the final control element is “reverse-acting” in that a controller output current value of 4 mA tells the FCE to go to its “full” (100%) capacity and a controller output current value of 20 mA commands the FCE to go to its minimum (0%) capacity. Such is the case with an I/P transducer driving an “air-to-close” pneumatic control valve, where the valve’s spring works to push the throttling mechanism open and air pressure on the valve diaphragm works to push the throttling mechanism shut. A practical reason for designing a control system like this is if the dictates of process safety require the valve go wide-open if ever the instrument air supply fails or the 4-20 mA output signal circuit fails.

In such applications, we need to configure the controller in such a way that the output display (digital read-out and/or bargraph) is *reverse-indicating* so as to avoid confusing any human operator using the controller. Since 4 mA represents a wide-open control valve and 20 mA represents a fully shut control valve, a reverse-indicating controller will display 0% output when the current signal is 20 mA and 100% output when the current signal is 4 mA (i.e. the controller display is a direct representation of *control valve stem position*, not of the current signal itself):

*Air-to-Close valve with controller configured for “reverse indication” on its output display*

It should be noted that direct or reverse *indication* on the controller’s faceplate is unrelated to direct or reverse *control action* of the controller’s algorithm. The former is merely the way in which the output signal is graphically represented to the human operator while the latter is the relationship between the process variable (PV) signal and the controller’s output (MV) signal necessary for negative-feedback control. For the sake of argument, this controller’s automatic action could still be *direct* (i.e. greater PV signal = greater output signal) even though its output bargraph indication is *reverse* in order to faithfully show valve stem position to the human operator.

## 13.4 4-wire (“self-powered”) transmitter current loops

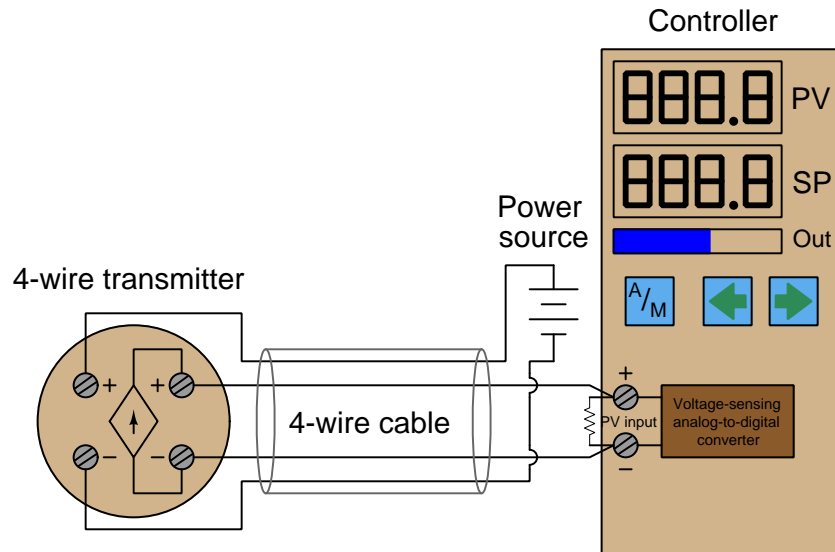

DC electric current signals may also be used to communicate process measurement information from transmitters to controllers, indicators, recorders, alarms, and other input devices. Recall that the purpose of a *transmitter* is to sense some physical variable (e.g. pressure, temperature, flow) and then report that quantity in the form of a signal, in this case a 4 to 20 milliamp DC current proportional to that measured quantity. The simplest form of 4-20 mA measurement loop is one where the transmitter has two terminals for the 4-20 mA signal wires to connect, and two more terminals where a power source connects. These transmitters are called “4-wire” or “self-powered” units. The current signal from the transmitter connects to the *process variable input* terminals of the controller to complete the loop:

Some process controllers are not equipped to directly accept milliamp input signals, but rather can only interpret DC voltage signals. In such cases we must connect a precision resistor across the controller's input terminals to convert the 4-20 mA transmitter signal into a standardized analog voltage signal the controller can understand. A voltage signal range of 1 to 5 volts is standard, although some models of controller use different voltage ranges and therefore require different precision resistor values. If the voltage range is 1-5 volts and the current range is 4-20 mA, the precision resistor value must be 250 ohms according to Ohm's Law.

Since this is a digital controller, the input voltage at the controller terminals is interpreted by an analog-to-digital converter (ADC) circuit, which converts the measured voltage into a digital number the controller's microprocessor can interpret.

In some installations, transmitter power is supplied through additional wires in the cable from a power source located near the controller:

The obvious disadvantage of this scheme is the requirement of two more conductors in the cable. More conductors means the cable will be larger-diameter and more expensive for a given length. Cables with more conductors will require larger electrical conduit to fit in to, and all field wiring panels will have to contain more terminal blocks to marshal the additional conductors. If no suitable electrical power source exists at the transmitter location, though, a 4-wire cable is necessary to service a 4-wire transmitter.

## 13.5 2-wire (“loop-powered”) transmitter current loops

It is possible to convey electrical power *and* communicate analog information over the same two wires using 4 to 20 milliamps DC, if we design the transmitter to be *loop-powered*. A loop-powered transmitter connects to a process controller with only two wires, which is why loop-powered transmitters are synonymously known as *2-wire transmitters*:

Here, the transmitter is not really a current *source* in the sense that a 4-wire transmitter is. Instead, a 2-wire transmitter’s circuitry is designed to act as a current *regulator*, limiting current in the series loop to a value representing the process measurement, while relying on a remote source of power to motivate the electric current. Please note the direction of the arrow in the transmitter’s dependent current source symbol, and how it relates to the voltage polarity marks. Refer back to the illustration of a 4-wire transmitter circuit for comparison. The current “source” in this loop-powered transmitter actually behaves as an electrical *load*<sup>6</sup>, while the current source in the 4-wire transmitter functioned as a true electrical source.

A loop-powered transmitter gets its operating power from the minimum terminal voltage and current available at its two terminals. With the typical source voltage being 24 volts DC, and the maximum voltage dropped across the controller’s 250 ohm resistor being 5 volts DC, the transmitter should always have at least 19 volts available at its terminals. Given the lower end of the 4-20 mA signal range, the transmitter should always have at least 4 mA of current to function on. Thus, the transmitter will always have a certain minimum amount of electrical power available on which to operate, while regulating current to signal the process measurement to the receiving instrument.

<sup>6</sup>Some of my students have referred to such a circuit as a *smart load*, since it functions as a load but nevertheless exerts control over the circuit current.

Internally, the electronic hardware of a 2-wire transmitter circuitry resembles the following (simplified) diagram. Note that everything shown within the shaded rectangle is represented by the “2-wire transmitter” circle in the previous diagram:

All sensing, scaling, and output conditioning circuitry inside the transmitter must be designed to operate on less than 4 mA of DC current, and at a modest terminal voltage. In order to create loop currents exceeding 4 mA – as the transmitter must do in order to span the entire 4 to 20 milliamp signal range – the transmitter circuitry uses a transistor to shunt (bypass) extra current from one terminal to the other as needed to make the total current indicative of the process measurement. For example, if the transmitter’s internal operating current is only 3.8 mA, and it must regulate loop current at a value of 16 mA to represent a condition of 75% process measurement, the shunt transistor will be driven by the opamp to bypass exactly 12.2 mA of current (because 3.8 mA + 12.2 mA = 16.0 mA).

The very low amount of electrical power available at a 2-wire transmitter’s terminals limits its functionality. If the transmitter requires more electrical power than can be delivered with 4 milliamps and 19 volts (minimum each), the only solution is to go with a 4-wire transmitter where the power conductors are separate from the signal conductors. An example of a process transmitter that must be 4-wire is a chemical analyzer such as a chromatograph, requiring enough power to operate an electrical heater, solenoid valves, and an on-board computer to process the sensor data. There is simply no way to operate a machine as complex and power-hungry as a 2010-era chromatograph on 4 milliamps and 19 volts!

Early current-based industrial transmitters were not capable of operating on such low levels of electrical power, and so used a different current signal standard: 10 to 50 milliamps DC. Loop power supplies for these transmitters ranged upwards of 90 volts to provide enough power for the transmitter. Safety concerns made the 10-50 mA standard unsuitable for some industrial

installations, and modern microelectronic circuitry with its reduced power consumption made the 4-20 mA standard practical for nearly all types of process transmitters.

### 13.6 4-wire “passive” versus “active” output transmitters

Some self-powered (4-wire) analog electronic transmitters are designed to behave as electrical loads rather than as electrical sources. Such transmitters are commonly referred to as having *passive* or *sinking* 4-20 mA outputs, as opposed to the *active* or *sourcing* 4-wire transmitters previously described:

At first this seems needlessly confusing. Why build a self-powered transmitter requiring a second power supply in the circuit to drive the 4-20 mA signal? The reason for this type of transmitter's existence is the sheer popularity of loop-powered 2-wire 4-20 mA transmitters. Loop-powered field instruments have become so popular in industry that many control systems, PLCs, indicators, and other receiving devices have their own loop power supply built in so that these systems can *only* connect to loads and are therefore incompatible with current-sourcing 4-wire transmitters. Thus, "passive" or "sinking" 4-wire transmitters were developed to accommodate control systems designed to work (only) with loop-powered instruments.

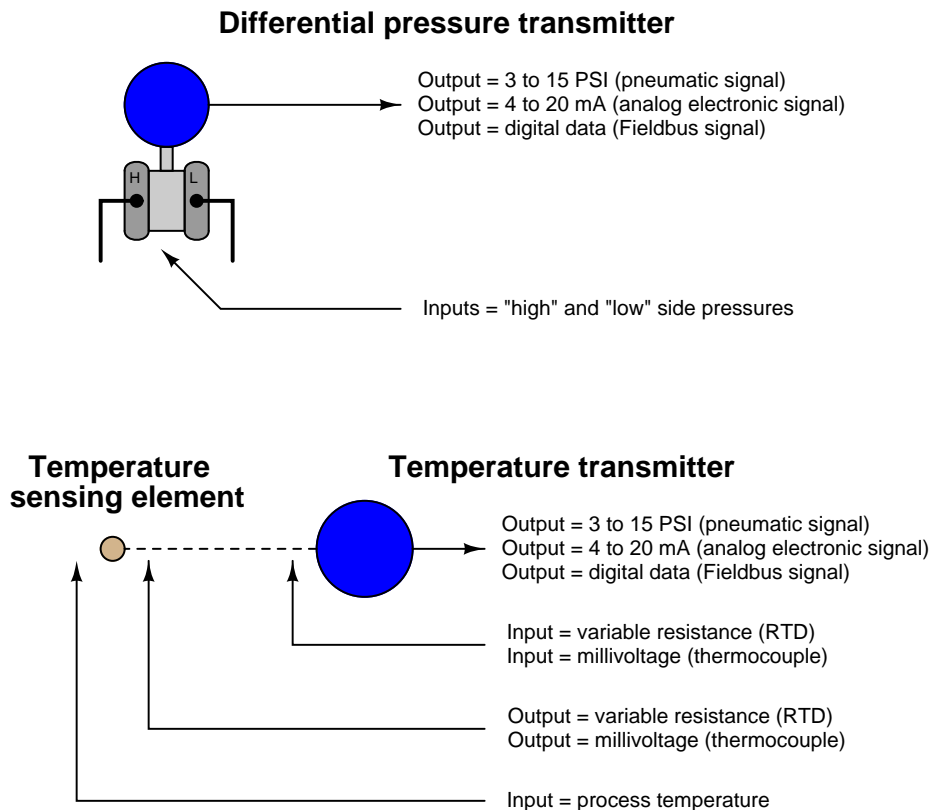

Some 4-wire transmitters are configurable for either passive or active (i.e. sinking versus sourcing) operation, requiring the installing technician to pay close attention in order for the circuit to properly function.

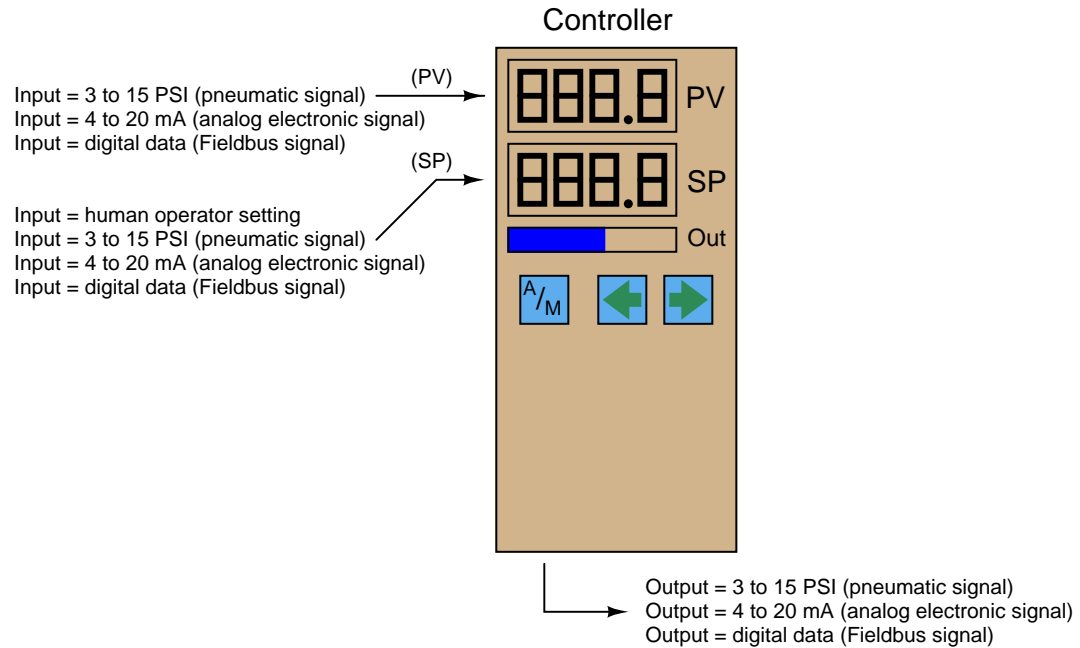

## 13.7 Troubleshooting current loops

A fundamental principle in instrumentation system troubleshooting is that every instrument has at least one input and at least one output, and that the output(s) should accurately correspond to the input(s). If an instrument's output is not properly corresponding to its input according to the instrument's design function, there must be something wrong with that instrument.

Consider the inputs and outputs of several common instruments: transmitters, controllers, indicators, and control valves. Each of these instruments takes in (input) data in some form, and generates (output) data in some form. In any instrument "loop," the output of one instrument feeds into the input of the next, such that information passes from one instrument to another. By intercepting the data communicated between components of an instrument system, we are able to locate and isolate faults. In order to properly understand the intercepted data, we must understand the inputs and outputs of the respective instruments and the basic functions of those instruments.

The following illustrations highlight inputs and outputs for instruments commonly found in control systems:

In order to check for proper correspondence between instrument inputs and outputs, we must be able to use appropriate test equipment to intercept the signals going into and out of those instruments. For 4-20 mA analog signal-based instruments, this means we must be able to use electrical meters capable of accurately measuring current and voltage.

### 13.7.1 Using a standard milliammeter to measure loop current

Since the signal of interest is represented by an electric current in an instrumentation current “loop” circuit, the obvious tool to use for troubleshooting is a multimeter capable of accurately measuring DC milliamperes. Unfortunately, though, there is a major disadvantage to the use of a milliammeter: the circuit must be “broken” at some point to connect the meter in series with the current, and this means the current will fall to 0 mA until the meter is connected (then fall to 0 mA when the meter is removed from the circuit). Interrupting the current means interrupting the flow of information conveyed by that current, be it a process measurement or a command signal to a final control element. This *will* have adverse effects on a control system unless certain preparatory steps are taken.

Before “breaking the loop” to connect your meter, one must first warn all appropriate personnel that the signal will be interrupted at least twice, falling to a value of  $-25\%$  each time. If the signal to be interrupted is coming from a process transmitter to a controller, the controller should be placed in Manual mode so it will not cause an upset in the process (by moving the final control element in response to the sudden loss of PV signal). Also, process alarms should be temporarily disabled so they do not cause panic. If this current signal also drives process shutdown alarms, these should be temporarily disabled so that nothing shuts down upon interruption of the signal.

If the current signal to be interrupted is a command signal from a controller to a final control element, the final control element either needs to be manually overridden so as to hold a fixed setting while the signal varies, or it needs to be bypasses completely by some other device(s). If the final control element is a control valve, this typically takes the form of opening a bypass valve and closing at least one block valve:

Since the manually-operated bypass valve now performs the job the automatic control valve used to do, a human operator must remain posted at the bypass valve to carefully throttle it and maintain control of the process.

Block and bypass valves for a large gas flow control valve may be seen in the following photograph:

In consideration of the labor necessary to safely interrupt the current signal to a control valve in a live process, we see that the seemingly simple task of connecting a milliammeter in series with a 4-20 mA current signal is not as easy as it may first appear. Better ways must exist, no?

### 13.7.2 Using a clamp-on milliammeter to measure loop current

One better way to measure a 4-20 mA signal without interrupting it is to do so magnetically, using a clamp-on milliammeter. Modern Hall-effect sensors are sensitive and accurate enough to monitor the weak magnetic fields created by the passage of small DC currents in wires. Ammeters using Hall-effect sensors have are completely non-intrusive because they merely clamp around the wire, with no need to “break” the circuit. An example of a such a clamp-on current meter is the Fluke model 771, shown in this photograph:

Note how this milliammeter not only registers loop current (3.98 mA as shown in the photograph), but it also converts the milliamp value into a percentage of range, following the 4 to 20 mA signal standard. One disadvantage to be aware of for clamp-on milliammeters is the susceptibility to error from strong external magnetic fields. Steady magnetic fields (from permanent magnets or DC-powered electromagnets) may be compensated for by performing a “zero” adjustment with the instrument held in a similar orientation prior to measuring loop current through a wire.

### 13.7.3 Using “test” diodes to measure loop current

Another way to measure a 4-20 mA signal without interrupting it involves the use of a rectifying diode, originally installed in the loop circuit when it was commissioned. A “test” diode may be placed anywhere in series within the loop in such a way that it will be forward-biased. During normal operation, the diode will drop approximately 0.7 volts, as is typical for any silicon rectifying diode when forward biased. The following schematic diagram shows such a diode installed in a 2-wire transmitter loop circuit:

If someone connects a milliammeter in parallel with this diode, however, the very low input resistance of the ammeters “shorts past” the diode and prevents any substantial voltage drop from forming across it. Without the necessary forward voltage drop, the diode effectively turns off and conducts 0 mA, leaving the entire loop current to pass through the ammeter:

When the milliammeter is disconnected, the requisite 0.7 volt drop appears to turn on the diode, and all loop current flows through the diode again. At no time is the loop current ever interrupted, which means a technician may take current measurements this way and never have to worry about generating false process variable indications, setting off alarms, or upsetting the process.

Such a diode may be installed at the nearest junction box, between terminals on a terminal strip, or even incorporated into the transmitter itself. Some process transmitters have an extra pair of terminals labeled “Test” for this exact purpose. A diode is already installed in the transmitter, and these “test” terminals serve as points to connect the milliammeter across.

The following photograph shows an example of this on a Rosemount model 3051 differential pressure transmitter:

Note the two test points labeled “TEST” below and to the right of the main screw terminals where the loop wiring attaches. Connecting an ammeter to these two test points allows for direct measurement of the 4-20 mA current signal without having to un-do any wire connections in the circuit.

Transmitters equipped with analog meter movements for direct visual indication of the 4-20 mA signal usually connect the analog milliammeter in parallel with just such a diode. The reason for doing this is to maintain loop continuity in the event the fine-wire coil inside the milliammeter movement were to accidentally break open.

### 13.7.4 Using shunt resistors to measure loop current

A similar method for non-invasively measuring current in a 4-20 mA instrumentation circuit is to install a precision resistor in series. If the resistance value is precisely known, the technician merely needs to measure voltage across it with a voltmeter and use Ohm's Law to calculate current:

In electronics, such a precision resistor used for measuring current is often referred to as a *shunt* resistor. Shunt resistor values are commonly very small, for their purpose is to assist in current measurement without imposing undue voltage drop within a circuit. It is rare to find a 250 ohm resistor used strictly as a diagnostic shunt resistor, because the extra voltage drop (1 to 5 volts, depending on the current signal level) may “starve” loop-powered instruments of voltage necessary to operate. Shunt resistor values as low as 1 ohm may be found installed in 4-20 mA current loops at strategic locations where technicians may need to measure loop current<sup>7</sup>.

---

<sup>7</sup>Of course, a 1 ohm resistor would drop 4 mV at 4 mA loop current, and drop 20 mV at 20 mA loop current. These small voltage values necessitate a highly accurate DC voltmeter for field measurement!

### 13.7.5 Troubleshooting current loops with voltage measurements

If neither component (diode nor shunt resistor) is pre-installed in the circuit, and if a Hall-effect (clamp-on) precision milliammeter is unavailable, a technician may still perform useful troubleshooting measurements using nothing but a DC voltmeter. Here, however, one must be careful of how to interpret these voltage measurements, for they may not directly correspond to the loop current as was the case with measurements taken in parallel with the precision resistor.

Take for example this 4-20 mA loop where a controller sends a command signal to an I/P transducer:

There is no standardized resistance value for I/P transducer coils, and so the amount of voltage dropped across the I/P terminals for any given amount of loop current will be unique for every different model of I/P. The Fisher model 567 I/P transducer built for 4-20 mA signals has a normal coil resistance of 176 ohms. Thus, we would expect to see a voltage drop of approximately 0.7 volts at 4 mA and a drop of approximately 3.5 volts at 20 mA across the I/P terminals. Since the controller output terminals are directly in parallel with the I/P terminals, we would expect to see approximately the same voltage there as well (slightly greater due to wire resistance). The lack of known precision in the I/P coil resistance makes it difficult to tell exactly how much current is in the loop for any given voltage measurement we take with a voltmeter. However, if we do know the approximate coil resistance of the I/P, we can at least obtain an estimate of loop current, which is usually good enough for diagnostic purposes.

If the I/P coil resistance is completely unknown, voltage measurements become useless for quantitative determination of loop current. Voltage measurements would be useful only for qualitatively determining loop continuity (i.e. whether there is a break in the wiring between the controller and I/P).

Another example for consideration is this loop-powered 4-20 mA transmitter and controller circuit, where the controller supplies DC power for the loop:

It is very common to find controllers with their own built-in loop power supplies, due to the popularity of loop-powered (2-wire) 4-20 mA transmitters. If we know the transmitter requires a DC voltage source somewhere in the circuit to power it up, it makes sense to include one in the controller, right?

The only voltage measurement that directly and accurately corresponds to loop current is the voltage directly across the 250 ohm precision resistor. A loop current of 4 mA will yield a voltage drop of 1 volt, 12 mA will drop 3 volts, 20 mA will drop 5 volts, etc.

A voltage measurement across the transmitter terminals will show us the *difference* in voltage between the 26 volt power supply and the voltage dropped across the 250 ohm resistor. In other words, the transmitter's terminal voltage is simply what is left over from the source voltage of 26 volts after subtracting the resistor's voltage drop. This makes the transmitter terminal voltage inversely proportional to loop current: the transmitter sees approximately 25 volts at 4 mA loop current (0% signal) and approximately 21 volts at 20 mA loop current (100% signal).

The use of the word "approximate" is very intentional here, for loop power supplies are usually non-regulated. In other words, the "26 volt" rating is approximate and subject to change! One of the advantages of the loop-powered transmitter circuit is that the source voltage is largely irrelevant, so long as it exceeds the minimum value necessary to ensure adequate power to the transmitter. If the source voltage drifts for any reason, it will have no impact on the measurement signal at all, because the transmitter is built as a *current regulator*, regulating current in the loop to whatever value represents the process measurement, regardless of slight changes in loop source voltage, wire resistance, etc. This rejection of power supply voltage changes means the loop power supply need not be regulated, and so in practice it rarely is.

This brings us to a common problem in loop-powered 4-20 mA transmitter circuits: maintaining sufficient operating voltage at the transmitter terminals. Recall that a loop-powered transmitter

relies on the voltage dropped across its terminals (combined with a current of less than 4 mA) to power its internal workings. This means the terminal voltage must not be allowed to dip below a certain minimum value, or else the transmitter will not have enough electrical power to continue its normal operation. This makes it possible to “starve” the transmitter of voltage if the loop power supply voltage is insufficient, and/or if the loop resistance is excessive.

To illustrate how this can be a problem, consider the following 4-20 mA measurement loop, where the controller supplies only 20 volts DC to power the loop, and an indicator is included in the circuit to provide operators with a field-mounted indication of the transmitter’s measurement:

The indicator contains its own 250 ohm resistor to provide a 1-5 volt signal for the meter mechanism to sense. This means the total loop resistance has now risen from 250 ohms to 500 ohms (plus any wire resistance). At full current (20 mA), this total circuit resistance will drop (at least) 10 volts, leaving 10 volts or less at the transmitter terminals to power the transmitter’s internal workings. 10 volts may not be enough for the transmitter to successfully operate, though. The Rosemount model 3051 pressure transmitter, for example, requires a minimum of 10.5 volts at the terminals to operate.

However, the transmitter *will* operate just fine at lower loop current levels. When the loop current is only 4 mA, for example, the combined voltage drop across the two 250 ohm resistors will be only 2 volts, leaving about 18 volts at the transmitter terminals: more than enough for practically any model of 4-20 mA loop-powered transmitter to successfully operate. Thus, the problem of insufficient supply voltage only manifests itself when the process measurement nears 100% of range. This could be a difficult problem to diagnose, since it appears only during certain process conditions and not others. A technician looking only for wiring faults (loose connections, corroded terminals, etc.) would never find the problem.

When a loop-powered transmitter is starved of voltage, its behavior becomes erratic. This is especially true of “smart” transmitters with built-in microprocessor circuitry. If the terminal voltage

dips below the required minimum, the microprocessor circuit shuts down. When the circuit shuts down, the current draw decreases accordingly. This causes the terminal voltage to rise again, at which point the microprocessor has enough voltage to start up. As the microprocessor “boots” back up again, it increases loop current to reflect the near-100% process measurement. This causes the terminal voltage to sag, which subsequently causes the microprocessor to shut down again. The result is a slow on/off cycling of the transmitter’s current, which makes the process controller think the process variable is surging wildly. The problem disappears, though, as soon as the process measurement decreases enough that the transmitter is allowed enough terminal voltage to operate normally.

### 13.7.6 Using loop calibrators

Special-purpose electronic test instruments called *loop calibrators* exist for the express purpose of 4-20 mA current loop circuit troubleshooting. These versatile instruments are generally capable of not only measuring current, but also *sourcing* current to unpowered devices in a loop, and also *simulating* loop-powered 4-20 mA transmitters.

A very popular loop calibrator unit is the Altek model 334A, a battery-powered, hand-held unit with a rotary knob for current adjustment and toggle switches for mode setting. The following illustration shows how this calibrator would be used to measure current in a functioning input signal loop<sup>8</sup>:

Here, the loop wiring is broken at the negative terminal of the loop-powered transmitter, and the calibrator connected in series to measure current. If this loop had a test diode installed, the calibrator could be connected in parallel with the diode to achieve the same function. Note the polarity of the calibrator's test leads in relation to the circuit being tested: the calibrator is acting

<sup>8</sup>In the following illustrated examples, the transmitter is assumed to be a pressure transmitter with a calibrated range of 0 to 750 inches of water column, 4-20 mA. The controller's PV (process variable) display is appropriately ranged to display 0 to 750 as well.

as a passive device (i.e. as a *load* rather than as a *source*), with the more positive loop terminal connected to the calibrator's red test lead and the more negative terminal connected to the black test lead.

The same loop calibrator may be used to *source* (or *drive*) a 4-20 mA signal into an indicating instrument to test the function of that instrument independently. Here, we see the Altek calibrator used as a current source to send a 16.00 mA signal to the PV (process variable) input of the controller, in order to check that the controller properly senses and displays the analog current signal:

No transmitter need be included in this illustration, because the calibrator takes its place. Note how the calibrator functions here as an active *source* of current rather than a passive load as it was in the last example. Not only does it supply the information (i.e. regulate the current), but it also provides the energy in the circuit. The DC power source inside the controller is not used for loop power, because the calibrator in "source" mode provides the necessary power to drive current through the 250 ohm resistor.

A very common use of a loop calibrator in “source” mode is to test a control valve for proper calibration, quick response, and to measure friction. Here, the loop calibrator takes place of the loop controller output, serving as the sole source of current to the I/P transducer:

This circuit configuration is extremely useful to any instrument technician testing the response of a control valve, because it allows the signal to be finely adjusted while in the direct presence of the valve to monitor its motion. If a control valve is suspected of having excessive friction in its moving parts, for instance, a technician may test the valve by incrementing and decrementing the loop calibrator's source current in progressively smaller steps. Large step-changes in current should cause the valve to overcome friction and move, but small step-changes will fail to move the valve mechanism when frictional forces exceed the incremental forces produced by the changing pressure.

A photograph showing this very use of a loop calibrator in a valve rebuild shop appears here:

In this particular example, the loop calibrator connects to a device on the control valve called a *positioner*, which is a more sophisticated device than an I/P transducer. In addition to converting a 4-20 mA signal into an air pressure, the positioner also actively monitors the valve stem's position to ensure it goes to the correct position for any given 4-20 mA command signal. Here, the technician is using the loop calibrator to verify the control valve faithfully obeys the command signal through the entire 4 to 20 milliamp signal range.

An alternative method of sending a known current signal into an indicating instrument providing loop power is to set the loop calibrator such that it mimics (or *simulates*) the behavior of a loop-powered (2-wire) transmitter. In this mode, the calibrator regulates loop current at a user-determined value, but provides no motivating voltage to drive this current. Instead, it passively relies on the loop's regular voltage source to provide the necessary power:

Note the polarity of the calibrator's test leads: current entering the red lead and exiting the black lead, behaving as an electrical *load* just the same as a loop-powered transmitter. Like a 2-wire transmitter, the calibrator in simulate mode regulates the circuit current while depending on an external voltage source for energy.

A loop calibrator's *simulate transmitter* mode is especially useful for testing the transmitter cable and controller input to ensure any 4-20 mA signal sent by a transmitter will be correctly received and displayed by the controller. This sort of test is commonly performed on newly-installed control systems as part of the commissioning procedure, prior to start-up of the controlled process, in order to verify the controller's process variable input, 24 VDC power supply, and transmitter wiring are all properly functioning. Typically an instrument technician would simulate several different current values (e.g. 4 mA, 8 mA, 12 mA, 16 mA, 20 mA) with the calibrator in "simulate" mode while someone else monitors the controller's PV display and alarms to check for proper function.

A legacy loop calibrator still familiar to many instrument technicians at the time of this writing is the classic Transmation model 1040:

Other examples of vintage loop calibrator technology include the Nassau model 8060 (left) and the Biddle Versa-Cal (right):

A modern loop calibrator manufactured by Fluke is the model 705:

With this calibrator, the *measure*, *source*, and *simulate* modes are accessed by repeatedly pushing a button, with the current mode displayed on the screen:

Note the dual-numeric display, showing both loop current and percentage (assuming a 4-20 mA range).

### 13.7.7 NAMUR signal levels

One of the intrinsic benefits of a “live zero” analog signal standard such as 4-20 mA is that a wire break (open fault) can immediately be detected by the absence of current in the circuit. If the signal scale started at zero (e.g. 0-20 mA), there would be no way to electrically distinguish between a broken wire and a legitimate 0% signal value. In other words, the “live” LRV point of a 4-20 mA signal provides us with a way to indicate a certain type of circuit fault in addition to indicating an analog measurement during normal operation.

The *NAMUR* signal standard takes this philosophy one step further by defining specific diagnostic meaning to values of current lying outside the 4-20 mA range:

Signal level	Fault condition
$\text{Output} \leq 3.6 \text{ mA}$	Sensing transducer failed low
$3.6 \text{ mA} < \text{Output} < 3.8 \text{ mA}$	Sensing transducer failed (detected) low
$3.8 \text{ mA} \leq \text{Output} < 4.0 \text{ mA}$	Measurement under-range
$21.0 > \text{Output} \geq 20.5 \text{ mA}$	Measurement over-range
$\text{Output} \geq 21.0 \text{ mA}$	Sensing transducer failed high

NAMUR-compliant transmitters are designed to limit their output signals between 3.8 mA and less than 21 mA when functioning properly. Signals lying outside this range indicate some form of failure has occurred within the transmitter or the circuit wiring.

NAMUR-compliant control systems will recognize these errant milliamp values as fault states, and may be programmed to take specific action upon receiving these signal values. Such actions include forcing controllers into manual mode, initiating automatic shutdown procedures, or taking some other form of safe action appropriate to the knowledge of a failed process transmitter.

## 13.8 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader's view of this chapter's concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **Linear equations:** any function represented by a straight line on a graph may be represented symbolically by the slope-intercept formula  $y = mx + b$ . Relevant to instrument input/output scaling.
- **Electrical sources versus loads:** electrical power sources output current (conventional flow) on their positive terminals and input current on their negative terminals (e.g. batteries and generators). Electrical loads do the opposite (e.g. resistors). Relevant to determining voltage drops and current directions in analog current loop circuits, as well as matching polarities between field instruments and controllers.
- **Voltage versus current sources:** voltage sources try to maintain constant voltage with variable current, while current sources try to maintain constant current with variable voltage. Relevant to the operation of 4-20 mA signaling circuits: loop transmitter act as current sources (or in some cases as current regulators), dropping as much or as little voltage as needed to maintain the desired amount of current in the circuit.
- **Self-balancing opamp circuits:** all self-balancing operational amplifier circuits work on the principle of negative feedback maintaining a nearly zero differential input voltage to the opamp. Making the "simplifying assumption" that the opamp's differential input voltage is exactly zero assists in circuit analysis, as does the assumption that the input terminals draw negligible current.

## Chapter 14

# Pneumatic instrumentation

While electricity is commonly used as a medium for transferring energy across long distances, it is also used in instrumentation to transfer *information*. A simple 4-20 mA current “loop” uses direct current to represent a process measurement in percentage of span, such as in this example:

The transmitter senses an applied fluid pressure from the process being measured, regulates electric current in the series circuit according to its calibration (4 mA = no pressure ; 20 mA = full pressure), and the indicator (ammeter) registers this measurement on a scale calibrated to read in pressure units. If the calibrated range of the pressure transmitter is 0 to 250 PSI, then the indicator’s scale will be labeled to read from 0 to 250 PSI as well. No human operator reading that scale need worry about how the measurement gets from the process to the indicator – the 4-20 mA signal medium is transparent to the end-user as it should be.

Air pressure may be used as an alternative signaling medium to electricity. Imagine a pressure transmitter designed to output a *variable air pressure* according to its calibration rather than a *variable electric current*. Such a transmitter would have to be supplied with a source of constant-pressure compressed air instead of an electric voltage, and the resulting output signal would be conveyed to the indicator via tubing instead of wires:

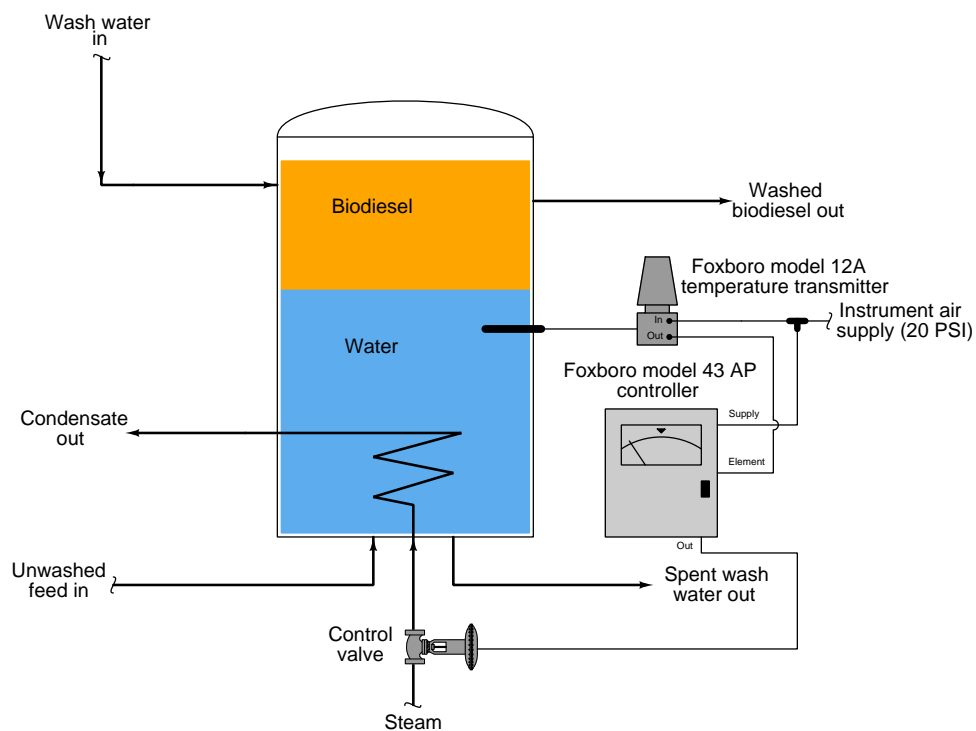

The indicator in this case would be a special pressure gauge, calibrated to read in units of process pressure although actuated by the pressure of clean compressed air from the transmitter instead of directly by process fluid. The most common range of air pressure for industrial pneumatic instruments is 3 to 15 PSI. An output pressure of 3 PSI represents the low end of the process measurement scale and an output pressure of 15 PSI represents the high end of the measurement scale. Applied to the previous example of a transmitter calibrated to a range of 0 to 250 PSI, a lack of process pressure would result in the transmitter outputting a 3 PSI air signal and full process pressure would result in an air signal of 15 PSI. The face of this special “receiver” gauge would be labeled from 0 to 250 PSI, while the actual mechanism would operate on the 3 to 15 PSI range output by the transmitter. As with the 4-20 mA loop, the end-user need not know how the information gets transmitted from the process to the indicator. The 3-15 PSI signal medium is once again transparent to the operator.

Typically, a 3 PSI pressure value represents 0% of scale, a 15 PSI pressure value represents 100% of scale, and any pressure value in between 3 and 15 PSI represents a commensurate percentage in between 0% and 100%. The following table shows the corresponding current and percentage values for each 25% increment between 0% and 100%. Every instrument technician tasked with maintaining 3-15 PSI pneumatic instruments commits these values to memory, because they are referenced so often:

Pressure value	% of scale
3 PSI	0%
6 PSI	25%
9 PSI	50%
12 PSI	75%
15 PSI	100%

Pneumatic temperature, flow, and level control systems have all been manufactured to use the same principle of 3-15 PSI air pressure signaling. In each case, the transmitter and controller are both supplied clean compressed air at some modest pressure (20 to 25 PSI, usually) and the instrument signals travel via tubing. The following illustrations show what some of these applications look like:

## Biodiesel "wash column" temperature control

## Two-element boiler steam drum level control

Instruments operating on compressed air, and process measurement signals transmitted as air pressures through long runs of metal tubing, was the norm for industrial instrumentation prior to the advent of reliable electronic instruments. In honor of this paradigm, instrument technicians were often referred to as *instrument mechanics*, for these air-powered devices were mechanically complex and in frequent need of adjustment to maintain high accuracy.

Back in the days of control room panels populated by rows and rows of pneumatic indicators, recorders, and controllers, clean and organized routing of all the instrument signal tubes was a significant concern. By contrast, electrical wires are relatively easy to organize through the use of marshaling panels and terminal blocks – bundles of tubes (especially metal tubes!) are not. A photograph taken of the upper rear portion of an old control room panel shows a portion of a marshaling board where dozens of bulkhead-style 1/4 inch instrument tube fittings are organized in neat rows<sup>1</sup>, where a multitude of pneumatic instrument signal lines once attached:

Each bulkhead fitting bears a numbered tag<sup>2</sup>, for easy identification and documentation of tube connections. Loop diagrams of pneumatic control systems documented each bulkhead fitting where an instrument signal passed, in the same way that modern loop diagrams document each terminal block where an electrical signal connection is made.

<sup>1</sup>Note the staggered layout of the tube fittings, intended to improve access to each one. Remember that the technician used a 9/16 inch wrench to loosen and tighten the tube fitting nuts, so it was important to have working room between fittings in which to maneuver a wrench.

<sup>2</sup>The numbers are difficult to see here, because the entire panel has been painted in a thick coat of grey paint. This particular panel was stripped of all pneumatic instruments and outfitted with electronic instruments, so the rows of bulkhead fittings no longer serve a purpose, but to remind us of legacy technology. I must wonder if some day in the future I will include a photograph of an empty terminal strip in another chapter of this book, as I explain how wired “legacy” instruments have all but been replaced by wireless (radio) instruments! Let the ghosts of the past speak to you, dear reader, testifying to the endless march of technological evolution.

Pneumatic instruments still find wide application in industry, although it is increasingly rare to encounter completely pneumatic control loops. One of the most common applications for pneumatic control system components is control valve actuation, where pneumatic technology still dominates. Not only is compressed air used to create the actuation force in many control valve mechanisms, it is still often the signal medium employed to command the valve's position. Quite often this pneumatic signal originates from a device called an *I/P transducer*, or *current-to-pressure converter*, taking a 4-20 mA control signal from the output of an electronic controller and translating that information as a pneumatic 3-15 PSI signal to the control valve's positioner or actuator.

## 14.1 Pneumatic sensing elements

Most pneumatic instruments use a simple but highly sensitive mechanism for converting mechanical motion into variable air pressure: the *baffle-and-nozzle* assembly (sometimes referred to as a *flapper-and-nozzle* assembly). A baffle is nothing more than a flat object obstructing the flow of air out of a small nozzle by close proximity:

The physical distance between the baffle and the nozzle alters the resistance of air flow through the nozzle. This in turn affects the air pressure built up inside the nozzle (called the nozzle *backpressure*). Like a voltage divider circuit formed by one fixed resistor and one variable resistor, the baffle/nozzle mechanism “divides” the pneumatic source pressure to a lower value based on the ratio of restrictiveness between the nozzle and the fixed orifice.

This crude assemblage is surprisingly sensitive, as shown by the graph. With a small enough orifice, just a few thousandths of an inch of motion is enough to drive the pneumatic output between its saturation limits. Pneumatic transmitters typically employ a small sheet-metal lever as the baffle. The slightest motion imparted to this baffle by changes in the process variable (pressure,

temperature, flow, level, etc.) detected by some sensing element will cause the air pressure to change in response.

The principle behind the operation of a baffle/nozzle mechanism is often used directly in quality-control work, checking for proper dimensioning of machined metal parts. Take for instance this shaft diameter checker, using air to determine whether or not a machined shaft inserted by a human operator is of the proper diameter after being manufactured on an assembly line:

If the shaft diameter is too small, there will be excessive clearance between the shaft and the inside diameter of the test jig, causing less air pressure to register on the gauge. Conversely, if the shaft diameter is too large, the clearance will be less and the gauge will register a greater air pressure because the flow of air will be obstructed by the reduced clearance. The exact pressure is of no particular consequence to the quality-control operator reading the gauge. What does matter is that the pressure falls within an acceptable range, reflecting proper manufacturing tolerances for the shaft. In fact, just like the 3-15 PSI “receiver gauges” used as pneumatic instrument indicators, the face of this pressure gauge might very well lack pressure units (such as kPa or PSI), but rather be labeled with a colored band showing acceptable limits of mechanical fit:

This is another example of the *analog* nature of pneumatic pressure signals: the pressure registered by this gauge *represents* a completely different variable, in this case the mechanical fit of the shaft to the test jig.

Although it is possible to construct a pneumatic instrument consisting *only* of a baffle/nozzle mechanism, this is rarely done. Usually the baffle/nozzle mechanism is just one of several components comprising a “balancing” mechanism in a pneumatic instrument. It is this concept of self-balancing that we will study next.

## 14.2 Self-balancing pneumatic instrument principles

A great many precision instruments use the principle of *balance* to measure some quantity. Perhaps the simplest example of a balance-based instrument is the common balance-beam scale used to measure mass in a laboratory:

A specimen of unknown mass is placed in one pan of the scale, and precise weights are placed in the other pan until the scale achieves a condition of balance. When balance is achieved, the mass of the specimen is known to be equal to the sum total of mass in the other pan. An interesting detail to note about the scale itself is that it has no need of routine calibration. There is nothing to “drift” out of spec which would cause the scale to read inaccurately. In fact, the scale itself doesn’t even have a gauge to register the mass of the specimen: all it has is a single mark indicating a condition of balance. To express this more precisely, the balance beam scale is actually a *differential mass* comparison device, and it only needs to be accurate at a single point: zero. In other words, it only has to be correct when it tells you there is zero difference in mass between the specimen and the standard masses piled on the other pan.

The elegance of this mechanism allows it to be quite accurate. The only real limitation to accuracy is the certainty to which we know the masses of the balancing weights.

Imagine being tasked with the challenge of automating this laboratory scale. Suppose we grew weary of employing a lab technician to place standard weights on the scale to balance it for every new measurement, and we decided to find a way for the scale to balance itself. Where would we start? First we would need some sort of mechanism to sense when the scale was out of balance, and another mechanism to apply more or less downward force on the other pan whenever an out-of-balance condition was detected.

The baffle/nozzle mechanism previously discussed would suffice quite well as a detection mechanism: simply attach a baffle to the end of the pointer on the scale, and attach a nozzle adjacent to the baffle at the “zero” position (where the pointer should come to a rest at balance). Such a mechanism might look like this:

Now we have a highly sensitive means of indicating when the scale is balanced, but we still have not yet achieved full automation. The scale cannot balance itself, at least not yet.

Suppose now instead of using precise, machined, brass weights placed on the other pan to counter the mass of the specimen, we employ a pneumatically-actuated force generator operated by the backpressure of the nozzle. An example of such a “force generator” is a *bellows*: a device made of thin sheet metal with circular corrugations in it, such that it resembles the bellows on an accordion. Pneumatic pressure applied to the interior of the bellows causes it to elongate, the amount of force applied to the bellows’ end being the product of air pressure and the end surface area:

A photograph of a brass bellows unit appears here, taken from a Foxboro model 130 pneumatic controller:

If the bellows' expansion is externally restrained so it does not stretch appreciably – and therefore the metal never stretches enough to act as a restraining spring – the force exerted by the bellows on that restraining object will *exactly* equal the pneumatic pressure multiplied by the cross-sectional area of the bellows' end.

Applying this to the problem of the self-balancing laboratory scale, imagine fixing a bellows to the frame of the scale so it presses downward on the pan where the brass weights normally go, then connecting the bellows to the nozzle backpressure:

Now the scale *will* self-balance. When mass is added to the left-hand pan, the pointer (baffle) will move ever so slightly toward the nozzle until enough backpressure builds up behind the nozzle to make the bellows exert an equal and opposing force to re-balance the mechanism. This balancing action is entirely automatic: the nozzle backpressure adjusts to whatever value is necessary to

maintain the pointer in the balanced position, applying or venting pressure to the bellows as needed to keep the system in a condition of equilibrium. What we have created is a *negative feedback system*, where the output of the system (nozzle backpressure) continuously adjusts to match and balance the input (the applied weight).

This is all well and good, but how does this help us determine the weight of the specimen in the left-hand pan? What good is this self-balancing scale if we cannot *read* the balancing force? All we have achieved so far is to make the scale self-balancing. The next step is making the balancing force readable to a human operator.

Before we add the final piece to this automated scale, it is worthwhile to reflect on what has been done so far. By adding the baffle/nozzle and bellows mechanisms to the scale, we have abolished the need for brass weights and instead have substituted air pressure. In effect, the scale translates applied weight into a proportional air pressure: air pressure has now become an *analogue* for specimen weight. What we really need is a way to now translate that air pressure into a human-readable indication of weight.

To make this air pressure readable to a human operator, all we must add to the system is a pressure gauge. The gauge operates on air pressure, but now the air pressure is proportionately equivalent to specimen weight. In honor of this proportionality, we may label the face of the pressure gauge in units of ounces or grams instead of PSI or kPa:

It is very important to note how the pressure gauge performs an entirely different function with the feedback bellows in place. With just a baffle-nozzle mechanism at work, the pressure gauge was hyper-sensitive to any motion of the scale's balance beam – it served only as a highly sensitive indicator of balance. Now, with the addition of the feedback bellows, the pressure gauge actually indicates how much weight is in the specimen pan, not merely whether the scale is balanced or not. As we add more mass to the specimen pan, the gauge's indication proportionately increases. As we take away mass from the specimen pan, the gauge's indication proportionately decreases.

Although it may seem as though we are done with the task of fully automating the laboratory scale, we can go a step further. Building this pneumatic negative-feedback balancing system provides us with a capability the old manually-operated scale never had: *remote indication*. There is no reason why the indicating gauge must be located near the scale. Nothing prevents us from locating the receiver gauge some distance from the scale, and using long lengths of tubing to connect the two:

By equipping the scale with a pneumatic self-balancing apparatus, we have turned it into a *pneumatic weight transmitter*<sup>3</sup>, capable of relaying the weight measurement in analog pneumatic

<sup>3</sup>In ISA parlance, this would be a "WT" instrument, "W" signifying weight and "T" signifying transmitter.

form to an indicating gauge far away. This is the basic *force-balance* principle used in most pneumatic industrial transmitters to convert some process measurement into a 3-15 PSI pneumatic signal.

### 14.3 Pilot valves and pneumatic amplifying relays

Self-balancing mechanisms consisting solely of a baffle/nozzle detector coupled to a feedback bellows, while functional, are not always practical as field instruments. Nozzles and orifices must be made rather small in diameter in order to minimize compressed air usage<sup>4</sup>, but this means the mechanism will require significant time to alter its output pressure (i.e. to fill and empty the bellows and associated air tubing). Such a pneumatic mechanism will be impractically slow if connected to a remote indicating instrument through a long run of tubing, owing to the relatively large volume of that tube.

A practical solution to the compromise between air consumption and responsiveness inherent to simple baffle/nozzle/bellows mechanisms is to boost the nozzle backpressure (and volume) using a pneumatic “amplifier” device. With a pneumatic amplifier in place, the detector (baffle/nozzle) need not leak great quantities of compressed air, since the amplifier will provide the volume boost necessary to quickly fill (and vent) the bellows and signal tubing.

The design challenge for us, then, is how to construct such a pneumatic amplifier: a mechanism to amplify small pneumatic signal changes into larger pneumatic signal changes. In essence, we need to find a pneumatic equivalent of the electronic *transistor*: a device that lets a small signal control a larger signal.

---

<sup>4</sup>Compressed air is a valuable commodity because much energy is required to compress and distribute high-pressure air. Every pneumatic instrument’s nozzle is essentially a “leak” in the compressed air system, and the combined effect of many operating pneumatic instruments is that the air compressor(s) must continually run to meet demand.

First, let us analyze the following pneumatic mechanism and its electrical analogue (as shown on the right):

*Pneumatic mechanism*

*Equivalent electrical circuit*

As the control rod is moved up and down by an outside force, the distance between the plug and the seat changes. This changes the amount of resistance experienced by the escaping air, thus causing the pressure gauge to register varying amounts of pressure. Moving the control rod up opens the variable restriction formed by the plug and seat, venting air more easily and decreasing the output pressure. Moving the control rod down closes off the vent, causing output pressure to rise. These up-and-down rod motions are analogous to the variable resistor decreasing and increasing resistance, respectively, causing the output voltage to change in direct relation to the variable resistance.

There is little functional difference between this mechanism and a baffle/nozzle mechanism. Both work on the principle of one variable restriction and one fixed restriction (the orifice) “dividing” the pressure of the compressed air source to some lesser value.

The sensitivity of this pneumatic mechanism may be improved by extending the control rod and adding a second plug/seat assembly. The resulting mechanism, with dual plugs and seats, is known as a pneumatic *pilot valve*. An illustration of a pilot valve is shown here, along with its electrical analogue (on the right):

*Pneumatic pilot valve*

*Equivalent electrical circuit*

As the control rod is moved up and down, *both* variable restrictions change in complementary fashion. As the control rod moves up, the upper restriction closes off (restricting supply air) while the lower restriction opens up (venting more), causing the output pressure signal to decrease. As the rod moves down, the upper restriction opens (allowing more supply air in) and the lower restriction closes off (venting less), causing the output pressure to rise. The combination of *two* restrictions changing in opposite direction results in a much more aggressive change in output pressure for a given amount of rod motion than the previous mechanism with its fixed restriction and single variable restriction.

A similar design of pilot valve reverses the directions of the two plugs and seats. The only operational difference between this pilot valve and the previous design is an inverse relationship between control rod motion and pressure:

*Pneumatic pilot valve*

*Equivalent electrical circuit*

Now, moving the control rod up increases pressure while moving it down decreases pressure: precisely opposite the action of the previous pilot valve.

At this point, all we've managed to accomplish is build a better baffle/nozzle mechanism. We still do not yet have a pneumatic equivalent of an electronic transistor. To accomplish that, we must have some way of allowing an air pressure signal to control the motion of a pilot valve's control rod.

If we add a *diaphragm* to the pilot mechanism, we will create a proper *pneumatic relay*. The following relay and its electronic analogue are shown here:

*Pneumatic relay*

*Equivalent electronic circuit*

The diaphragm is nothing more than a thin disk of sheet metal, upon which an incoming air pressure signal presses. Force on the diaphragm is a simple function of signal pressure ( $P$ ) and diaphragm area ( $A$ ), as described by the standard force-pressure-area equation:

$$F = PA$$

If the diaphragm is taut, the elasticity of the metal allows it to also function as a spring. This allows the force to translate into displacement (motion), forming a definite relationship between applied air pressure and control rod position. Thus, the applied air pressure input will exert control over the output pressure.

It is easy to see how the input air signal exerts control over the output air signal in these two illustrations:

Since there is a direct relationship between input pressure and output pressure in this pneumatic relay, we classify it as a *direct-acting relay*. If we were to add an actuating diaphragm to the first pilot valve design, we would have a *reverse-acting relay* as shown here:

The *gain* ( $A$ ) of any pneumatic relay is defined just the same as the gain of any electronic amplifier circuit, the ratio of output change to input change:

$$A = \frac{\Delta \text{Output}}{\Delta \text{Input}}$$

For example, if an input pressure change of  $\Delta 2$  PSI results in an output pressure change of  $\Delta 12.9$  PSI, the gain of the pneumatic relay is 6.45.

Whether or not a pneumatic relay provides a pressure gain, it is guaranteed to provide a *volume gain* which is necessary to make pneumatic field instruments practical. Note how the diaphragm chamber where the input pressure goes is sealed off: this means there will be no continual draw (or leakage) of input signal air volume. Any pneumatic sensing element sending a pressure signal to the input of a pneumatic relay will *not* be “loaded” by the relay. The relay, on the other hand, is able to supply or vent a continual flow of air at its output port as needed. Just as a transistor amplifier circuit presents a light load to the input signal and a comparatively “heavy” source/sink capacity to any load connecting to its output terminals, pneumatic relays similarly boost the volume capacity of a pneumatic signal. Recall that this was precisely our goal for increasing the responsiveness of a baffle/nozzle mechanism: to have a pneumatic amplifier capable of boosting the nozzle’s backpressure signal.

Adding a pneumatic pressure-amplifying relay to a force-balance system such as our hypothetical laboratory scale improves the performance of that pneumatic system in multiple ways:

The pressure gain of the pneumatic amplifying relay makes the force-balancing bellows respond more aggressively to changes in baffle position than it could on its own. This makes the scale more sensitive, better able to sense small changes in applied weight.

The volume gain of the pneumatic amplifying relay results in greatly decreased response time to changes in applied weight. Without a relay in the system, the rate at which the force-balance bellows fills and empties with compressed air is a direct function of the orifice's and nozzle's restrictiveness, respectively. Nozzles and orifices designed for high restriction (small diameters) work well to conserve air usage over time, but they also limit the rate of air flow in or out of the feedback bellows. With an amplifying relay in place, however, we get the best of both worlds: the nozzle and orifice bores may be minimized for minimum air consumption, while the relay's valves may be made large enough to ensure high flow capacity to and from the bellows for quick response.

It should be noted that the principles of self-balancing mechanisms, baffles and nozzles, amplifying relays, and the like are not limited to pneumatic systems. It is also possible to build self-balancing *hydraulic* systems using all the same principles, the only difference being the use of liquid (oil) as the working fluid instead of gas (air). An example of a force-balance hydraulic system is the ASCO model NH90 "Hydramotor" linear actuator, which uses a self-contained hydraulic pump and reservoir to provide pressurized oil for the mechanism, a baffle/nozzle mechanism to detect out-of-balance conditions, and a hydraulic amplifying relay to boost the nozzle backpressure signal to perform useful work through a hydraulic actuating cylinder.

The Foxboro corporation designed a great many of their pneumatic instruments using just one style of (highly sensitive) amplifying relay:

The motion of the diaphragm actuates a pair of valves: one with a cone-shaped plug and the other with a metal ball for a plug. The ball-plug admits supply air to the output port, while the cone-shaped “stem valve” plug vents excess air pressure to the vent port.

The following photograph shows one of these relay units:

Two slotted-drive screws attach the relay to the rest of the controller mechanism, while two smaller (Phillips-drive) screws hold the relay assembly together.

The Fisher corporation used a different style of amplifying relay in some of their legacy pneumatic instruments:

The following photograph shows one of these relay units (colored black) attached to the back of a model 546 I/P transducer (colored grey):

The pressure gain of this Fisher relay is much less than that of the Foxboro relay, since output pressure in the Fisher relay acts against input pressure by exerting force on a sizable diaphragm. The movable vent seat in the Fisher relay makes this design a “non-bleeding” type, meaning it possesses the ability to close both supply and vent valves at the same time, allowing it to hold an output air pressure between saturation limits without bleeding a substantial amount of compressed air to atmosphere through the vent. The Foxboro relay design, by contrast, is a “bleeding type,” whose ball and stem valves cannot close simultaneously, and thus always bleeds some compressed air to atmosphere so long as the output pressure remains somewhere between saturation limits.

## 14.4 Analogy to opamp circuits

Self-balancing pneumatic instrument mechanisms are very similar to negative-feedback operational amplifier circuits, in that negative feedback is used to generate an output signal in precise proportion to an input signal. This section compares simple operational amplifier (“opamp”) circuits with analogous pneumatic mechanisms for the purpose of illustrating how negative feedback works, and learning how to generally analyze pneumatic mechanisms.

In the following illustration, we see an opamp with no feedback (open loop), next to a baffle/nozzle mechanism with no feedback (open loop):

For each system there is an input and an output. For the opamp, input and output are both electrical (voltage) signals:  $V_{in}$  is the differential voltage between the two input terminals, and  $V_{out}$  is the single-ended voltage measured between the output terminal and ground. For the baffle/nozzle, the input is the physical gap between the baffle and nozzle ( $x_{in}$ ) while the output is the backpressure indicated by the pressure gauge ( $P_{out}$ ).

Both systems have very large gains. Operational amplifier open-loop gains typically exceed 200000 (over 100 dB), and we have already seen how just a few thousandths of an inch of baffle motion is enough to drive the backpressure of a nozzle nearly to its limits (supply pressure and atmospheric pressure, respectively).

Gain ( $A$ ) is always defined as the ratio between output and input for a system. Mathematically, it is the quotient of output *change* and input *change*, with “change” represented by the triangular Greek capital-letter delta ( $\Delta$ )<sup>5</sup>:

$$\text{Gain} = A = \frac{\Delta \text{Output}}{\Delta \text{Input}}$$

Normally, gain is a unitless ratio. We can easily see this for the opamp circuit, since both output and input are voltages, any unit of measurement for voltage would cancel in the quotient, leaving a unitless quantity. This is not so evident in the baffle/nozzle system, with the output represented in units of pressure and the input represented in units of distance.

<sup>5</sup>A more precise way to express gain as a ratio of changes is to use the “derivative” notation of calculus:  $\frac{d\text{Output}}{d\text{Input}}$

If we were to add a bellows to the baffle/nozzle mechanism, we would have a system that inputs and outputs fluid pressure, allowing us to more formally define the gain of the system as a unitless ratio of  $\frac{\Delta P_{out}}{\Delta P_{in}}$ :

We may modify this mechanism slightly to make it an even more realistic analogue of an operational amplifier circuit by adding a second input bellows in direct opposition to the first:

Now our mechanism is a *differential-input pneumatic relay*. Pressure applied to the “noninverting” input bellows presses the baffle toward the nozzle, causing the output pressure to rise dramatically. Pressure applied to the “inverting” input bellows presses the baffle away from the nozzle, causing the output pressure to fall dramatically. Exactly equal pressures simultaneously applied to both bellows causes no baffle motion at all, resulting in no change in output pressure. This is analogous to an electronic operational amplifier: positive voltage applied to the noninverting (+) input strongly drives the output voltage more positive, while positive voltage applied to the inverting (−) input strongly drives the output voltage more negative.

Given the extreme sensitivity of a baffle/nozzle mechanism, the pneumatic gain of this device will be quite large. Like its electronic counterpart – the opamp circuit – miniscule input signal levels are sufficient to fully saturate the output.

Electronic operational amplifiers and pneumatic relays find their greatest application where we use *feedback*, sending all or part of the output signal back to one of the inputs of the device. The most common form of feedback is *negative feedback*, where the output signal works in such a way as to negate (compensate) itself. The general effect of negative feedback is to decrease the gain of a system, and also make that system's response more linear over the operating range. This is not an easy concept to grasp, however, and so we will explore the effect of adding negative feedback in detail for both systems.

The simplest implementation of negative feedback is a condition where the entire strength of the output signal gets “fed back” to the amplifier system in degenerative fashion. For an opamp, this simply means connecting the output terminal directly to the inverting input terminal, to form a circuit known as a *voltage follower*:

We call this “negative” or “degenerative” feedback because its effect is counteractive in nature. If the output voltage rises too high, the effect of feeding this signal to the inverting input will be to bring the output voltage back down again. Likewise, if the output voltage is too low, the inverting input will sense this and act to bring it back up again. *Self-correction* is the hallmark of any negative-feedback system.

Having connected the inverting input directly to the output of the opamp leaves us with the noninverting terminal as the sole input. Thus, our input voltage signal is a ground-referenced voltage just like the output. Electronics students learn that the voltage gain of this circuit is unity (1), meaning that the output will assume whatever voltage level is present at the input, within the limits of the opamp's power supply. This is why the circuit is called a “voltage follower”: the output voltage mimics, or follows, the input voltage. If we were to send a voltage signal of 5 volts to the noninverting terminal of this opamp circuit, it would output 5 volts, provided that the power supply exceeds 5 volts in potential from ground. What is not always taught to electronics students is *why* this is true.

Let's mathematically analyze why the gain of a “voltage follower” opamp circuit is unity. First, we will start with the equation representing the open-loop output of an opamp, as a function of its differential input voltage:

$$V_{out} = A_{OL}(V_{in(+)} - V_{in(-)})$$

As stated before, the open-loop voltage gain of an opamp is typically very large ( $A_{OL} = 200000$  or more!) which means only a tiny voltage difference between the noninverting and inverting inputs ( $V_{in(+)} - V_{in(-)}$ ) is necessary to drive the opamp's output voltage to saturation.

Connecting the opamp's output terminal to its own inverting input terminal simplifies the scenario because it makes those two terminals equipotential to each other (i.e. the output and inverting input terminals now have the same potential at all times):

With these two terminals directly connected,  $V_{out}$  and  $V_{in(-)}$  are now one and the same. This means we may substitute  $V_{out}$  for  $V_{in(-)}$  in the equation, while  $V_{in(+)}$  simply becomes  $V_{in}$  since it is now the only remaining input. Reducing the equation to the two variables of  $V_{out}$  and  $V_{in}$  and a constant ( $A_{OL}$ ) allows us to solve for overall voltage gain ( $\frac{V_{out}}{V_{in}}$ ) as a function of the opamp's internal voltage gain ( $A_{OL}$ ). The following sequence of algebraic manipulations shows how this is done:

$$V_{out} = A_{OL}(V_{in} - V_{out})$$

$$V_{out} = A_{OL}V_{in} - A_{OL}V_{out}$$

$$A_{OL}V_{out} + V_{out} = A_{OL}V_{in}$$

$$V_{out}(A_{OL} + 1) = A_{OL}V_{in}$$

$$\text{Overall gain} = \frac{V_{out}}{V_{in}} = \frac{A_{OL}}{A_{OL} + 1}$$

If we assume an internal opamp gain of 200000, the overall gain will be very nearly equal to unity (0.999995). Moreover, this near-unity gain will remain quite stable despite large changes in the opamp's internal (open-loop) gain. The following table shows the effect of major  $A_{OL}$  changes on overall voltage gain ( $A_V$ ):

$A_{OL}$ Internal gain	$A_V$ Overall gain
100000	0.99999
200000	0.999995
300000	0.999997
500000	0.999998
1000000	0.999999

Note how an order of magnitude change<sup>6</sup> in  $A_{OL}$  (from 100000 to 1000000) results in a miniscule change in overall voltage gain (from 0.99999 to 0.999999). Negative feedback clearly has a stabilizing effect on the closed-loop gain: the internal gain of the operational amplifier may drift considerably over time with negligible effect on the voltage follower circuit's overall gain. It was this principle that led Harold Black in the late 1920's to apply negative feedback to the design of very stable telephone amplifier circuits. His discovery led to the development of electronic amplifiers exhibiting very stable gains despite internal changes such as vacuum tube aging, power supply drift, etc.

---

<sup>6</sup>An "order of magnitude" is nothing more than a ten-fold change. Do you want to sound like you're really smart and impress those around you? Just start comparing ordinary differences in terms of orders of magnitude. "Hey dude, that last snowboarder's jump was an *order of magnitude* higher than the one before!" "Whoa, that's some big air . . ." Just don't make the mistake of using decibels in the same way ("Whoa dude, that last jump was at least 10 dB higher than the one before!") – you don't want people to think you're a nerd.

If we subject our voltage follower circuit to a constant input voltage of exactly 5 volts, we may expand the table to show the effect of changing open-loop gain on the output voltage, and also the differential voltage appearing between the opamp's two input terminals:

$A_{OL}$ Internal gain	$A_V$ Overall gain	$V_{out}$ Output voltage	$V_{in(+)} - V_{in(-)}$ Differential voltage
100000	0.99999	4.99995	0.00005
200000	0.999995	4.999975	0.000025
300000	0.999997	4.99998	0.00002
500000	0.999998	4.99999	0.00001
1000000	0.999999	4.999995	0.000005

With such extremely high open-loop voltage gains, it hardly requires any difference in voltage between the two input terminals to generate the necessary output voltage to match the input. Negative feedback has “tamed” the opamp’s extremely large gain to a value that is nearly 1. Thus,  $V_{out} = V_{in}$  for all practical purposes, and the opamp’s differential voltage input is zero for all practical purposes.

One of the “simplifying assumptions” electronics technicians and engineers make when analyzing opamp circuits is that the differential input voltage in *any* negative feedback circuit is zero. As we see in the above table, this assumption is very nearly true<sup>7</sup>. Following this assumption to its logical consequence allows us to predict the output voltage of any negative feedback opamp circuit quite simply. For example:

*Applying the “simplifying assumption”  
of zero differential input voltage*

Building on this assumption, we may conclude that the opamp will output whatever voltage it *must* to maintain zero differential voltage between its inputs. In other words, we assume zero volts between the two input terminals of the opamp, then calculate what the output voltage must be in order for that condition to remain true. If we assume there will be zero differential voltage between the two input terminals of the opamp, we see that the output voltage will exactly equal the input voltage, for that is what *must* happen here in order for the two opamp input terminals to see equal potentials. We don't even need to evaluate a mathematical formula to tell what the voltage follower will do with a 5 volt input – the simplifying assumption lets us directly conclude  $V_{out} = V_{in}$ .

<sup>7</sup>In order for negative feedback to hold the input differential at zero volts, we must *also* assume the opamp has enough power supply voltage and output current capability to achieve this balance. No amplifier can output more voltage than its power supply gives it, nor can it output more current than its active components can conduct.

Now let us apply negative feedback to our differential-input pneumatic relay and analyze it similarly. The simplest and most direct form of negative feedback is to connect the output pressure line to the inverting bellows. This leaves only one input pressure port remaining:

It should be clear that the inverting bellows, which now experiences the same pressure ( $P_{out}$ ) as the pressure gauge, introduces negative feedback into the system. If the output pressure happens to rise too high, the baffle will be pushed away from the nozzle by the force of the feedback bellows, causing backpressure to decrease and stabilize. Likewise, if the output pressure happens to go too low, the baffle will move closer to the nozzle and cause the backpressure to rise again.

As we have seen already, the baffle/nozzle is exceptionally sensitive: only a few thousandths of an inch of motion being sufficient to saturate the nozzle backpressure to either extreme (supply air pressure or zero, depending on which direction the baffle moves). This is analogous to the high gain of an operational amplifier, requiring only a few microvolts of potential difference between the input terminals to saturate the amplifier's output to full "rail" voltage. This being the case, we may conclude the nozzle backpressure can assume any value needed with negligible pressure difference between the two opposed bellows. From this we may conclude the system naturally seeks a condition where the pressure inside the feedback bellows matches the pressure inside the "input" bellows. In other words,  $P_{out}$  will (very nearly) equal  $P_{in}$  with negative feedback in effect.

Introducing negative feedback to the opamp led to a condition where the differential input voltage was held to (nearly) zero. In fact, this potential was so small as to safely consider it a constant zero microvolts for the purpose of more easily analyzing the output response of the system. *We may make the exact same "simplifying assumption" for the pneumatic mechanism:* we will assume zero baffle/nozzle gap motion (i.e. the gap remains constant) so long as negative feedback is at work.

Building on this assumption, we may conclude the nozzle backpressure will rise or fall to *whatever value it must* in order to maintain a constant baffle/nozzle gap at all times. In other words, we may analyze the operation of a pneumatic feedback mechanism for any given input condition by assuming a constant baffle/nozzle gap, then calculate what the output pressure must be in order for that assumption to remain true.

If we simply assume the baffle/nozzle gap will be held constant through the action of negative feedback, we may conclude in this case that the output pressure is exactly equal to the input pressure, since that is what *must* happen in order for the two pressures to exactly oppose each other through two identical bellows to hold the baffle at a constant gap from the nozzle.

The analytical technique of assuming perfect balance in a negative feedback system works just as well for more complicated systems. Consider the following opamp circuit:

Here, negative feedback occurs through a voltage divider from the output terminal to the inverting input terminal, such that only one-half of the output voltage gets “fed back” degeneratively. If we follow our simplifying assumption that perfect balance (zero difference of voltage) will be achieved between the two opamp input terminals due to the balancing action of negative feedback, we conclude  $V_{out}$  must be exactly *twice* the magnitude of  $V_{in}$ . In other words, the output voltage must increase to twice the value of the input voltage in order for the divided feedback signal to exactly match the input signal. Thus, feeding back half the output voltage yields an overall voltage gain of two.

If we make the same (analogous) change to the pneumatic system, we see the same effect:

Here, the feedback bellows has half the surface area of the input bellows. This results in half the amount of force applied to the beam for the same amount of pressure. If we follow our simplifying assumption that perfect balance (zero baffle motion) will be achieved due to the balancing action of negative feedback, we conclude  $P_{out}$  must be exactly *twice* the magnitude of  $P_{in}$ . In other words, the output pressure must increase to twice the value of the input pressure in order for the divided feedback force to exactly match the input force and prevent the baffle from moving. Thus, our pneumatic mechanism has a pressure gain of two, just like the opamp circuit with divided feedback had a voltage gain of two.

We could have achieved the same effect by moving the feedback bellows to a lower position on the force beam instead of changing its surface area:

This arrangement effectively reduces the feedback force by placing the feedback bellows at a mechanical disadvantage to the input bellows. If the distance between the feedback bellows tip and the force beam pivot is exactly half the distance between the input bellows tip and the force beam pivot, the effective force ratio will be one-half. The result of this “divided” feedback force is that the output pressure must rise to *twice* the value of the input pressure, since the output pressure is at a mechanical disadvantage to the input. Once again, we see a balancing mechanism with a gain of two.

Pneumatic instruments built such that bellows’ forces directly oppose one another in the same line of action to constrain the motion are known as “force balance” systems. Instruments built such that bellows’ forces oppose one another through different lever lengths pivoting around the same fulcrum point (such as in the last system) are technically known as “*moment*<sup>8</sup> balance” systems. Instead of two equal forces balancing, we have two equal “moments” or torques balancing. However, one will often find that “moment balance” instruments are commonly referred to as “force balance” because the two principles are so similar. In either case, the result of the balance is that actual motion is constrained to an absolute minimum, like a tug-of-war where the two sides are perfectly matched in pulling force.

<sup>8</sup>In physics, the word *moment* refers to the product of force times lever length (the “moment arm”). This is alternatively known as *torque*. Thus, we could classify this pneumatic mechanism as a *torque-balance* system, since the two bellows’ forces are converted into torques (about the pivot point) which then cancel even though the forces themselves are unequal.

An entirely different classification of pneumatic instrument is known as *motion balance*. The same “simplifying assumption” of zero baffle/nozzle gap motion holds true for the analysis of these mechanisms as well:

In this particular mechanism there is no fixed pivot for the beam. Instead, the beam hangs between the ends of two bellows units, affixed by pivoting links. As input pressure increases, the input bellows expands outward, attempting to push the beam closer to the nozzle. However, if we follow our assumption that negative feedback holds the nozzle gap constant, we see that the feedback bellows must expand the same amount, and thus (if it has the same area and spring characteristics<sup>9</sup> as the input bellows) the output pressure must equal the input pressure:

We call this a *motion* balance system instead of a *force* balance system because we see two *motions* working in complementary fashion to maintain a constant baffle/nozzle gap instead of two *forces* working against each other to maintain all components in their original positions.

The distinction between motion-balance and force-balance is a source of confusion for many people, but it is an important concept to master in order to analyze the responses of each and to understand how to calibrate each type of instrument. Perhaps the easiest way to distinguish one from the other is to apply the “simplifying assumption” of a constant baffle/nozzle gap and ask the question, “Must the components *move* as the signal pressures explore their full ranges?” An analogy to help distinguish force-balance from motion-balance is that of tug-of-war contestants versus ballroom dancers. Two people competing in a tug-of-war maintain a steady gap between themselves and the line only by precisely countering each other’s force: if their forces are perfectly balanced (equal and opposite), they will not move relative to the line. By contrast, two ballroom dancers maintain a steady gap between themselves only by moving the same distance: if their motions are perfectly balanced, the gap between them will not change. Again, the same question applies: do

<sup>9</sup>An important feature of motion-balance mechanisms is that the bellows function as calibrated spring elements in addition to being force generators. Force-balance systems move so slightly that the spring characteristics of the bellows is irrelevant – not so with motion-balance mechanisms! In fact, some motion-balance mechanisms actually place coil springs inside of brass bellows to more precisely fix the elastic properties of the assembly.

the people actually *move* in the act of maintaining equilibrium? If so, theirs is a motion-balance system; if not, theirs is a force-balance system.

In a force-balance pneumatic mechanism, the components (ideally) do not move. In fact, if there were such a thing as an infinitely sensitive baffle/nozzle mechanism (where the baffle/nozzle gap held perfectly constant at all times), *there would be absolutely no motion at all occurring in a force-balance mechanism!* However, even with an infinitely sensitive baffle/nozzle detector, a motion-balance mechanism would still visibly move in its effort to keep the baffle-nozzle gap constant as the pneumatic pressures rose and fell over their respective ranges. This is the most reliable “test” I have found to distinguish one type of mechanism from the other<sup>10</sup>.

The gain of a motion-balance pneumatic instrument may be changed by altering the bellows-to-nozzle distance such that one of the two bellows has more effect than the other. For instance, this system has a gain of 2, since the feedback bellows must move twice as far as the input bellows in order to maintain a constant nozzle gap:

Force-balance (and moment-balance) instruments are generally considered more accurate than motion-balance instruments because motion-balance instruments rely on the pressure elements (bellows, diaphragms, or bourdon tubes) possessing predictable spring characteristics. Since pressure must accurately translate to motion in a motion-balance system, there must be a predictable relationship between pressure and motion in order for the instrument to maintain accuracy. If anything happens to affect this pressure/motion relationship such as metal fatigue or temperature change, the instrument’s calibration will drift. Since there is negligible motion in a force-balance system, pressure element spring characteristics are irrelevant to the operation of these devices, and their calibrations remain more stable over time.

<sup>10</sup>In my teaching experience, students try hard to find simplistic ways to distinguish force-balance from motion-balance systems. For example, many will try to associate fulcrums with force-balance, assuming all motion-balance systems lack pivot points (which is not true!). Another example is to associate pivoting links with motion-balance mechanisms, which is likewise untrue. The problem with these efforts is that they are usually based on analysis of just a few different pneumatic mechanisms, making it easy to over-generalize. The truth of the matter is that a wide variety of pneumatic designs exist, defying easy categorization. My advice to you is the same as my advice to my students: you are going to have to *think* your way through the analysis of these mechanisms rather than *memorize* simple rules. Perform “thought experiments” whereby you imagine the effects of an increasing or decreasing input signal and then “see” for yourself whether the mechanism balances force with force or motion with motion, keeping in mind the simplifying assumption of an absolutely constant baffle/nozzle gap.

Both force- and motion-balance pneumatic instruments are usually equipped with an *amplifying relay* between the nozzle backpressure chamber and the feedback bellows. The purpose of an amplifying relay in a self-balancing pneumatic system is twofold: first, it boosts the open-loop gain of the mechanism so that its overall gain may be more predictable and stable; second, it provides additional flow capacity to fill and empty long pneumatic signal tubes necessary to convey the output air pressure signal to remote locations. The following illustration shows how a pneumatic amplifying relay may be used to improve the performance of our demonstration force-balance mechanism:

Adding a relay to a self-balancing pneumatic system is analogous to increasing the open-loop voltage gain of an opamp ( $A_{OL}$ ) by several-fold: it makes the overall gain *closer to ideal*. The overall gain of the system, though, is dictated by the ratio of bellows leverage on the force beam, just like the overall gain of a negative-feedback opamp circuit is dictated by the feedback network and *not* by the opamp's internal (open-loop) voltage gain.

## 14.5 Analysis of practical pneumatic instruments

To better understand the design and operation of self-balancing pneumatic mechanisms, it is helpful to examine the workings of some actual instruments. In this section, we will explore three different pneumatic instruments: the Foxboro model 13A differential pressure transmitter, the Foxboro model E69 I/P (electro-pneumatic) transducer, the Fisher model 546 I/P (electro-pneumatic) transducer, and the Fisher-Rosemount model 846 I/P (electro-pneumatic) transducer.

### 14.5.1 Foxboro model 13A differential pressure transmitter

Perhaps one of the most popular pneumatic industrial instruments ever manufactured is the Foxboro model 13 differential pressure transmitter. A photograph of one with the cover removed is shown here:

A functional illustration of this instrument identifies its major components:

Part of the reason for this instrument's popularity is the extreme utility of differential pressure transmitters in general. A "DP cell" may be used to measure pressure, vacuum, pressure differential,

liquid level, liquid or gas flow, and even liquid density. A reason for this *particular* differential transmitter's popularity is its excellent design: the Foxboro model 13 transmitter is rugged, easy to calibrate, and quite accurate.

Like so many pneumatic instruments, the model 13 transmitter uses the *force-balance* (more precisely, the *moment-balance*) principle whereby any shift in position is sensed by a detector (the baffle/nozzle assembly) and immediately corrected through negative feedback to restore equilibrium. As a result, the output air pressure signal becomes an analogue of the differential process fluid pressure sensed by the diaphragm capsule. In the following photograph you can see my index finger pointing to the baffle/nozzle mechanism at the top of the transmitter:

Let's analyze the behavior of this transmitter step-by-step as it senses an increasing pressure on the "High pressure" input port. As the pressure here increases, the large diaphragm capsule is forced to the right. The same effect would occur if the pressure on the "Low pressure" input port were to decrease. This is a *differential* pressure transmitter, meaning it responds to fluid pressure *differences* sensed between the two input ports.

This resultant motion of the capsule tugs on the thin flexure connecting it to the force bar. The force bar pivots at the fulcrum (where the small diaphragm seal is located) in a counter-clockwise rotation, tugging the flexure at the top of the force bar. This motion causes the range bar to also pivot at its fulcrum (the sharp-edged "range wheel"), moving the baffle closer to the nozzle.

As the baffle approaches the nozzle, air flow through the nozzle becomes more restricted, accumulating backpressure in the nozzle. This backpressure increase is greatly amplified in the relay, sending an increasing air pressure signal both to the output line and to the bellows at the bottom of the range bar. Increasing pneumatic pressure in the bellows causes it to push harder on the bottom of the range bar, negating the initial motion<sup>11</sup> and returning the range bar (and force

---

<sup>11</sup>This negating action is a hallmark of force-balance systems. When the system has reached a point of equilibrium, the components will have returned to (very nearly) their original positions. With motion-balance systems, this is not the case: one component moves, and then another component moves in response to keep the baffle/nozzle detector at a near-constant gap, but the components definitely do *not* return to their original positions or orientations.

bar) to their near-original positions.

Calibration of this instrument is accomplished through two adjustments: the zero screw and the range wheel. The zero screw simply adds tension to the bottom of the range bar, pulling it in such a direction as to further oppose the bellows' force as the zero screw is turned clockwise. This action attempts to push the baffle closer to the nozzle and therefore increases air pressure to the bellows to achieve equilibrium. Turning the range wheel alters the lever ratio of the range bar, changing the ratio of capsule force to bellows force and thereby adjusting the transmitter's span. The following photograph shows the range bar and range wheel of the instrument:

As in all instruments, the zero adjustment works by *adding or subtracting* a quantity, while the span adjustment works by *multiplying or dividing* a quantity. In the Foxboro model 13 pneumatic transmitter, the quantity in question is force, since this is a force-balance mechanism. The zero screw adds or subtracts force to the mechanical system by tensioning a spring, while the range wheel multiplies or divides force in the system by changing the mechanical advantage (force ratio) of a lever.

### 14.5.2 Foxboro model E69 “I/P” electro-pneumatic transducer

The purpose of any “I/P” transducer is to convert an electrical signal into a corresponding pneumatic signal. In most cases, this means an input of 4-20 mA DC and an output of 3-15 PSI, but alternative ranges do exist.

An example of an I/P transducer manufactured by Foxboro is the model E69, shown here:

Two pressure gauges indicate supply and output pressure, respectively. Wires convey the 4-20 mA electrical signal into the coil unit inside the transducer.

A view with the cover removed shows the balancing mechanism used to generate a pneumatic pressure signal from the electric current input. The baffle/nozzle may be seen at the left of the mechanism, the nozzle located at the end of a bent tube, facing the flat baffle on the surface of the circular coil unit:

As electric current passes through the coil, it produces a magnetic field which reacts against a permanent magnet's field to generate a torque. This torque causes the coil to rotate counter-clockwise (as viewed in the picture), with the baffle connected to the rotating assembly. Thus, the baffle moves like the needle of an analog electric meter movement in response to current: the more current through the coil, the more the coil assembly moves (and the baffle moves with it).

The nozzle faces this baffle, so when the baffle begins to move toward the nozzle, backpressure within the nozzle rises. This rising pressure is amplified by the relay, with the output pressure applied to a bellows. As the bellows expands, it draws the nozzle away from the advancing baffle, achieving balance by matching one motion (the baffle's) with another motion (the nozzle's). In other words, the nozzle "backs away" as the baffle "advances toward:" the *motion* of one is matched by the *motion* of the other, making this a *motion-balance* instrument.

A closer view shows the baffle and nozzle in detail:

Increased current through the wire coil causes the baffle to move toward the right (as pictured) toward the nozzle. The nozzle in response backs away (also to the right) to hold the baffle/nozzle gap constant.

Interestingly, the model E69 transducer employs the same pneumatic amplifying relay used in virtually every Foxboro pneumatic instrument:

This amplifying relay makes the system more responsive than it would be otherwise, increasing sensitivity and precision. The relay also serves as an air volume amplifier, either sourcing (supplying) or sinking (venting) air to and from a control valve actuator much more rapidly than the nozzle and orifice could do alone.

As in all instruments, the zero adjustment works by *adding or subtracting* a quantity, while the span adjustment works by *multiplying or dividing* a quantity. In the Foxboro model E69 transducer, the quantity in question is motion, since this is a motion-balance mechanism. The zero adjustment adds or subtracts motion by offsetting the position of the nozzle closer to or farther away from the baffle. A close-up photograph of the zero adjustment screw shows it pressing against a tab to rotate the mounting baseplate upon which the coil unit is fixed. Rotating this baseplate add or subtracts angular displacement to/from the baffle's motion:

The span adjustment consists of changing the position of the nozzle relative to the baffle's center of rotation (axis), so that a given amount of rotation equates to a different amount of balancing motion required of the nozzle. If the nozzle is moved farther away from the baffle's axis, the same rotation (angle) will result in greater nozzle motion (more output pressure) because the nozzle “sees” greater baffle movement. If the nozzle is moved closer toward the baffle's axis, the same rotation (angle) will result in less nozzle motion (less output pressure) because the nozzle “sees” less baffle movement<sup>12</sup>. The effect is not unlike the difference between a baseball striking the tip of a swung bat versus striking in the middle of a swung bat: the baseball struck by the tip of the bat “sees” a faster-moving bat than the baseball struck by the middle of the bat.

This span adjustment in the E69 mechanism consists of a pair of nuts locking the base of the bellows unit at a fixed distance from the baffle's axis. Changing this distance alters the effective radius of the baffle as it swings around its center, therefore altering the gain (or span) of the motion-balance system:

---

<sup>12</sup>A good problem-solving technique to apply here is *limiting cases*, where we imagine the effects of extreme changes. In this case, we may imagine what would happen if the nozzle were moved all the way to the baffle's axis, as a limiting case of moving closer to this axis. With the nozzle in this position, no amount of baffle rotation would cause the nozzle to move away, because there is no lateral motion at the axis. Only at some radius away from the axis will there be any tangential motion for the nozzle to detect and back away from, which is why the gain of the mechanism may be altered by changing the nozzle's location with respect to the baffle's axis.

### 14.5.3 Fisher model 546 “I/P” electro-pneumatic transducer

The Fisher model 546 I/P transducer performs the same signal-conversion function (mA into PSI) as the Foxboro model E69, but it does so quite differently. The following photograph shows the internal mechanism of the model 546 transducer with its cover removed:

This particular instrument's construction tends to obscure its function, so I will use an illustrative diagram to describe its operation:

The heart of this mechanism is a ferrous<sup>13</sup> beam, located between the poles of a permanent magnet assembly, and centered within an electromagnet coil (solenoid). Current passing through the electromagnet coil imparts magnetic poles to the ends of the beam. Following the arrow head/tail convention shown in the coil windings (the dots versus X marks) representing conventional flow vectors pointing out of the page (top) and going into the page (bottom) for the coil wrapped around the beam, the right-hand rule tells us that the beam will magnetize with the right-hand side being “North” and the left-hand side being “South.” This electro-magnetic polarity interacts with the permanent-magnetic poles to torque the beam clockwise around its pivot point (fulcrum), pushing the right-hand side down toward the nozzle.

<sup>13</sup>“Ferrous” simply means any substance containing the element *iron*.

Any advance of the beam toward the nozzle will increase nozzle backpressure, which is then fed to the balancing bellows at the other end of the beam. That bellows provides a restoring force to the beam to return it (nearly) to its original position. The phenomenon of an input force being counter-acted by a balancing force to ensure negligible motion is the defining characteristic of a *force-balance* system. This is the same basic principle applied in the Foxboro model 13 differential pressure transmitter: an input force countered by an output force.

If you examine the diagram carefully, you will notice that this instrument's amplifying relay is not located within the force-balance feedback loop. The nozzle's backpressure is *directly* fed back to the balancing bellows with no amplification at all. A relay does exist, but its purpose is to provide a modest (approximately 2:1) pressure gain to raise the nozzle backpressure to standard levels (3-15 PSI, or 6-30 PSI).

The next photograph shows the solenoid coil, force beam, and nozzle. If you look closely, you can see the copper-colored windings of the coil buried within the mechanism. The zero-adjustment spring is located above the beam, centered with the nozzle (below the beam):

Fisher manufactured these I/P transducers with two different pneumatic ranges: 3-15 PSI and 6-30 PSI. The mechanical difference between the two models was the size of feedback bellows used in each. In order to achieve the greater pressure range (6-30 PSI), a *smaller* feedback bellows was used. This may seem backward at first, but it makes perfect sense if you mentally follow the operation of the force-balance mechanism. In order to generate a greater air pressure for a given electric current through the coil, we must place the air pressure at a mechanical *disadvantage* to force it to rise higher than it ordinarily would in achieving balance. One way to do this is to decrease the effective area of the bellows<sup>14</sup>, so that it takes a greater air pressure to generate the same amount of balancing force on the beam.

---

<sup>14</sup>Recall the mathematical relationship between force, pressure, and area:  $F = PA$ . If we desire a greater pressure ( $P$ ) to generate the same force ( $F$ ) as before, we must decrease the area ( $A$ ) upon which that pressure acts.

A 3-15 PSI bellows (left) is contrasted against a 6-30 PSI bellows (right) in this pair of photographs:

The span adjustment for this I/P transducer functions by varying the permanent-magnetic field strength acting against the beam's electro-magnetic field. Adjustment occurs through the use of a magnetic *shunt*: a ferrous plate moved closer to or farther away from the permanent magnets, providing an alternate (shunt, or bypass) path for magnetic flux away from the force beam. Moving the shunt farther away from the magnets strengthens the magnetic field “seen” by the beam, resulting in a multiplication of force on the beam and therefore a multiplication of output pressure. Moving the shunt closer to the magnets bypasses more of the magnetic flux, weakening the magnetic field “seen” by the beam and thereby diminishing the reaction force and also the output pressure.

A view of the mechanism's other side reveals the magnetic shunt plate, complete with an instructional arrow showing the correct direction to turn the adjustment screw to increase output span:

#### 14.5.4 Fisher-Rosemount model 846 “I/P” electro-pneumatic transducer

The Fisher-Rosemount model 846 is a more modern I/P transducer than either the Foxboro model E69 or the Fisher model 546. It employs neither the force-balance nor the motion-balance principle in its operation, which makes it unique to analyze. This I/P unit is also unique in that it features a modular design allowing very convenient replacement of internal components when in service.

This next photograph shows three model 846 I/P transducers attached to a metal panel, below a set of five Rosemount model 1151 pressure transmitters:

A closer photograph reveals the unit in more detail:

When one of the end-covers is unscrewed, the internal workings of the I/P may be removed as a single module. Both the removed module and the housing are shown in this photograph:

Shown separately, you can see where the module's current input terminals connect with matching pins in the housing. Even the zero and span adjustment potentiometers on the module circuit board are equipped with Velcro (hook and loop) pads, matching with pads attached to calibration screws on the housing. This simple yet effective mechanical coupling allows screws located on the exterior housing to adjust resistances on the module's circuit board for zero and span calibration, yet without exposing those delicate potentiometers to ambient weather conditions:

Pneumatic (air) connections are made to the housing through standard 1/4 inch female NPT pipe threads. Compressed air passes to the module (and from the module back out to the housing) through ports, sealed from each other by O-rings<sup>15</sup> located on the module.

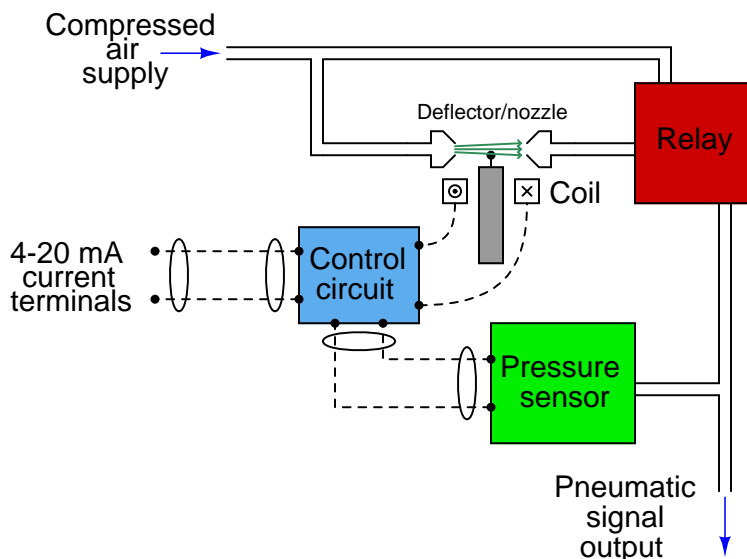

The primary benefit of this modular design is ease of maintenance in the field. If a module fails for any reason, it may be very quickly removed and replaced, with no disconnection and re-connection of signal wires or pneumatic tubes necessary.

---

<sup>15</sup>It is quite easy to dislodge these small-section, large-diameter O-rings from their respective grooves during re-assembly of the unit. Be very careful when inserting the module back into the housing!

As mentioned before, the feedback mechanism for this particular I/P transducer employs neither the force-balance nor the motion-balance principle. Rather, the negative feedback and balancing of this unit is done electronically rather than mechanically. The following diagram shows how this works:

An electronic pressure sensor continuously monitors the output pressure, with its signal being electronically compared to the input (4-20 mA) signal by the control circuit to check for equivalence. If the output does not match the input, the control circuit drives the deflector motor with more or less current as needed, to deflect the air jet more or less as it exits one nozzle and is intercepted by the other to stimulate the pneumatic amplifying relay. Thus, we see the “balancing” internal to this I/P is done electronically rather than mechanically as it was in the other I/P relays (Foxboro model E69, Fisher model 546) explored in this section.

Electronic components are less likely to drift in their calibration, and are less susceptible to the effects of mechanical vibration and mounting orientation, than mechanical balancing components.

## 14.6 Proper care and feeding of pneumatic instruments

Perhaps the most important rule to obey when using pneumatic instruments is to *maintain clean and dry instrument air*. Compressed air containing dirt, rust, oil, water, or other contaminants will cause operational problems for pneumatic instruments. First and foremost is the concern that tiny orifices and nozzles inside the pneumatic mechanisms will clog over time. Clogged orifices tend to result in decreased output pressure, while clogged nozzles tend to result in increased output pressure. In either case, the “first aid” repair is to pass a welding torch tip cleaner through the plugged hole to break loose the residue or debris plugging it.

Moisture in compressed air tends to corrode metal parts inside pneumatic mechanisms. This corrosion may break loose to form debris that plugs orifices and nozzles, or it may simply eat through thin diaphragms and bellows until air leaks develop. Grossly excessive moisture will cause erratic operation as “plugs” of liquid travel through thin tubes, orifices, and nozzles designed only for air passage.

A common mistake made when installing pneumatic instruments is to connect them to a general-service (“utility”) compressed air supply instead of a dedicated instrument-service compressed air system. Utility air systems are designed to supply air tools and large air-powered actuators with pneumatic power. These high-flow compressed air systems are often seeded with antifreeze and/or lubricating chemicals to prolong the operating life of the piping and air-consuming devices, but the same liquids will wreak havoc on sensitive instrumentation. Instrument air supplies should be sourced by their own dedicated air compressor(s), complete with automatic air-dryer equipment, and distributed through stainless steel, copper, or plastic tubing (never black iron or galvanized iron pipe!).

The worst example of moisture in an instrument air system I have ever witnessed is an event that happened at an oil refinery where I worked as an instrument technician. Someone on the operations staff decided they would use 100 PSI instrument air to purge a process pipe filled with acid. Unfortunately, the acid pressure in the process pipe exceeded 100 PSI, and as a result acid flushed backward into the instrument air system. Within days most of the pneumatic instruments in that section of the refinery failed due to accelerated corrosion of metal components within the instruments. The total failure of multiple instruments over such a short time could have easily resulted in a disaster, but fortunately the crisis was minimal. Once the first couple of faulty instruments were disassembled after removal, the cause of failure became evident and the technicians took action to flush the lines of acid before too many more instruments suffered the same fate.

Pneumatic instruments must be fed compressed air of the proper pressure as well. Just as electronic circuits require power supply voltages within specified limits, pneumatic instruments do not operate well if their air supply pressure is too low or too high. If the supply pressure is too low, the instrument cannot generate a full-scale output signal. If the supply pressure is too high, internal failure may result from ruptured diaphragms, seals, or bellows. Many pneumatic instruments are equipped with their own local pressure regulators directly attached to ensure each instrument receives the correct pressure despite pressure fluctuations in the supply line.

Another “killer” of pneumatic instruments is mechanical vibration. These are precision mechanical devices, so they do not generally respond well to repeated shaking. At the very least, calibration adjustments may loosen and shift, causing the instrument’s accuracy to suffer. At worst, actual failure may result from component breakage<sup>16</sup>.

---

<sup>16</sup>Having said this, pneumatic instruments can be remarkably rugged devices. I once worked on a field-mounted

## 14.7 Advantages and disadvantages of pneumatic instruments

The disadvantages of pneumatic instruments are painfully evident to anyone familiar with both pneumatic and electronic instruments. Sensitivity to vibration, changes in temperature, mounting position, and the like affect calibration accuracy to a far greater degree for pneumatic instruments than electronic instruments. Compressed air is an expensive utility – much more expensive per equivalent watt-hour than electricity – making the operational cost of pneumatic instruments far greater than electronic. The installed cost of pneumatic instruments can be quite high as well, given the need for special (stainless steel, copper, or tough plastic) tubes to carry supply air and pneumatic signals to distant locations. The volume of air tubes used to convey pneumatic signals over distances acts as a low-pass filter, naturally damping the instrument’s response and thereby reducing its ability to respond quickly to changing process conditions. Pneumatic instruments cannot be made “smart” like electronic instruments, either. With all these disadvantages, one might wonder why pneumatic instruments are still used at all in modern industry.

Part of the answer is legacy. For an industrial facility built decades ago, it makes little sense to replace instruments that still work just fine. The cost of labor to remove old tubing, install new conduit and wires, and configure new (expensive) electronic instruments often is not worth the benefits.

However, pneumatic instruments actually enjoy some definite technical advantages which secure their continued use in certain applications even in the 21<sup>st</sup> century. One decided advantage is the *intrinsic safety* of pneumatic field instruments. Instruments that do not run on electricity cannot generate electrical sparks. This is of utmost importance in “classified” industrial environments where explosive gases, liquids, dusts, and powders exist. Pneumatic instruments are also self-purging. Their continual bleeding of compressed air from vent ports in pneumatic relays and nozzles acts as a natural clean-air purge for the inside of the instrument, preventing the intrusion of dust and vapor from the outside with a slight positive pressure inside the instrument case. It is not uncommon to find a field-mounted pneumatic instrument encrusted with corrosion and filth on the outside, but factory-clean on the inside due to this continual purge of clean air. Pneumatic instruments mounted inside larger enclosures with other devices tend to protect them all by providing a positive-pressure air purge for the entire enclosure.

Some pneumatic instruments can also function in high-temperature and high-radiation environments that would damage electronic instruments. Although it is often possible to “harden” electronic field instruments to such harsh conditions, pneumatic instruments are practically immune by nature.

An interesting feature of pneumatic instruments is that they may operate on compressed gases other than air. This is an advantage in remote natural gas installations, where the natural gas itself is sometimes used as a source of pneumatic “power” for instruments. So long as there is compressed natural gas in the pipeline to measure and to control, the instruments will operate. No air compressor or electrical power source is needed in these installations. What *is* needed, however,

---

pneumatic controller attached to the same support structure as a severely cavitating control valve. The vibrations of the control valve transferred to the controller through the support, causing the baffle to hammer repeatedly against the nozzle until *the nozzle’s tip had been worn down to a flattened shape*. Remarkably, the only indication of this problem was the fact the controller was having some difficulty maintaining setpoint. Other than that, it seemed to operate adequately! I doubt any electronic device would have fared as well, unless completely “potted” in epoxy.

is good filtering equipment to prevent contaminants in the natural gas (dirt, debris, liquids) from causing problems within the sensitive instrument mechanisms.

## 14.8 Review of fundamental principles

Shown here is a partial listing of principles applied in the subject matter of this chapter, given for the purpose of expanding the reader's view of this chapter's concepts and of their general inter-relationships with concepts elsewhere in the book. Your abilities as a problem-solver and as a life-long learner will be greatly enhanced by mastering the applications of these principles to a wide variety of topics, the more varied the better.

- **Linear equations:** any function represented by a straight line on a graph may be represented symbolically by the slope-intercept formula  $y = mx + b$ . Relevant to instrument input/output scaling.
- **Pascal's principle:** changes in fluid pressure are transmitted evenly throughout an enclosed fluid volume. Relevant to pneumatic signaling, where air pressure is evenly distributed throughout a signal tube so that the pressure at one end will be equal to the pressure at the other.
- **Amplification:** the control of a relatively large signal by a relatively small signal. Relevant to the role of pneumatic relays, controlling relatively large amounts of air pressure and air flow based on the command of a much smaller air pressure signal generated by a baffle/nozzle assembly.
- **Negative feedback:** when the output of a system is degeneratively fed back to the input of that same system, the result is decreased (overall) gain and greater stability. Relevant to the internal construction of pneumatic instruments, where negative feedback is used in the form of either force-balance or motion-balance to achieve a highly linear response between input and output.
- **Self-balancing pneumatic mechanisms:** all self-balancing pneumatic instruments work on the principle of negative feedback maintaining a nearly constant baffle-nozzle gap. Force-balance mechanisms maintain this constant gap by balancing force against force with negligible motion, like a tug-of-war. Motion-balance mechanisms maintain this constant gap by balancing one motion with another motion, like two dancers moving in unison.
- **Self-balancing opamp circuits:** all self-balancing operational amplifier circuits work on the principle of negative feedback maintaining a nearly zero differential input voltage to the opamp. Making the "simplifying assumption" that the opamp's differential input voltage is exactly zero assists in circuit analysis, as does the assumption that the input terminals draw negligible current.

## Chapter 15

# Digital data acquisition and networks

The advent of digital electronic circuitry has brought a steady stream of technological progress to industrial instrumentation. From early applications of digital computing in the 1960's to the first distributed control systems (DCS) in the 1970's to the “smart” transmitter revolution of the 1980's, digital technology has expanded on the capabilities and information-sharing ability of measuring and control instruments. It is the purpose of this chapter to give a general overview of digital technology as it applies to data acquisition (measuring and recording process data) and digital communication, highlighting some of the more common standards used in industry. Subsequent chapters will be devoted to more in-depth discussions of specific digital instrumentation standards.

One of the greatest advantages of digital technology over analog is the ability to communicate vast amounts of data over a limited number of data channels. In the world of 4-20 mA signaling (or 3-15 PSI signaling, for that matter!) each pair of electrical wires (or pneumatic tube) could communicate only *one* variable. In the world of digital networks, one pair of wires can communicate a nearly limitless number of variables, the only limit being the *speed* of that data communication<sup>1</sup>.

This one-signal-per-channel limit of 4-20 mA analog signals represents a technological “bottleneck” restricting data transfer between instruments and control systems. While it certainly is possible to devote a dedicated wire pair to each and every variable in an instrument system, this is very expensive to do. It is particularly cumbersome for instruments generating multiple variables of measurement, such as Coriolis flowmeters which simultaneously measure process fluid mass flow rate, fluid density, and fluid temperature; or “smart” valve positioners which continuously measure the stem position, actuator air pressure(s), air supply pressure, and temperature of a control valve. The data-rich capabilities of digital field instruments demands a digital form of communication to overcome the “bottleneck” of analog 4-20 mA signals.

Rosemount's HART standard was an early attempt to provide the “best of both worlds” in industrial instrumentation. With HART digital signals superimposed on 4-20 mA analog signals, one could retain the simplicity, fast response, and reliability of analog signaling while enjoying the multi-

---

<sup>1</sup>The technical term for the “speed limit” of any data communications channel is *bandwidth*, usually expressed as a frequency (in Hertz).

variable communication benefits offered by digital signaling. However, wired-HART communication is rather slow by any standard, restricting its use to maintenance (range changes, diagnostic data polling) and process control for slow processes<sup>2</sup> only.

There exist many different digital communication standards (generally called “fieldbuses”) designed to interconnect industrial instruments. An incomplete list is shown here:

- HART
- Modbus
- FOUNDATION Fieldbus
- Profibus PA
- Profibus DP
- Profibus FMS
- EtherNet/IP
- AS-I
- CANbus
- ControlNET
- DeviceNet
- LonWorks
- BACnet

The utility of digital “fieldbus” instruments becomes apparent through the host system these instruments are connected to (typically a *Distributed Control System*, or *DCS*). Fieldbus-aware host systems usually have means to provide instrument information (including diagnostics) in very easy-to-navigate formats.

---

<sup>2</sup>HART communications occur at a rate of 1200 bits per second, and it is this slow by design: this slow data rate avoids signal reflection problems that would occur in unterminated cables at higher speeds. For more insight into how and why this works, refer to the “transmission lines” section 5.10 beginning on page 475. An example of a “slow” process variable suitable for HART digital monitoring or control is the *temperature* of a large building or machine, where the sheer mass of the object makes temperature changes slow by nature, and therefore does not require a fast digital data channel to report that temperature.

For example, the following computer screenshot shows the field instrument devices connected to a small-scale DCS used in an educational lab. Each instrument appears as an icon, which may be explored further simply by pointing-and-clicking with the mouse<sup>3</sup>:

<sup>3</sup>The host system in this case is an Emerson DeltaV DCS, and the device manager software is Emerson AMS.

Another application of digital communication technology to industrial measurement and control is what is generally referred to as a *SCADA* (“Supervisory Control And Data Acquisition”) system. A SCADA system might be thought of as a distributed control system (DCS) spread over a geographically large area, such as across the span of a city or even across national borders. Typical applications of SCADA technology include:

- Electric power generation and distribution (power line, substation) systems
- Water and wastewater treatment and distribution (water line, pumping stations) systems
- Gas and oil exploration and distribution (pipeline) systems
- Large-scale agricultural (irrigation, harvesting) systems
- Storage tank monitoring systems

Process data in a SCADA system is sensed by various measurement devices (transmitters), converted to digital form by a device called an *RTU* (“Remote Terminal Unit”), and communicated to one or more *MTUs* (“Master Terminal Units”) at a central location where human operators may monitor the data and make command decisions.

If the flow of information is one-way (simplex, from measurement devices to human operators), the system is more properly referred to as a *telemetry* system rather than a SCADA system. “SCADA” implies two-way (duplex) information flow, where human operators not only monitor process data but also issue commands back to the remote terminal units to effect change.

The saying “necessity is the mother of invention” certainly holds true for the development of remote telemetry and SCADA systems. The need for remote monitoring and control of electric power distribution systems led to the development of “power line carrier” analog telemetry systems as far back in time as the 1940’s. These systems superimposed<sup>4</sup> high-frequency (50 kHz to 150 kHz) “carrier” signals on low-frequency (50 Hz and 60 Hz) power line conductors to communicate such basic information as human voice (like a telephone network, only dedicated for power system operators), power flow (wattmeter, MVAR meter) monitoring, and protective relay (automatic trip) controls. These SCADA systems were among the first to enjoy the benefits of digital technology in the 1960’s. Large-scale electric power systems simply cannot be operated safely and effectively without remote data monitoring and control, and this operational necessity pushed technological development of telemetry and SCADA systems beyond their small-scale (industrial manufacturing) counterparts.

Whether it is a “smart” temperature transmitter, a panel-mounted process controller with Ethernet communication capability, a variable-speed electric motor drive with Modbus signaling, a large-scale DCS controlling an oil refinery, or a SCADA system monitoring an international power distribution system, digital measurement and communication is an essential part of modern measurement and control systems. This chapter focuses on some of the basic principles of digital data formatting and communication, referencing practical applications wherever possible.

---

<sup>4</sup>This concept is not unlike HART, where audio-tone AC signals are superimposed on DC signal cables, so that digital data may be communicated along with DC signal and power.

## 15.1 Digital representation of numerical data

Process measurements are often of an analog nature: the temperature of a furnace, the rate of fluid flow through a pipe, the pressure of a fluid, etc. These data are all *analog* quantities: infinitely variable, not discrete. Discrete process measurements such as the number of units passed by on a conveyor belt are relatively easy to sense and to log in digital form, but analog measurements require special circuitry and methods of numerical representation in order for control systems to manage them.

In order for any digital device to successfully interface with an analog signal, that signal must be *digitized* by means of an *analog-to-digital converter* or *ADC*. In general, ADC circuits receive analog voltage signals from sensors and output binary numbers (*count* values) proportional to those signals. A typical scale for an ADC is a count of zero (all binary bits = 0) with 0 millivolts input, and a full-scale count (all binary bits = 1) when the voltage input value is at its maximum (full-scale). The “full scale” value of an ADC circuit is often a modest DC voltage value of 5 or 10 volts. Details of ADC performance are discussed in a subsequent section of this chapter.

Many of the concerns discussed in this section are relevant to circuits converting digital values into analog signals as well. These *digital-to-analog converters*, or *DACs*, are generally used to produce the analog drive signals required of final control elements (e.g. the output of a digital PID controller driving a 4-20 mA analog signal to a control valve positioner).

### 15.1.1 Integer number formats

An *integer* is any whole number or its negative counterpart (e.g. 2, 7, 241, 0, -35, -1022). All modern digital systems represent integer quantities using *binary* numeration, where integer numbers consists of strings of “bits,” each bit having two possible values: 0 or 1. Unlike the *decimal* numeration system most people are familiar with where the place-weight values are powers of ten, the place-weight values of binary numeration are powers of two. The following example shows how the integer number six hundred and three is represented in both decimal and binary formats:

#### Six hundred and three

$$\begin{array}{c} 6 \quad 0 \quad 3 \\ \hline 10^2 \quad 10^1 \quad 10^0 \end{array} = (6 \times 10^2) + (3 \times 10^0) \quad \text{Decimal representation}$$

$$\begin{array}{c} 1 \quad 0 \quad 0 \quad 1 \quad 0 \quad 1 \quad 1 \quad 0 \quad 1 \quad 1 \\ \hline 2^9 \quad 2^8 \quad 2^7 \quad 2^6 \quad 2^5 \quad 2^4 \quad 2^3 \quad 2^2 \quad 2^1 \quad 2^0 \end{array} = 2^9 + 2^6 + 2^4 + 2^3 + 2^1 + 2^0 \quad \text{Binary representation}$$

The largest integer value representable in any positive place-weighted format is the base raised to the power of the number of places, minus one. So, for a three-digit decimal number, the largest possible value is  $10^3 - 1$  ( $1000 - 1 = 999$ ). For a ten-bit binary number, the largest possible value is  $2^{10} - 1$  ( $1024 - 1 = 1023$ ).

The beauty of binary representation is that the individual “bits” are easy to encode in physical form. “1” and “0” values may take the form of voltage levels (“high” or “low”) in an electronic circuit, magnetization states on a magnetic disk or magnetic tape, AC signal frequencies (“high” or “low”) transmitted on a two-conductor cable, pulses of light transmitted through a fiber optic cable, or any other medium capable of representing two different states. This makes binary a natural form of numerical representation for computers.

When representing negative integers, the convention for written numerals is to prepend a “negative” symbol to the left-hand side of the number. In digital machines, this may be emulated by including an extra “sign bit” having a value of either 0 or 1 indicating whether the number is positive or negative. A more common method for negative value representation in digital machines, however, is called *two’s complement* notation.

Two’s complement notation works by assigning the most significant place-weight a negative weight value. To use a ten-bit binary example showing the number negative three hundred and ninety six:

**Negative three hundred and ninety six**  
(*Two’s complement binary notation*)

$$\begin{array}{cccccccccc} 1 & 0 & 0 & 1 & 1 & 1 & 0 & 1 & 0 & 0 \\ \hline -2^9 & 2^8 & 2^7 & 2^6 & 2^5 & 2^4 & 2^3 & 2^2 & 2^1 & 2^0 \end{array} = -2^9 + 2^6 + 2^5 + 2^4 + 2^2$$

Using this system to represent integer values, the greatest positive number possible is when all bits are “1” with the exception of the most significant bit (MSB). In the case of this ten-bit field, this number would be 011111111, equaling  $2^9 - 1$  or 511. The greatest negative number possible is when the only “1” bit is the MSB. In the case of this ten-bit integer, this number would be 100000000, equaling  $-2^9$  or  $-512$ . Thus, a ten-bit two’s complement integer may represent values ranging from  $-512$  to  $+511$ , inclusive.

Whether binary numbers in a computer use the two’s complement system of notation or not is often the choice of the human being programming the computer. For this reason, it is important to define whether a binary integer used within a computer system to represent data is *signed* or *unsigned*. If the integer in question is “signed,” it means the binary number is capable of representing both positive and negative integer values (usually via two’s complement notation). If the integer in question is “unsigned,” it means the binary number is capable only of representing positive values.

For example, an “unsigned” 16-bit integer has a possible numerical value range of 0 to 65535. However, the same 16-bit field – if designated as “signed” using two’s complement place-weighting – has a range of  $-32768$  to  $+32767$ .

Digital computers usually organize binary numbers as clusters of bits with a set number of bits. A cluster of eight bits is called a *byte*. The standard number of bits for most modern computers exceeds one byte, with 16, 32, or even 64 bits’ length being common. Whatever the standard bit-length of a computer’s binary number field may be, it is defined for that computer as a *word*. Thus, if a digital computer is built to process binary data in 32-bit clusters, one “word” of data within that computer will be 32 bits in length. A “double-word” value for that computer is one where the binary number consists of 64 bits.

Given the typically large bit-lengths of numbers in modern computers, it is conventional to express such quantities in “shorthand” form using *hexadecimal* numeration. The basic idea of hexadecimal is that every four bits (half of a byte, or one *nybble*) of a binary number are represented by a single hex character ranging in value from 0 through F (0,1,2,3,4,5,6,7,8,9,A,B,C,D,E,F). For example, the 16-bit binary number 1001001111011110 is equivalent to the four-digit hexadecimal number 93DE:

Quite obviously, the hexadecimal number 93DE is a lot easier for human beings to manage than the binary number 1001001111011110. Computer systems providing users with live “views” of numerical values often format those values using hexadecimal numeration, just to simplify the task of interpretation.

### 15.1.2 Fixed-point number formats

The main limitation of integer numbers is their inability to represent quantities between whole numbers such as fractions. For example, a 4-bit integer number may have one of sixteen possible values (zero through fifteen), but it can never represent *two-and-a-half*.

One solution to this limitation is to re-assign place-weight values to the bits of a binary number, giving some of those bits fractional weights. For example, here is a ten-bit binary number field with a “binary point” separating whole-weighted bits from fractional-weighted bits, representing the quantity 70.375:

#### *Fixed-point binary notation*

$$\begin{array}{cccccccccc} 1 & 0 & 0 & 0 & 1 & 1 & 0 & \bullet & 0 & 1 & 1 \\ \frac{2^6}{2^6} & \frac{2^5}{2^5} & \frac{2^4}{2^4} & \frac{2^3}{2^3} & \frac{2^2}{2^2} & \frac{2^1}{2^1} & \frac{2^0}{2^0} & & \frac{2^{-1}}{2^{-1}} & \frac{2^{-2}}{2^{-2}} & \frac{2^{-3}}{2^{-3}} \end{array} = 2^6 + 2^2 + 2^1 + 2^{-2} + 2^{-3}$$

$$= \mathbf{70.375} \text{ (decimal notation)}$$

This form of binary notation is referred to as *fixed-point*, because the “binary point” is fixed in its location. Like any integer variable, this 10-bit binary number consisting of seven whole-weighted bits and three fractional-weighted bits has a definite range of possible values: in this particular case, from 0 to 127.875.

A variation on this theme is to use an integer number whose decimal value is some power-of-ten-times larger than it needs to be, but regard it as though it had a decimal point between two of its digits. I will illustrate this concept by way of anecdote: I once worked on a digital travel-measurement system which displayed the distance a hydraulic ram’s piston traveled using an LED numerical display. The sensor was a *pulse encoder* providing ten pulses per inch of travel, and this pulse signal directly fed a digital counter circuit which drove the LED display. When the hydraulic ram moved 19.3 inches, the LED display incremented by 193 counts. In order to make this LED display easy to read for human operators, I placed a dab of bright-red fingernail polish on the LED display to make it look as though a decimal point were permanently fixed between the least-significant digit and the next-significant digit. With the fingernail polish dot in place, 193 counts would read as 19.3. A text label saying “inches” was affixed to the right of the LED display, completing the indicator.

This solution is common to many industrial devices. Variable-frequency motor drives (VFDs), for example, often accept speed command values in integer format even though it is often necessary to specify drive frequency down to fractions of a Hertz. In such cases, the VFD manufacturer will program the VFD to imply a decimal point in the received integer number. For instance, if the fixed-point format is specified as **XXX.X** it means an integer value of 2057 sent to the VFD will be interpreted as 205.7 Hz; a value of 439 will be interpreted as 43.9 Hz; etc.

While fixing a “binary point” in the bit field escapes the limitation of whole-number resolution, a more sophisticated approach known as *floating-point* representation is a far more flexible way of representing fractional quantities in binary form. This is how most digital computers represent real-world analog quantities in digital form, and is the topic of the next subsection.

### 15.1.3 Floating-point number formats

Integer numbers, while very commonly used in computers for representing data, are insufficient for tasks requiring the representation of fractional (non-whole) values. Most industrial data points fall into this category, whether it be a temperature measurement (e.g. 428.21 °C), a gas concentration (e.g. 5.09 ppm of carbon monoxide), a control valve position (e.g. 27.58% open), or a motor speed (e.g. 1592.1 RPM). What we need is a form of binary representation capable of expressing fractional quantities.

One way to do this is to use *floating-point* number format, where we represent binary quantities using a form resembling scientific notation. Some control systems refer to floating-point numbers as *real* numbers. Recall how we use scientific notation to represent decimal numbers:

$$1002349 = 1.002349 \times 10^6$$

$$678.331 = 6.78331 \times 10^2$$

$$0.00004532 = 4.523 \times 10^{-5}$$

The power-of-ten multiplier has the effect of “floating” the decimal point to any position we desire, so that the significant digits of the number may be expressed in “normalized” form (between 1 and 10). This is where the term “floating-point” comes from.

In binary floating-point notation, we use a designated set of bits to represent the significant bits of the number ( $m$ ), and a second designated set of bits to represent the power-of-two exponent ( $E$ ):

$$\pm 1.m \times 2^E$$

Alert readers will note that the format shown here ( $\pm 1.m \times 2^E$ ) provides no way to represent the number zero, since  $1.0 \times 2^0$  ( $m = 0$  and  $E = 0$ ) is actually equal to one! Here, floating-point notation must provide *special cases* of representation. In the IEEE standard, the format shifts to  $\pm 0.m \times 2^E$  if ever all exponent bits are 0 ( $E = 0$ ). In order to still be able to represent 1 ( $1.0 \times 2^0$ ), the IEEE standard assumes the exponent value is *biased* with a negative number, so that an exponent bit field of 0 does not mean  $2^0$ , but rather  $2^{-bias}$ . This makes it possible to have an exponent value of 0 using non-zero  $E$  bits. Similarly, an exponent field consisting entirely of 1 bits is used as special representation for *infinity* or for an error code called *Not a Number* (NaN), depending on the values of the  $m$  bits. These special representations are important for handling the results of calculations such as division-by-zero and the square-roots or logarithms of negative numbers.

Given these special cases of representation required in floating-point notation, the task of doing calculations with floating-point numbers requires special processor circuitry designed to implement these rules. Inside a digital computer, this task is managed by a *floating-point processor* unit, usually a special section<sup>5</sup> of the microprocessor. Some simpler microprocessors cannot support floating-point

---

<sup>5</sup>In the early days of personal computers, many microprocessor chips lacked floating-point processing capability. As a result, floating-point calculations had to be implemented in software, with programmed algorithms instructing the microprocessor how to do floating-point arithmetic. Later, floating-point processor chips were added alongside the regular microprocessor to implement these algorithms in hardware rather than emulated them through software, resulting in increased processing speed. After that, these floating-point circuits were simply added to the internal architecture of microprocessor chips as a standard feature. Even now, however, computer programmers understand that floating-point math requires more processor cycles than integer math, and should be avoided in applications

arithmetic, and thus some control system hardware (e.g. low-cost PLCs) must do all tasks using integer numbers (or fixed-point notation, if fractional quantities must be represented).

The ANSI/IEEE standard 754-1985 specifies multiple floating-point number formats, including one that is 32 bits in length (“single-precision”) and another that is 64 bits in length (“double-precision”). In the IEEE standard, one bit is reserved for the sign of the number (0 for positive and 1 for negative), a certain number of bits for the power-of-two exponent<sup>6</sup>, and the rest of the bits for the *mantissa* (the fractional portion of the normalized value). Both formats are shown here:

*Single-precision IEEE floating-point number format*

*Double-precision IEEE floating-point number format*

A third floating-point IEEE standard called *extended* uses 80 total bits: 1 for the sign, 15 for the exponent, and 64 for the mantissa.

Floating-point number representation greatly simplifies the task of digitally calculating real-world values. Integer numbers, by contrast, are rather clumsy when used to represent most real-world measurements or statistics. For this reason, floating-point numbers are sometimes referred to as *real* values in digital computer systems.

Specific details on IEEE floating-point representation and arithmetic rules extend beyond the scope of this book. For a good primer on the subject, I recommend Michael L. Overton’s excellent paper “Floating Point Representation”.

---

where speed is essential and floating-point representation is not. In applications demanding a small microprocessor chip and optimum speed (e.g. embedded systems), fixed-point notation is best for representing numbers containing fractional quantities.

<sup>6</sup>Note how the place-weights shown for the exponent field do not seem to allow for negative values. There is no negative place-weight in the most significant position as one might expect, to allow negative exponents to be represented. Instead the IEEE standard implies a *bias value* of  $-127$ . For example, in a single-precision IEEE floating-point number, an exponent value of 11001101 represents a power of 78 (since  $11001101 = 205$ , the exponent’s actual value is  $205 - 127 = 78$ ).

### 15.1.4 Example of industrial number formats

To illustrate how different digital data formats are used in industrial systems, we shall explore an example of a human-machine interface (HMI) panel providing graphical view and control of data within a programmable logic controller (PLC). HMI panels are nothing more than special-purpose computers equipped with graphic display screens for displaying data to human operators and pushbuttons (sometimes touch-sensitive graphic screens) for receiving input from human operators.

The following illustration shows how an HMI may be used with a PLC to control electric power to a motor:

When the operator presses a button on the HMI display to tell the motor to start, the HMI panel sends digital data to the PLC instructing the program within the PLC to activate the motor. The PLC, in turn, receives this data from the HMI and determines whether or not<sup>7</sup> to start the motor. If the motor starts, the PLC sends data back to the HMI confirming the motor's "run" status, which the HMI indicates to the operator in graphic form.

<sup>7</sup>This motor may be "interlocked" to prevent start-up if certain conditions are not met, thereby automatically prohibiting the operator's instruction to start.

The configuration software used to set up communication between an HMI panel and the control device typically requires the human programmer (engineer or technician) to specify which data points inside the control device will be accessed by the HMI panel. This is specified in a list called the *tag name database*. A screen-shot of the tag name database for a particular HMI panel configured to communicate with a PLC using Modbus protocol appears here:

No.	Tag Name	Data Type	PLC Address	Device Name	Attribute	
1	START_PUSHBUTTON	Discrete	10024	PLC_01	R	
2	STOP_PUSHBUTTON	Discrete	10031	PLC_01	R	
3	MOTOR_RUN	Discrete	00005	PLC_01	R/W	
4	MOTOR_RUN_TIMER	Unsigned int 32	40010	PLC_01	R/W	
5	START_COUNTER	Unsigned int 16	40242	PLC_01	R/W	
6	MOTOR_TEMPERATURE	Floating PT 32	30008	PLC_01	R	
7	ERROR_MESSAGE	Ascii String	40560	PLC_01	R/W	
8	MOTOR_SPEED	Floating PT 32	30017	PLC_01	R	

This database table shows the “tag name” assigned to each data point (for easy programming reference), the type of digital data format used, the memory address within the control device (the PLC), the network name of the PLC, and whether the data point is read-only (R), write-only (W), or read/write (R/W) from the perspective of the HMI panel.

Note how the first three tag names are all classified as *discrete* data. The word “discrete” here is synonymous with *Boolean*, because it represents single-bit data having only two possible states: on or off, 1 or 0. As the tag names imply, these particular data points are associated with simple on/off states: a pushbutton for starting a motor, another pushbutton for stopping a motor, and a bit representing the motor’s “run” status. Once these tag names, data types, and device address values have been established, the programmer may then link the tags to graphic objects on the screen of the HMI panel. Perhaps a square box with the words “Motor start” may serve to activate the START\_PUSHBUTTON bit and cause the PLC to energize the electric motor. An animated graphic image of a motor may be programmed to show rotation if the MOTOR\_RUN bit is set, and show no motion if that same bit is cleared.

Four other data types appear in this tag name database, each one representing different forms of information:

- Unsigned 16-bit integer
- Unsigned 32-bit integer
- Floating-point 32-bit (also known as “Real” number format)
- ASCII string

Two “unsigned integer” data points represent motor run time and a “start counter” for keeping count of how many times the motor has been started. The timer is a 32-bit integer value, while the counter is a 16-bit integer value. Being unsigned integers (no two’s complement notation), the numerical range of the timer is 0 to 4,294,967,295 ( $2^{32} - 1$ ) and the numerical range of the counter is 0 to 65535 ( $2^{16} - 1$ ). The large range afforded by the timer’s 32-bit word length allows up to 136.2 years’ worth of recorded continuous motor run time, assuming a timer resolution of one second per count.

Two of these data points use 32-bit floating-point format to represent analog motor data: motor temperature and motor speed. Given the units of measurement common to these types of variables (degrees Celsius or Fahrenheit, revolutions per minute), a resolution of  $\pm 1$  as given by an integer number would probably be insufficient for the task. Instead, the operator should be able to read *fractions* of a degree in temperature, and *fractions* of an RPM motor speed. This necessity to display numerical values with resolution less than 1 unit dictates the use of the floating-point data type<sup>8</sup>.

The last data type represented in this tag name database is an “ASCII string,” which means a series of bytes (8-bit groupings) representing text data, such as a message. In this particular case, the tag name itself betrays the purpose of the data: `ERROR.MESSAGE`. The PLC obviously has the ability to generate text messages and send them to the HMI panel to communicate specific errors to the operator.

---

<sup>8</sup>It is also possible to “simulate” fractional resolution using an integer number, by having the HMI insert a decimal point in the numerical display. For instance, one could use a 16-bit signed integer having a numerical range of  $-32768$  to  $+32767$  to represent motor temperature by programming the HMI to insert a decimal point between the hundreds’ and the tens’ place. This would give the motor temperature tag a (displayed) numerical range of  $-327.68$  degrees to  $+327.67$  degrees, and a (displayed) resolution of  $\pm 0.01$  degree. This is basically the concept of a *fixed-point* number, where a fixed decimal point demarcates whole digits (or bits) from fractional digits (or bits).

## 15.2 Digital representation of text

Binary patterns are not just able to represent numerical values. Given a standardized *code*, they may represent other types of data as well, such as alphabetical characters. The ability to encode non-numerical data in digital form is what allows computers to manipulate and communicate text. In this subsection, we will explore some of the ways language characters are digitally encoded.

The representation of text by discrete (on/off) signals is rooted in ancient practice. The Greek historian Polybius described one such system in his *Histories* written in the second century BCE, used to communicate information about military maneuvers. In this passage Polybius describes the problem posed by primitive fire signals, and presents an improved method:

“It is evident to all that in every matter, and especially in warfare, the power of acting at the right time contributes very much to the success of enterprises, and fire signals are the most efficient of all the devices that aid us to do this. For they show what has recently occurred and what is still in the course of being done, and by means of them anyone who cares to do so even if he is at a distance of three, four, or even more days’ journey can be informed. So that it is always surprising how help can be brought by means of fire messages when the situation requires it. Now in former times, as fire signals were simple beacons, they were for the most part of little use to those who used them. It was possible for those who had agreed to convey a signal that a fleet had arrived in Oreus, Peparethus, or Chalcis, but when it came to some of the citizens having changed sides or having been guilty of treachery or a massacre having taken place in town, or anything of the kind, things that often happen, but cannot all be foreseen – and it is chiefly unexpected occurrences which require instant consideration and help – all such matters defied communication by fire signal. It was quite impossible to have a preconceived code for things which there was no means of foretelling.

This is the vital matter; for how can anyone consider how to render assistance if he does not know how many of the enemy have arrived, or where? And how can anyone be of good cheer or the reverse, or in fact think of anything at all, if he does not understand how many ships or how much corn has arrived from the allies?

The most recent method, devised by Cleoxenus and Democleitus and perfected by myself, is quite definite and capable of dispatching with accuracy every kind of urgent messages, but in practice it requires care and exact attention. It is as follows: We take the alphabet and divide it into five parts, each consisting of five letters. Each of the two parties who signal to each other must get ready five tablets and write one division of the alphabet on each tablet. The dispatcher of the message will raise the first set of torches on the left side indicating which tablet is to be consulted; i.e., one torch if it is the first, two if it is the second, and so on. Next he will raise the second set on the right on the same principle to indicate what letter of the tablet the receiver should write down.”

We no longer use burning torches to convey information over long distances, but we do face a similar challenge: *how might we convey messages of arbitrary length and complexity using a limited range of signals?* Like Polybius, many modern solutions are based on encodings of an alphabet, which then may be used to communicate any message reducible to written language.

### 15.2.1 Morse and Baudot codes

In the early days of communication, Morse code was used to represent letters of the alphabet, numerals (0 through 9), and some other characters in the form of “dot” and “dash” signals. Each “dot” or “dash” signal is one *bit* of data, equivalent to “1” and “0”. In the International Morse Code, no character requires more than five bits of data, and some (such as the common letters E and T) require only one bit.

A table showing how International Morse code represents all characters of the English alphabet and the numerals 0 through 9 appears here:

International Morse Code (English letters and Arabic numerals only)

A	•—	J	•— — —	S	•••	0	— — — — —
B	— •••	K	— • —	T	—	1	• — — — —
C	— • — •	L	• — ••	U	•• —	2	•• — — —
D	— ••	M	— —	V	••• —	3	••• — —
E	•	N	— •	W	• — —	4	•••• —
F	•• — •	O	— — — —	X	— •• —	5	•••••
G	— — •	P	• — — •	Y	— • — —	6	— ••••
H	••••	Q	— — • —	Z	— — ••	7	— — — ••
I	••	R	• — •			8	— — — — ••
						9	— — — — •

The variable bit-length of Morse code, though very efficient<sup>9</sup> in terms of the total number of “dots” and “dashes” required to communicate text messages, was difficult to automate in the form of teletype machines. In answer to this technological problem, Emile Baudot invented a different code where each and every character was five bits in length. Although this gave only 32 characters, which is not enough to represent the 26-letter English alphabet, plus all ten numerals and punctuation symbols, Baudot successfully addressed this problem by designating two of the characters as “shift” characters: one called “letters” and the other called “figures.” The other 30 characters had dual (overloaded) meanings, depending on the last “shift” character transmitted<sup>10</sup>.

<sup>9</sup>Morse code is an example of a *self-compressing* code, already optimized in terms of minimum bit count. Fixed-field codes such as Baudot and the more modern ASCII tend to waste bandwidth, and may be “compressed” by removing redundant bits.

<sup>10</sup>For example, the Baudot code 11101 meant either “Q” or “1” depending on whether the last shift character was “letters” or “figures,” respectively. The code 01010 meant either “R” or “4”. The code 00001 meant either “T” or a “5”. This overloading of codes is equivalent to using the “shift” key on a computer keyboard to switch between numbers and symbols (e.g. “5” versus “%”, or “8” versus “\*”). The use of a “shift” key on a keyboard allows single keys on the keyboard to represent multiple characters.

### 15.2.2 EBCDIC and ASCII

A much more modern attempt at encoding characters useful for text representation was *EBCDIC*, the “Extended Binary Coded Decimal Interchange Code” invented by IBM in 1962 for use with their line of large (“mainframe”) computers. In EBCDIC, each character was represented by a one-byte (eight bit) code, giving this code set 256 ( $2^8$ ) unique characters. Not only did this provide enough unique characters to represent all the letters of the English alphabet (lower-case *and* capital letters separately!) and numerals 0 through 9, but it also provided a rich set of *control characters* such as “null,” “delete,” “carriage return,” “linefeed,” and others useful for controlling the action of electronic printers and other peripheral devices.

A number of EBCDIC codes were unused (or seldom used), though, which made it somewhat inefficient for large data transfers. An attempt to improve this state of affairs was *ASCII*, the “American Standard Code for Information Interchange” first developed in 1963 and then later revised in 1967, both by the American National Standards Institute (ANSI). ASCII is a seven-bit code, one bit shorter per character than EBCDIC, having only 128 unique combinations as opposed to EBCDIC’s 256 unique combinations. The compromise made with ASCII versus EBCDIC was a smaller set of control characters.

IBM later created their own “extended” version of ASCII, which was eight bits per character. In this extended code set were included some non-English characters plus special graphic characters, many of which may be placed adjacently on a paper printout or on a computer console display to form larger graphic objects such as lines and boxes.

ASCII is by far the most popular digital code for representing English characters, even today. Nearly every digital transmission of English text in existence employs ASCII as the character encoding<sup>11</sup>. Nearly every text-based computer program’s source code is also stored on media using ASCII encoding, where 7-bit codes represent alphanumeric characters comprising the program instructions.

---

<sup>11</sup>Including the digital source code for this textbook!

The basic seven-bit ASCII code is shown in this table, with the three most significant bits in different columns and the four least significant bits in different rows. For example, the ASCII representation of the upper-case letter “F” is 1000110, the ASCII representation of the equal sign (=) is 0111101, and the ASCII representation of the lower-case letter “q” is 1110001.

#### ASCII code set

↓ LSB / MSB →	000	001	010	011	100	101	110	111
0000	NUL	DLE	SP	0	@	P	‘	p
0001	SOH	DC1	!	1	A	Q	a	q
0010	STX	DC2	”	2	B	R	b	r
0011	ETX	DC3	#	3	C	S	c	s
0100	EOT	DC4	\$	4	D	T	d	t
0101	ENQ	NAK	%	5	E	U	e	u
0110	ACK	SYN	&	6	F	V	f	v
0111	BEL	ETB	’	7	G	W	g	w
1000	BS	CAN	(	8	H	X	h	x
1001	HT	EM	)	9	I	Y	i	y
1010	LF	SUB	*	:	J	Z	j	z
1011	VT	ESC	+	;	K	[	k	{
1100	FF	FS	,	<	L	\	l	
1101	CR	GS	–	=	M	]	m	}
1110	SO	RS	.	>	N	^	n	~
1111	SI	US	/	?	O	_	o	DEL

The aforementioned “control characters” occupy the “000” and “001” columns of the table. These characters, while not associated with a printed character on the page, nevertheless play roles the other “visible” characters cannot. The “LF” character (“line feed”), for example, tells the printer to go to the next line on the paper. The “CR” character (“carriage return”) tells the printing head to return to the left-hand side of the paper. The “ESC” character (“escape”) does not result in a printed character on paper, nor does it usually command a printing machine to do anything specific, but it is often used within software as a signal to jump up one level in a menu structure, or to switch modes.

### 15.2.3 Unicode

There exist *many* written languages whose characters cannot and are not represented by either EBCDIC or ASCII. In an attempt to remedy this state of affairs, a new standardized code set is being developed called *Unicode*, with sixteen bits per character. This large bit field gives 65536 possible combinations, which should be enough to represent every unique character in every written language in the entire world. In deference to existing standards, Unicode encapsulates both ASCII and EBCDIC as sub-sets within its defined character set<sup>12</sup>.

And no, I am not going to include a table showing all the Unicode characters!

## 15.3 Analog-digital conversion

In order to provide an interface between the internal (digital) world of a computer and the external (analog) world of process measurement and control, there must be some form of *conversion* taking place between these two types of data. Devices that generate digital representations of analog measurements are called *analog-to-digital converters*, or *ADCs*. You will find ADC circuits in process transmitters, where some process variable measurement (e.g. pressure, temperature, flow, etc.) must be converted into digital form for a computer to interpret. Devices that generate an analog representation of digital quantities are called *digital-to-analog converters*, or *DACs*. These are found in the output channels of digital control systems, where the controller must drive some field device (e.g. I/P transducer) with a 4-20 mA analog electronic signal based on a digital calculation (e.g. PID).

---

<sup>12</sup>To illustrate, the first 128 Unicode characters (0000 through 007F hexadecimal) are identical to ASCII's 128 characters (00 through 7F hexadecimal)

### 15.3.1 Converter resolution

Both ADCs and DACs relate analog voltage signals to multi-bit binary (digital) data. Perhaps the most obvious measure of ADC or DAC performance, then, is how many bits of output represent how many volts of analog signal. A simplified diagram of a 12-bit ADC is shown here for illustration:

Since the digital data “width” of this ADC is 12 bits, its digital output ranges from 000000000000 to 111111111111, constituting a 12-bit binary integer with a range extending from 000 hexadecimal to FFF hexadecimal, or 0 decimal to 4095 decimal. This integer number is called the *count* value of the ADC circuit. Although the ADC shown outputs its digital data in *parallel* form (with separate terminals for the 12 individual bits), many modern ADC chips are designed for *serial* data output, where a single terminal generates a sequential series of bits timed to the pulse of a clock signal.

Supposing this 12-bit ADC has an analog input voltage range of 0 to 10 volts, how do we relate any given digital number value to a voltage value, or vice-versa? The key here is to understand that the 12-bit *resolution* of this ADC means it has  $2^{12}$ , or 4096 possible count values. The 10 volt DC input range is therefore divided up into  $2^{12} - 1$ , or 4095, discrete increments:

$$\text{Analog resolution} = \frac{\text{Analog span}}{2^n - 1}$$

Where,

$n$  = Number of binary bits in the output “word”

For our hypothetical 0-10 VDC, 12-bit converter, the analog resolution is 2.442 millivolts. Thus, for any analog signal between 0 mV and 2.442 mV, the ADC’s output should be zero (binary 000000000000); for any analog signal between 2.442 mV and 4.884 mV, the ADC’s output should be one (binary 000000000001); and so on.

As previously mentioned, the digital value output by an ADC is commonly referred to as a *count*<sup>13</sup>. The word “count” is used in this context as a unit of measurement. For instance, if we subjected our 12-bit ADC to a full-scale input signal of 10 VDC, we would expect to see a full-scale digital output (binary 111111111111) of 4095 “counts.” Since most ADC circuits are designed to be linear, the mathematical relationship between input voltage and digital output “counts” is a simple proportionality:

$$\frac{V_{in}}{V_{fullscale}} = \frac{\text{Counts}}{2^n - 1}$$

We may use this formula to generate a partial table of input and output values for our 0-10 VDC, 12-bit ADC:

$V_{in}$	Counts (decimal)	Counts (hex)
0 V	0	000
2.46 mV	1	001
3.85 V	1576	628
4.59 V	1879	757
6.11 V	2502	9C6
9.998 V	4094	FFE
10 V	4095	FFF

In order to calculate a digital count value from a given input voltage, simply divide that voltage value by the full-scale voltage, then multiply by the full-scale count value and round down<sup>14</sup> to the nearest whole number. For any given voltage value input to the ADC, there is (ideally) one corresponding output “count” value. The converse cannot be said, however: for any given output “count” value, there is actually a *range* of possible input voltages (the span of that range being the analog resolution of the ADC, in this case 2.442 mV).

To illustrate, let us take one of the table entries as an example: an analog input of 6.11 volts should yield a digital output of (precisely) 2502 counts. However, a digital output of 2502 counts could represent any analog input voltage ranging between 6.10989 volts and 6.11233 volts. This uncertainty is inherent to the process of “digitizing” an analog signal: by using a discrete quantity to represent something infinitely variable, some detail is inevitably lost. This uncertainty is referred to as *quantization error*: the (potential) error resulting from “quantizing” (digitizing) an inherently analog quantity into a discrete representation.

<sup>13</sup>The origin of this word has to do with the way many ADC circuits are designed, using binary *counters*. In the *tracking* design of ADC, for instance, an up-down binary counter “tracks” the varying analog input voltage signal. The binary output of this counter is fed to a DAC (digital-to-analog converter) sending an analog voltage to a comparator circuit, comparing the digital counter’s equivalent value to the value of the measured analog input. If one is greater than the other, the up-down counter is instructed to either count up or count down as necessary to equalize the two values. Thus, the up-down counter repeatedly steps up or down as needed to keep pace with the value of that analog voltage, its digital output literally “counting” steps along a fixed scale representing the full analog measurement range of the ADC circuit.

<sup>14</sup>Whether or not the actual ADC will round *down* depends on how it is designed. Some ADCs round down, others “bobble” equally between the two nearest digital values, and others yet “bobble” proportionately between the two nearest values. No matter how you round in your calculation of count value, you will never be more than 1 count off from the real ADC’s value.

Quantization error may be reduced (but never eliminated) by using an ADC with greater resolution. A 14-bit ADC operating over the same 0-10 VDC analog input range would have approximately one-quarter the uncertainty of the 12-bit ADC (0.610 mV instead of 2.442 mV). A 16-bit ADC's uncertainty would only be (approximately) one-sixteenth that of the 12-bit ADC. The number of bits chosen for any particular ADC application is therefore a function of how precise the digitization must be.

In some data acquisition systems the digital “count” scale maps to a live-zero analog range. For example, the Siemens model 353 process controller represents process variable, setpoint, and output (“valve”) percentages on a displayed scale of  $-3.3\%$  to  $103.3\%$  with a 12-bit ADC count. For this controller, a digital count of zero (000 hexadecimal) represents an analog signal displayed on the controller's digital readout of  $-3.3\%$ , and a full-scale digital count value (FFF hexadecimal) represents a displayed value of  $103.3\%$ . We may show the relationship between these two scales in graphical form, like a number line:

At first, the task of translating any analog value into its corresponding digital count value for this scale may seem daunting, but it is really no different than translating an input value into its corresponding output value for *any* linear instrument. This is something every student of instrumentation learns to do when working with analog-signal instrumentation, where process measurements are represented by 4-20 mA current signals or 3-15 PSI pneumatic pressure signals. If you were given a temperature transmitter with an input range of  $-100$  to  $450$  degrees Celsius and an output range of 4 to 20 milliamps, and then asked to calculate the appropriate current value corresponding to 300 degrees in that range, the task would be simple. First, you could translate 300 degrees into a per-unit expression of range by subtracting the lower-range value (LRV) of  $-100$  and then dividing by the span (URV  $-$  LRV):

$$\frac{300 - (-100)}{450 - (-100)} = 0.7273 \text{ per unit}$$

After that, you would translate that per-unit figure into a current value:

$$(0.7273)(16) + 4 = 15.636 \text{ mA}$$

This general procedure of converting an input value into a per-unit representation of range, then converting that per-unit quantity into an output value, is described in detail in section 13.2.8 beginning on page 883. Other methods of performing the same translation between linear input and output ranges are explained in sections 13.2.7 and 13.2 (beginning on pages 881 and 865, respectively).

Converting a digital count value to its respective analog value (or vice-versa) follows the exact same procedure. All we need to do is identify the input and output ranges of the converter circuit, then apply the same formula. One of these ranges will be an analog voltage or current range, while the other will be a count range. If needed, the count value may be translated to or from hexadecimal or binary, because your manual calculations of course would need to be done in decimal format.

For example, suppose one of these Siemens controllers displayed a value of 26.7% on its front panel, and we wished to know what digital (count) value corresponded to this. First, we could translate the panel indication of 26.7% into a per-unit expression of range based on the scale being  $-3.3\%$  to  $103.3\%$ :

$$\frac{26.7 - (-3.3)}{103.3 - (-3.3)} = \frac{30}{106.6} = 0.2814 \text{ per unit}$$

Then, we may take this per-unit expression of 0.2814 and multiply it by the span of the known count range (4095 for a 12-bit converter) to arrive at 1152, or 480 hexadecimal (480h).

Similarly, if we knew the range of this 12-bit ADC in actual process engineering units, we could translate between ADC counts and the process value by the same method. Suppose we used one of these same controllers to display the temperature of a furnace, where the lower- and upper-range values were 900 deg F and 1850 deg F, respectively. It is important to realize that these lower- and upper-range values represent 0% and 100% of scale, and that the ADC is actually configured to cover a range from  $-3.3\%$  to  $103.3\%$ . In other words, the ADC range “spills over” the specified range of 0 to 100% (900 to 1850 °F) by 3.3% on both ends, equating to 31.35 °F above and below the specified range limits. Thus, the 12-bit ADC’s full-count range of 0 to 4095 (000 to FFF hex) actually covers a temperature range of 868.65 °F to 1881.35 °F:

Suppose we happened to know the ADC count inside this Siemens controller for a certain furnace temperature was A59 hexadecimal (A59h), equal to 2649 in decimal form:

To convert this count value into a temperature, first we convert the count value of 2649 into a per-unit value:

$$\frac{2649}{4095} = 0.6469 \text{ per unit}$$

Next, we translate this per-unit value into a temperature based on the known LRV and URV range points:

$$(0.6469)(1881.35 - 868.65) + 868.65 = 1523.75 \text{ degrees F}$$

### 15.3.2 Converter sampling rate and aliasing

The next major performance metric for analog signal digitization is how often the analog signal gets converted into digital form. Each time an ADC circuit “samples” its analog input signal, the resulting digital number is fixed until the next sample. This is analogous to monitoring a continuously moving object by taking a series of still-photographs. Any changes happening to the analog signal between sampling events are not detected by the converter, and therefore are not represented in the digital data coming from the converter.

It stands to reason, then, that the sampling rate of any ADC must be at least as often as significant changes are expected to take place in the analog measurement. According to the *Nyquist Sampling Theorem*, the absolute minimum sample rate necessary to capture an analog waveform is twice the waveform’s fundamental frequency. More realistic is to have the ADC sample the waveform *ten times* or more per cycle.

In general electronics work, for example with the design of electronic test equipment such as digital multimeters (DMMs) and digital storage oscilloscopes (DSOs), sampling rates must be rather fast. Modern digital oscilloscopes may have sampling rates in the *billions* of samples per second, to allow for the successful digitization of radio-frequency analog signals.

Industrial process measurements are far more forgiving than measurements commonly performed on an electronic technician’s workbench, thankfully. The temperature of a large furnace may be adequately sampled at a rate of only once per minute, if need be. Even “fast” feedback processes such as liquid flow and pressure control may be controlled with reasonable stability by digital systems sampling just a few times per second.

A sampling rate that is too slow (infrequent) may detrimentally affect a measurement or control system in more than one way. First, the time between samples is *dead time* to the system: time during which the digital system will be completely unresponsive to any changes in process measurement. Excessive dead time in an alarm system means an unnecessary time delay between the alarm event and the alarm signal. Excessive dead time in a feedback control loop leads to oscillation and instability. Another detrimental effect of low sampling rate is something called *aliasing*<sup>15</sup>: a condition where the digital system “thinks” the frequency of an analog signal is far lower than it actually is.

---

<sup>15</sup>A less-commonly-used synonym for aliasing is *folding*.

An example of signal aliasing is shown in the following illustration, where a sinusoidal signal (colored blue) is sampled at periods slightly slower than once per cycle (samples marked by red dots). The result (the red, dashed curve) is what appears to be a much lower-frequency signal as seen by the digital system, which only “sees” the values represented by the red dots<sup>16</sup>:

*Sample interval slightly longer than one wave cycle*

Aliasing can even occur when the sampling rate is slightly *faster* than the sinusoidal signal’s period, as shown in this illustration:

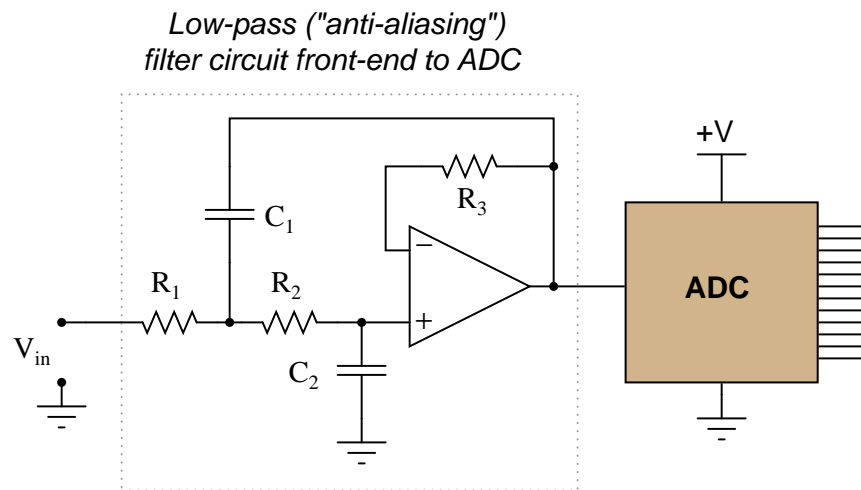

*Sample interval slightly shorter than one wave cycle*

As you can see from these illustrative examples, the troubling nature of aliasing is that it causes the ADC to report a *completely incorrect*, yet *completely plausible* signal. The only way to avoid aliasing is to ensure that the sampling rate is *much* faster than the signal period: a good rule here is to sample at least 10 times per period, for the highest signal frequency of interest.

<sup>16</sup>A mechanical demonstration of aliasing may be seen by using a *stroboscope* to “freeze” the motion of a rotating object. If the frequency of a flashing strobe light is set to exactly match the rotational speed of the object (e.g. 30 Hz flashing = 1800 RPM rotation), the object will appear to stand still because your eyes only see the object when it is at the exact same position every flash. This is equivalent to sampling a sinusoidal signal exactly once per cycle: the signal appears to be constant (DC) because the sine wave gets sampled at identical points along its amplitude each time. If the strobe light’s frequency is set slightly slower than the object’s rotational speed, the object will appear to slowly rotate in the forward direction because each successive flash reveals the object to be in a slightly further angle of rotation than it was before. This is equivalent to sampling a sinusoidal signal at a rate slightly slower than the signal’s frequency: the result appears to be a sinusoidal wave, but at a much slower frequency.

If we cannot set the sampling rate of the ADC to be significantly faster than the highest signal frequency we might encounter, we may avoid aliasing by preventing those high signal frequencies from ever reaching the ADC. This may be done by placing an analog low-pass filter circuit before the ADC's input. Such a “front-end” circuit is called an *anti-aliasing filter*:

Aliasing may still occur within digital systems, though, if one portion of a system “samples” the digital output of another portion at too slow of a rate. An example of this might be the rate at which a digital control system (such as a DCS) polls a process variable value collected by a digital sensor network (such as a network of radio-linked process transmitters, or digital fieldbus transmitters). If the DCS polling rate is sufficiently slow compared to the frequency of the signal reported by the digital transmitters, aliasing may result. The best guard against such potential troubles is to synchronize the sampling rates throughout the system, or (alternatively) ensure data sources always output values at a significantly slower rate than any functions reading them. Remember that a practical (minimum) sample rate to signal period ratio is 10:1 to ensure good analog-to-digital conversion integrity.

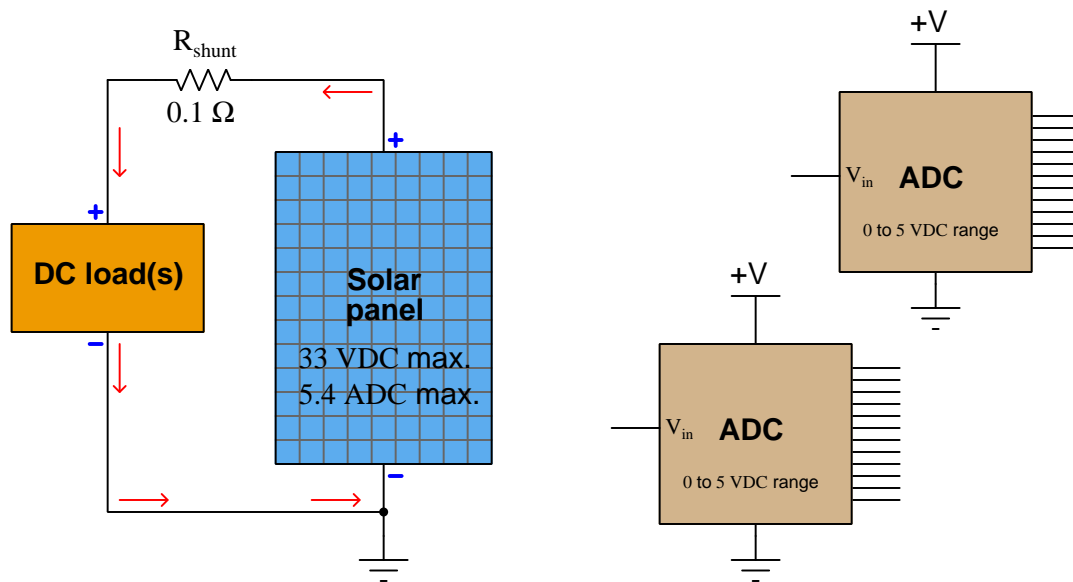

## 15.4 Analog signal conditioning and referencing

Modern analog-to-digital converters are phenomenally accurate, dependable, repeatable, and surprisingly inexpensive as integrated circuits considering their capabilities. However, even the best ADC is useless in a real application unless the analog voltage signal input to it is properly *conditioned*, or “made ready” for the ADC to receive. We have already explored one form of signal conditioning for ADC circuits, and that is the *anti-alias filter*, designed to block any signals from reaching the ADC with frequencies higher than the ADC can faithfully sample. An even more fundamental signal-conditioning requirement, though, is to ensure the analog input signal voltage is a good match for the voltage range of the ADC.

Most analog signals take the form of a varying *voltage*, but not all voltages are equally referenced. Recall the fundamental principle in electricity that “voltage” or “potential” is a relative quantity: *there is no such thing as a voltage existing at a single point*. Voltage is something that exists *between* two points. In electronic circuits, most voltage signals are referenced to a common point called “ground.” However, in many industrial measurement applications, the voltage signal of interest may not have one of its poles connected to ground. A voltage source may be “floating,” as in the case of an ungrounded thermocouple junction. A voltage source may also be “elevated,” which means both of its connection points are at some substantial amount of voltage with reference to ground. Whether or not a voltage signal source is “referenced” to ground poses a challenge for accurate and safe signal measurement, and it is a subject fraught with much confusion. This section of the book will explore some of these principles and applications, showing how to properly connect data acquisition (DAQ) hardware to voltage signal sources so as to overcome these problems.

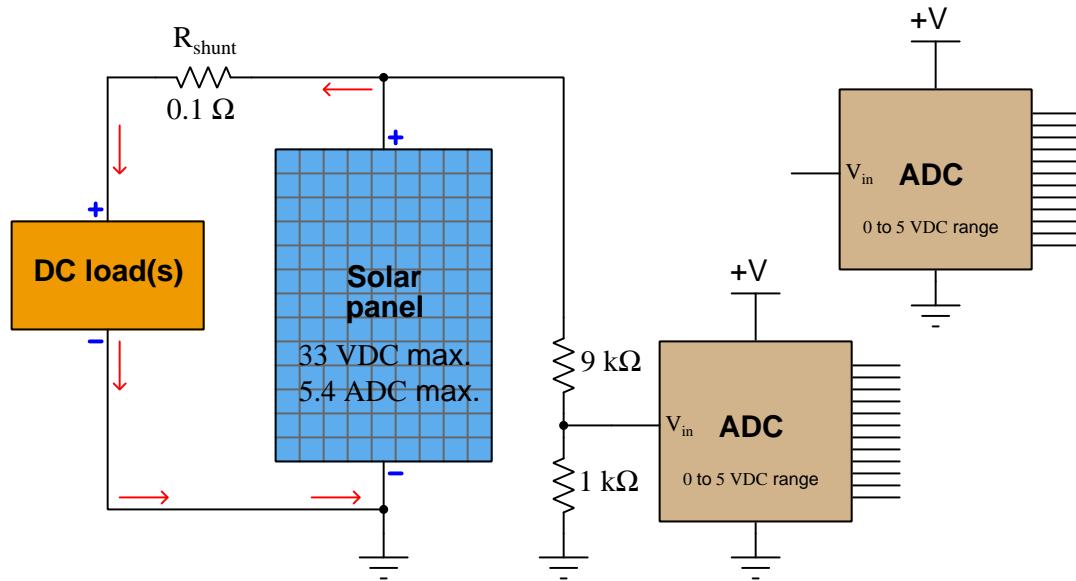

### 15.4.1 Instrumentation amplifiers

To illustrate the necessity of signal conditioning, and to introduce a critically important conditioning circuit called an “instrumentation amplifier,” let us examine a data acquisition application applied to a photovoltaic power system (solar electric panel) generating electricity from sunshine. Here, our goal is to use a pair of analog-to-digital converter circuits to monitor the solar panel’s voltage as well as its output current to the DC load. Since ADC circuits typically require *voltage* signals rather than current, a precision *shunt resistor* is placed in series with the solar panel to produce a measurable voltage drop directly proportional to load current:

The question we face now is, “how do we connect each ADC to the photovoltaic power system?” Each ADC is designed to digitize a DC voltage signal with reference to its ground connection, 0 to 5 volts DC producing a full range of “count” values. Right away we see that the maximum output voltage of the photovoltaic panel (33 volts DC) significantly exceeds the maximum input range of each ADC (5 volts DC), while the voltage produced by the shunt resistor for measuring load current will be very small (0.54 volts DC) compared to the input range of each ADC. Excessive signal voltage is obviously a problem, while a small voltage range will not effectively utilize the available measurement span or signal resolution.

The first problem – how to measure panel voltage when it greatly exceeds the ADC’s 5-volt maximum – may be easily solved by connecting one ADC to the panel through a precision voltage divider. In this particular case, a 10:1 divider circuit will do nicely:

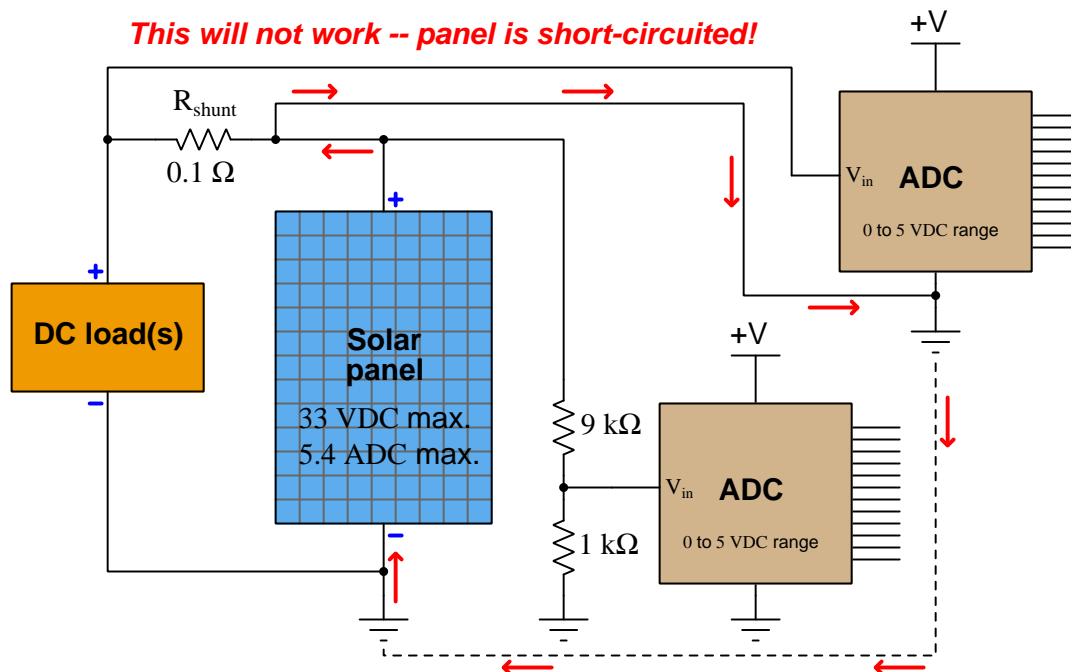

With this 10:1 voltage divider circuit in place, the panel’s 33 VDC maximum output will be seen as a 3.3 VDC maximum signal value at the ADC, which is both within its measurement range and yet spans a majority of the available range for good measurement resolution<sup>17</sup>. This simple voltage divider network thus *conditions* the solar panel’s 33 volt (maximum) output to a range acceptable to the ADC. Without such a divider in place, the ADC would be over-ranged at the very least – but most likely destroyed – by the solar panel’s relatively high voltage.

Please note how the ADC is really nothing but a voltmeter: sampling whatever voltage it senses between its  $V_{in}$  terminal and its Ground terminal. If you wish, you may visualize the ADC as being a voltmeter with red and black test leads, the red test lead being  $V_{in}$  and the black test lead being Ground.

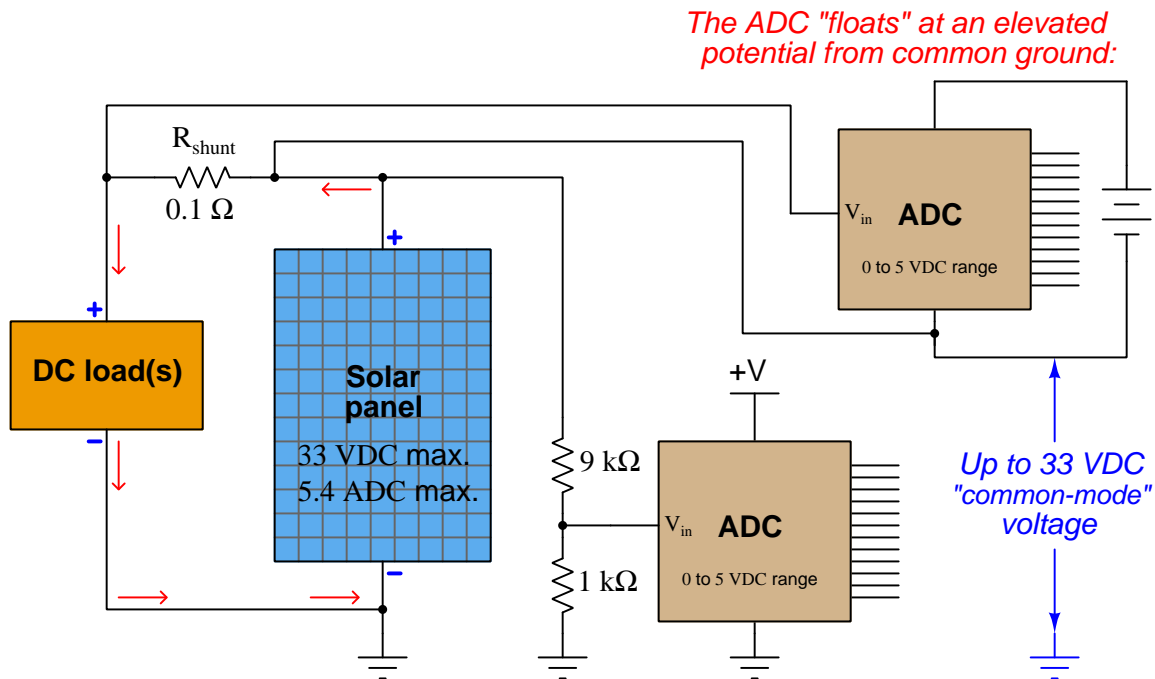

<sup>17</sup>Remember that an ADC has a finite number of “counts” to divide its received analog signal into. A 12-bit ADC, for example, has a count range of 0 to 4095. Used to digitize an analog signal spanning the full range of 0 to 5 VDC, this means each count will be “worth” 1.22 millivolts. This is the minimum amount of signal voltage that a 12-bit, 0-5 VDC converter is able to resolve: the smallest increment of signal it is able to uniquely respond to. 1.22 mV represents 0.037% of 3.3 volts, which means this ADC may “resolve” down to the very respectable fraction 0.037% of the solar panel’s 33 volt range. If we were to use the same ADC range to directly measure the shunt resistor’s voltage drop (0 to 0.54 VDC), however, it would only be able to resolve down to 0.226% of the 0 to 5.4 amp range, which is much poorer resolution.

Connecting the second ADC to the shunt resistor presents an even greater challenge, as we see in the following schematic. Treating the second ADC as a voltmeter (its “red” test lead being the  $V_{in}$  terminal and its “black” test lead being the Ground terminal), it might seem appropriate to connect those two terminals directly across the shunt resistor. However, doing so will immediately result in the panel’s full current output flowing through the Ground conductors:

Attempting to connect the ADC in parallel with the shunt resistor in order to measure its voltage drop results in unintentionally *short-circuiting* the solar panel through the ADC’s ground connection, as shown by the “fault current” path depicted in the schematic! Not only will this circuit configuration fail to function properly, but it may even result in overheated conductors. A failure to recognize the measurement problems inherent to “elevated” voltage signals is no academic matter: a mistake like this could very well end in disaster, especially if the power source in question is much larger than a single solar panel!

One way to try eliminating the fault current path is to avoid connecting the ADC to the same signal ground point shared by the first ADC. We could power the second ADC using a battery, and simply let it “float” at an elevated potential (up to 33 volts) from ground:

While this “floating ADC” solution does avoid short-circuiting the solar panel, it does not completely eliminate the fundamental problem. When we connect the ADCs’ digital output lines to a microprocessor so as to actually do something useful with the digitized signals, we face the problem of having the first ADC’s digital lines referenced to ground, while the second ADC’s digital lines are at an elevated potential from ground (up to 33 volts!). To a microprocessor expecting 5.0 volt TTL logic signals (0 volts = “low”, 5 volts = “high”) from each ADC, this makes the second ADC’s digital output unreadable (33 volts = ???, 38 volts = ???). The microprocessor must share the same ground connection as each ADC, or else the ADCs’ digital output will not be readable.

We refer to the added 33 volts as a *common-mode voltage* because that amount of voltage is common to both poles of the signal source (the shunt resistor terminals), and now is common to the digital output lines of the ADC as well. Most sensitive electronic circuits – microprocessors included – cannot effectively interpret signals having significant common-mode voltages. Somehow, we must find a way to eliminate this common-mode potential so that a microprocessor may sample both ADCs’ digital outputs.

An elegant solution to this problem involves the use of a *differential amplifier* to sample the voltage drop of the shunt resistor, then translate that voltage drop into a ground-referenced voltage ready for input to the second ADC, sharing the same ground as the first ADC. So long as this differential amplifier can tolerate the 33 VDC “common mode” voltage presented by the shunt resistor’s location on the ungrounded side of the solar panel, the shunt resistor’s signal will be properly conditioned for the ADC:

The task of the differential amplifier is to take the *difference* in potential between its two input lines and repeat that voltage at its output terminal, with reference to ground: effectively “shifting” the common-mode voltage from 33 volts to 0 volts. Thus, the differential amplifier takes a “floating” voltage signal and converts it into a ground-referenced voltage signal.

The following schematic shows how the differential amplifier does this, assuming a condition of maximum solar panel voltage and current (33 volts at 5.4 amps), and equal-value resistors in the differential amplifier circuit:

All voltages in the above schematic may be derived from the signal source (shunt resistor) and the general rule that an operational amplifier does its best to maintain zero differential voltage between its input terminals, through the action of negative feedback. The lower voltage-divider network presents half of the 33 volt solar panel potential (with reference to ground) to the noninverting opamp terminal. The opamp does its best to match this potential at its inverting input terminal (i.e. trying to keep the voltage difference between those two inputs at zero). This in turn drops 15.96 volts across the upper-left resistor (the difference between the “downstream” shunt resistor terminal voltage of 32.46 volts and the 16.5 volts matched by the opamp, both with respect to ground). That 15.96 volt drop results in a current through both upper resistors, dropping the same amount of voltage across the upper-right resistor, resulting in an opamp output voltage that is equal to 0.54 volts with respect to ground: the same potential that exists across the shunt resistor terminals, just lacking the common-mode voltage.

Not only does a differential amplifier translate an “elevated” voltage signal into a ground-referenced signal the ADC can digitize, but it also has the ability to overcome another problem we haven’t even discussed yet: amplifying the rather weak 0 to 0.54 volt shunt resistor potential into something larger to better match the ADC’s 0 to 5 volt input range. Most of the ADC’s 0 to 5 volt input range would be wasted digitizing a signal that never exceeds 0.54 volts, so amplification of this signal by some fixed gain would improve the resolution of this data channel.

Fortunately, it is a rather simple matter to equip our differential amplifier circuit with variable gain capability by adding two more operational amplifiers and three more resistors. The resulting configuration is called an *instrumentation amplifier*, so named because of its versatility in a wide variety of measurement and data acquisition applications:

A very convenient feature of the instrumentation amplifier is that its gain may be set by changing the value of a single resistor,  $R_G$ . All other resistors in an instrumentation amplifier IC are laser-trimmed components on the same semiconductor substrate as the opamps, giving them extremely high accuracy and temperature stability.  $R_G$  is typically an external resistor connected to the instrumentation amplifier IC chip by a pair of terminals.

As the formula shows us, the basic gain of an instrumentation amplifier may be adjusted from 1 ( $R_G$  open) to infinite ( $R_G$  shorted), inclusive. The input voltage range is limited only by the opamp power supplies. Thus, the instrumentation amplifier is a versatile signal-conditioning circuit for translating virtually *any* voltage signal into a ground-referenced, buffered, and amplified signal suitable for an analog-to-digital converter.

A typical DAQ (Data AcQuisition) module will have one instrumentation amplifier for every analog-to-digital converter circuit, allowing independent signal conditioning for each measurement “channel”:

The “MUX” module shown inside this data acquisition unit is a *digital multiplexer*, sequentially sampling the count values output by each ADC (one at a time) and transmitting those digital count values out to the network or “bus” cable to be read by some other digital device(s).

A final solution showing this DAQ module measuring solar panel voltage as well as current appears here:

### 15.4.2 Analog input references and connections

Most analog signals in industry come in the form of *voltages*. Even the ubiquitous 4 to 20 milliamp DC analog signal standard is typically converted into a 1 to 5 volt DC voltage signal before entering an electronic recorder, indicator, or controller. Therefore, the most common form of data acquisition device for analog measurement is one that accepts a DC voltage input signal. However, voltage signals cannot all be treated the same, especially with regard to a very important concept called *ground reference*. This portion of the book is devoted to an exploration of that concept, and how we may measure different kinds of voltage signals with real data acquisition devices.

First, let's examine some examples of analog voltage signal sources. For consistency, we will focus on different circuits that all sense temperature and output proportional DC voltages. Our first example is a simple voltage-divider circuit using an RTD (Resistance Temperature Detector) as the primary sensing element. An RTD is a variable resistance with a positive temperature coefficient: increasing resistance as temperature increases. Connected as shown, it will generate a signal voltage roughly<sup>18</sup> proportional to sensed temperature:

#### Ground-referenced voltage signal

The power source for this circuit is commonly referred to as an “excitation” source, hence the label  $V_{excite}$ . The voltage signal measurable across the RTD is what we might refer to as a *ground-referenced* voltage signal, because one pole of it is directly connected (common) to ground.

<sup>18</sup>The relationship of temperature to  $V_{signal}$  in this sensor circuit will not be precisely linear, especially if  $R_{fixed}$  is not tremendously larger than  $R_{RTD}$ .

Our next example is a device called a *thermocouple* – a pair of dissimilar-metal wires joined together to form a junction. Thermocouple junctions produce small amounts of voltage directly proportional to temperature. As such, they are self-powered devices, needing no “excitation” power sources to operate:

### Floating voltage signal

Real circuit

Voltage-source model

If the thermocouple junction is insulated from earth ground, we refer to it as a *floating* voltage signal. The word “floating” in this context refers to a complete lack of electrical connection to earth ground.

Returning to the use of RTDs for measuring temperature, another circuit design is the so-called *bridge* configuration, where an RTD comprises one or more “active” legs of a dual voltage divider. The excitation voltage source connects across two opposite ends of the bridge (powering both voltage dividers), while the signal voltage is measured across the other two opposite ends of the bridge (from one divider mid-point to the other):

### Elevated voltage signal (signal + common-mode voltage)

Real circuit

Voltage-source model

The purpose of a bridge circuit is to subtract the “live zero” voltage otherwise dropped by the RTD, which cannot produce a zero-ohm resistance at any temperature. This makes it possible to have a signal voltage range beginning at 0 volts, even though the RTD’s resistance will always be non-zero. The price we pay for this elimination of signal offset is the *elevation* of the signal from ground potential.

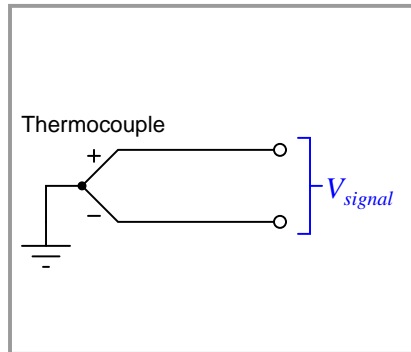

If the fixed-value resistors on the left-hand side of this bridge circuit each have the same resistance, the “common-mode” voltage will be one-half the excitation voltage. This presents an interesting situation from the perspective of measuring  $V_{signal}$ , as the common-mode voltage may greatly exceed the signal voltage. We are not particularly interested in measuring the common-mode voltage because it tells us nothing about the sensed temperature, yet this relatively large voltage is “elevating” our signal voltage from ground potential whether we like it or not, and any data acquisition hardware we connect to the bridge circuit must deal effectively with this common-mode voltage (i.e. not let it corrupt or otherwise influence the accuracy of the desired signal measurement).

Yet another type of analog voltage signal is one where the signal is “centered” around ground potential, as is the case with a grounded-tip thermocouple:

### Center-grounded voltage signal

Real circuit

Voltage-source model

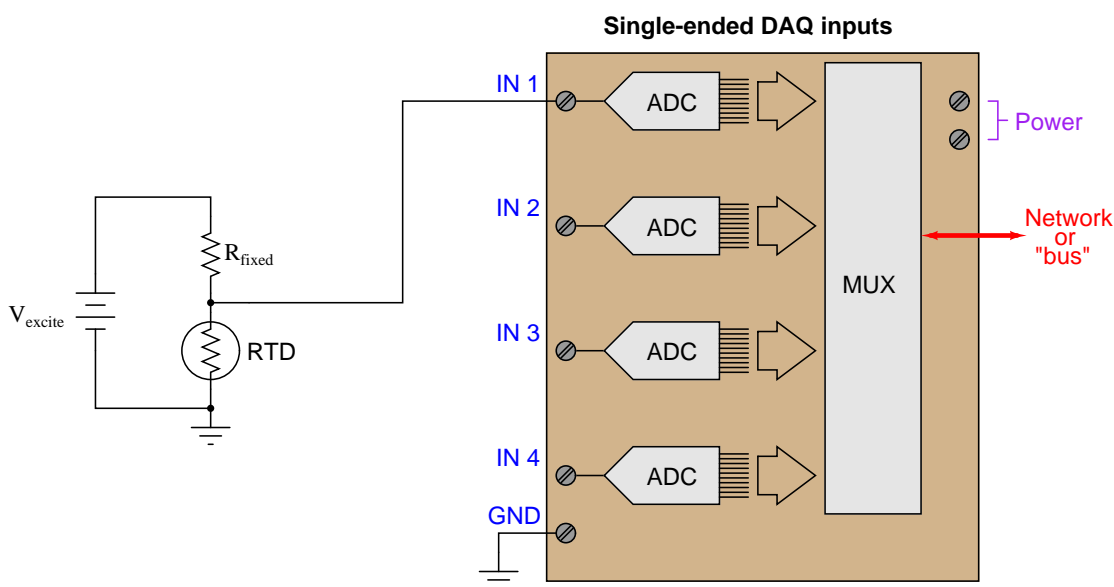

If the centering is perfectly symmetrical, the signal voltage will be evenly “split” about ground potential. The two poles of a 30 millivolt thermocouple signal, for example, will measure +15 mV and −15 mV from ground. This is electrically equivalent to the elevated voltage signal model except with a negative common-mode voltage equal to half the signal voltage:

### Center-grounded voltage signal

The type of analog voltage signal posed by our measurement application with becomes relevant when we connect it to a data acquisition device. Floating, ground-referenced, and elevated voltage signal sources each pose their own unique challenges to measurement, and any engineer or technician tasked with accurately measuring these signal types must understand these challenges. Data acquisition devices come in more than one type as well, and must be matched to the type of voltage signal in order to achieve good results.

Let's begin with our ground-referenced signal source: the simple RTD/resistor voltage divider circuit. If the divider is located close to the data acquisition (DAQ) analog input device, a single wire will suffice for connecting the two:

Each analog-to-digital converter (ADC) inside the DAQ unit is built to digitize a voltage with reference to ground, which is exactly the type of signal generated by our simple RTD voltage divider circuit. This type of DAQ analog input is called *single-ended*, and it is generally the default configuration on inexpensive DAQ units.

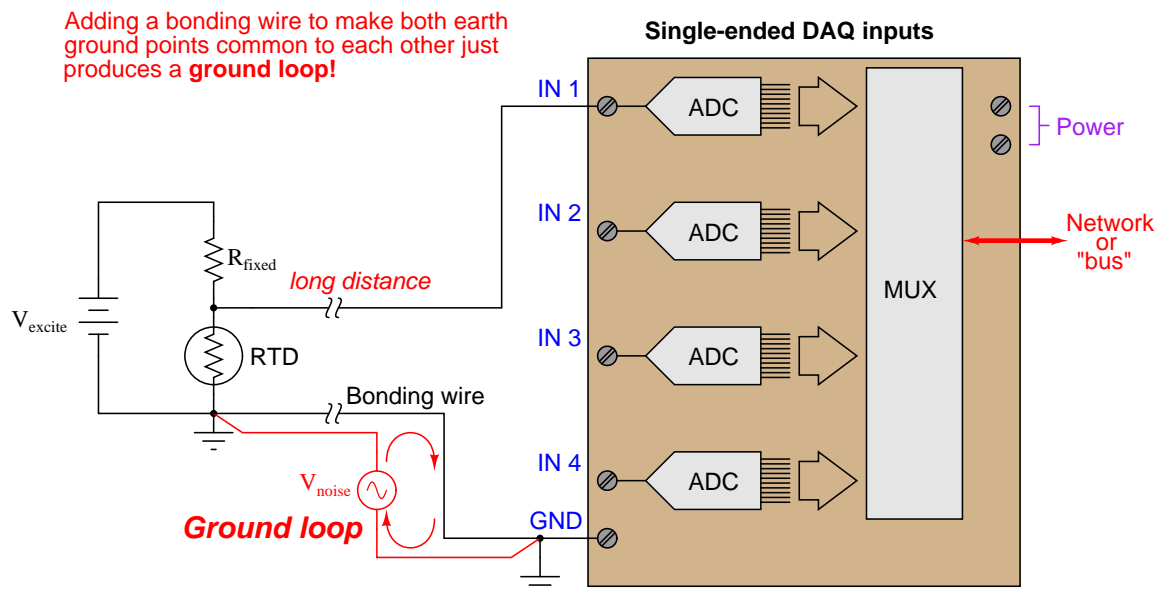

We cannot simply connect a single-ended DAQ input to a ground-referenced signal source using a single wire, however, if the two are located far apart from each other:

The problem here is that “all grounds are not created equal” over significant distances. If the ground path is literally through the earth (soil), there will be a myriad of noise sources adding spurious voltage to the measured signal: lightning strikes, ground leakage currents from AC power devices, and other sources of “noise” potential will become a part of the signal loop. Even continuous-metal ground paths over long distances can incur voltage drops significant enough to corrupt precision signal measurements. The grounding conductors used in AC power systems, for example, while continuous (no interruptions) between all points of use in the power system still drop enough millivoltage to significantly compromise instrumentation signals.

In essence, what appears to be a ground-referenced voltage signal source is actually an *elevated* voltage signal source, with the common-mode voltage being “noise” present between the two different ground locations.

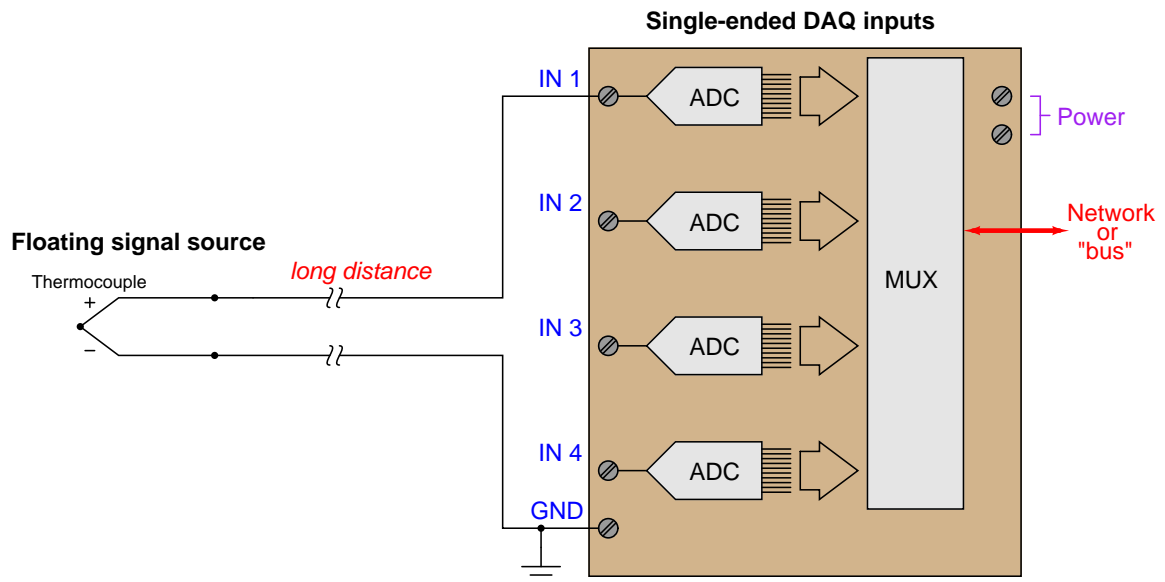

At first, it would seem that connecting the two grounds together with a dedicated length of wire would solve the differential ground problem. Unfortunately, it does not. The noise sources intercepted through the earth are often of significant power, which just means any conductor stretched between two different earth grounds may end up carrying substantial amounts of current, and subsequently dropping voltage along the way due to wire resistance ( $V_{noise} = I_{ground}R_{wire}$ ).

This is called a *ground loop*, and it should be avoided in signal circuits at all cost! Not only may the ground currents still produce significant noise voltage in the measurement circuit, but the ground currents may even become strong enough to damage the bonding wire! Ground loops are often unintentionally formed when the *shield* conductor of a long signal cable is earth-grounded at both ends.

A reasonable question to ask at this point is, "What constitutes a *long* distance when connecting ground-referenced signal sources to DAQ modules?" A simple rule to follow is that one cannot rely on ground points to be electrically common to each other (at least not common enough for precise signal-measurement purposes) if those points lie outside the same metal enclosure. If the signal source and DAQ analog input physically dwell inside the same metal enclosure, you can probably rely on the ground points being truly common to each other. If not, you should use some other means of measuring the signal. When in doubt, a sure test is to actually measure the potential difference between the source and DAQ ground points to see if any exists, being sure to check for AC noise voltage as well as DC.

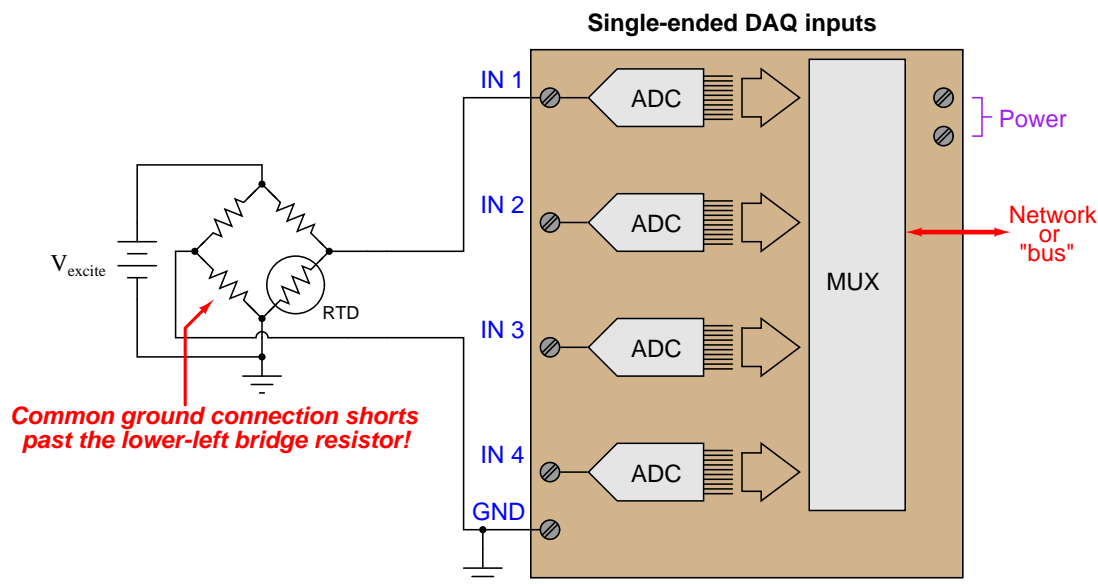

Here is an example of a single-ended DAQ module successfully measuring a voltage signal source located far away:

Since an ungrounded thermocouple has no connection whatsoever to any ground, there will be no ground loop when connected to a single-ended DAQ input. The same is true for battery-powered sensor circuits lacking connection to earth ground:

Single-ended analog DAQ inputs have trouble measuring elevated signal voltages regardless of distance. Here, we see an example where someone has tried to connect a single-ended DAQ input to a grounded-excitation RTD bridge, with common-mode voltage equal to one-half the excitation source voltage. The result is disastrous:

If you follow the bottom wire in this diagram carefully, you will see how it effectively jumpers past the lower-left resistor in conjunction with the two ground connections. Yet, eliminating the wire simply substitutes one problem for another: without the bottom wire in place, the voltage seen by input channel 1 on the DAQ will be  $V_{signal} + V_{common-mode}$  rather than  $V_{signal}$  all by itself.

A clever way to solve the problem of measuring elevated signal sources is to use *two* analog DAQ channels: one to measure  $V_{\text{signal}} + V_{\text{common-mode}}$  and the other to measure  $V_{\text{common-mode}}$ , and then digitally subtract one measurement from the other. Thus, two single-ended input channels may function as one *differential* input channel.

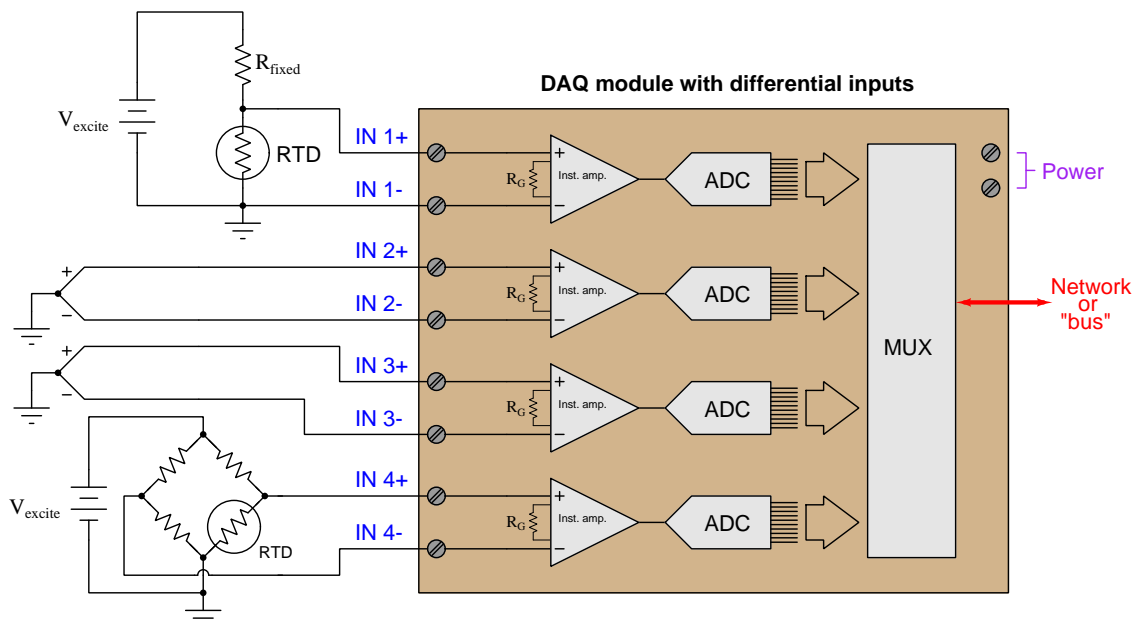

Here, we see an example of this measurement technique applied to the grounded-excitation RTD bridge:

The subtraction of the two channels' digitized values may take place in a controller separate from the DAQ module, or within the DAQ module if it is equipped with enough "intelligence" to perform the necessary calculations.

An added benefit of using this dual-channel method is that any noise voltage existing between the signal ground and the DAQ ground will be common to both channels, and thus should cancel when the two channels' signals are mathematically subtracted.

A more versatile hardware solution for measuring any form of voltage signal is a DAQ equipped with true *differential* input channels. Here, each ADC is equipped with its own instrumentation amplifier, measuring the difference in potential between two ungrounded input terminals:

In this example we see one DAQ module measuring four different voltage signal sources, with no interference from differential ground potentials or between the sources themselves. Each input channel of the ADC is electrically independent from the rest. The only limitation to this independence is a certain maximum common-mode voltage between the signal source and the DAQ's own power supply, determined by the design of the instrumentation amplifiers inside the DAQ module.

One important limitation of differential input channels, however, is that there must be some path for the instrumentation amplifiers' bias currents to the DAQ's power supply ground or else the channel will not function properly. This poses a problem where we intend to connect a differential analog input channel to a floating signal source like this:

One of the "simplifying assumptions" students learn about operational amplifier circuits is that the input terminals of an opamp draw negligible current. While this may be close enough to the truth when performing calculations on an opamp circuit, it is not absolutely true. All opamps exhibit some amount of *bias current* at their input terminals, small as these currents may be. Without a complete path to ground for these currents, the input transistor stage of the operational amplifier will not be properly biased, and the amplifier will fail to work as designed.

For this reason, we must connect high-value resistors (typically in the mega-ohm range so as not to load the signal voltage being measured) to each of the differential input terminals, and then to ground like this:

In summary, we may list some essential rules to follow when connecting analog DAQ inputs to voltage signal sources:

- Ground points in different locations may not actually be common (enough) to each other
- Never create ground loops through wiring (any conductor connected to ground at each end)
- Beware of common-mode (elevated) signal voltages
- Always ensure a path to power supply ground for amplifier bias currents

## 15.5 Digital data communication theory

One of the great benefits of digital technology is the ability to *communicate* vast amounts of information over networks. This very textbook you are reading was transmitted in digital form over the electronic network we call the *Internet*: a feat nearly impossible with any sort of analog electronic technology. The main benefit of digital data communication in industrial control is simple: no longer must we dedicate a single pair of wires to each and every variable we wish to measure and control in a facility as is necessary with analog (4-20 mA) signaling. With digital signaling, a single pair of wires or coaxial cable is able to convey a theoretically unlimited number of data points.

This benefit comes at a price, though: in order to communicate multiple variables (data points) over a single channel (wire pair), we must transmit and receive those signals one at a time. This means a digital communications system will necessarily exhibit some degree of *time delay* in acquiring, transmitting, receiving, and interpreting a signal. Analog systems, by contrast, are virtually instantaneous<sup>19</sup>. Thus, we see a contrast between analog and digital communication pitting channel capacity against speed:

Analog	Digital
Only one signal per channel	Many signals per channel possible
Instantaneous	Time-delayed

With modern electronic technology it is possible to build digital communication systems that are so fast, the time delays are negligible for most industrial processes, which renders the second comparison (instantaneous versus time-delayed) moot. If time is no longer an issue, the advantage that digital communication has over analog in terms of channel usage makes it the superior choice<sup>20</sup>.

Another important advantage of digital data communication for industrial processes is increased *noise immunity*. Analog data is *continuous* by nature: a signal of 11.035 milliamps has a different meaning than a signal of 11.036 milliamps, because any measurable increment in signal represents a corresponding increment in the physical variable represented by that signal. A voltage value in a 0-5 volt digital signaling system of 0.03 volts, however, means *the exact same thing* as a voltage value of 0.04 volts: either one is still interpreted as a “0” or “low” state. *Any* amount of electrical noise imposed on an analog signal corrupts that signal to some degree. A digital signal, however, may tolerate a substantial amount of electrical noise with no corruption whatsoever.

---

<sup>19</sup>To be fair, there is such a thing as a time-multiplexed analog system for industrial data communication (I’ve actually worked on one such system, used to measure voltages on electrolytic “pots” in the aluminum industry, communicating the voltages across hundreds of individual pots to a central control computer).

<sup>20</sup>There is, of course, the issue of *reliability*. Communicating thousands of process data points over a single cable may very well represent a dramatic cost savings in terms of wire, junction boxes, and electrical conduit. However, it also means you will lose all those thousands of data points if that one cable becomes severed! Even with digital technology, there may be reason to under-utilize the bandwidth of a signal cable.

Not surprisingly, though, the noise immunity enjoyed by digital signals comes with a price: a sacrifice in *resolution*. Analog signals are able to represent the smallest imaginable changes because they are continuously variable. Digital signals are limited in resolution by the number of bits in each data “word.” Thus, we see another contrast between analog and digital data representation:

Analog	Digital
Corrupted by any amount of noise	Immune to certain (limited) amounts of noise
Unlimited resolution	Limited resolution

With modern digital electronic technology, however, the “limited resolution” problem is almost nonexistent. 16-bit converter chipsets are commonly available today for input/output (I/O) modules on digital systems, providing a resolution of  $2^{16}$  (65536) counts, or  $\pm 0.00153\%$ , which is good enough for the vast majority of industrial measurement and control applications.

This section will focus on *serial* data transmission, as opposed to *parallel*. In order to transmit digital data in parallel form, the number of wires scales directly with the number of bits in each data “word.” For example, if a 16-bit ADC chip were to communicate its data to some other digital device using a parallel network, it would require a cable with 16 wires (plus a common “ground” wire) *at minimum*<sup>21</sup>. Since this approach undercuts the “fewer wires” advantage that digital communications theoretically enjoys over analog communication, parallel data transmission is rarely seen in industry except for within the internal construction of a digital device (e.g. a parallel data bus inside a personal computer, or inside a PLC or DCS rack).

In serial communications systems, digital data is sent over a wire pair (or fiber optic cable, or radio channel) *one bit at a time*. A 16-bit digital “word” (two *bytes* in length) then will require a succession of 16 bits transmitted one after the other in time. How we represent each bit as an electrical signal, how we arrange those bits in time to group them into meaningful “words,” and how multiple devices share access to a common communications channel, is our next subject of exploration: the technical details of serial data communication.

---

<sup>21</sup>A common technique for high-speed parallel data communication over short distances (e.g. on a printed circuit board) is *differential signaling*, where each bit requires its own dedicated *pair* of conductors. A 16-bit parallel digital signal communicated this way would require 32 conductors between devices!

### 15.5.1 Serial communication principles

The task of encoding real-life data as a series of on-and-off electrical signals, and then sending those signals long distances over electrical cables (or optical fibers, or radio waves) requires mutually-agreed *standards* for the encoding, the “packaging” of those bits, the speed at which the bits are sent, methods for multiple devices to use a common channel, and a host of other concerns. This subsection will delineate the major points of compatibility necessary for digital devices to communicate serially. We begin with a brief exploration of some of the standards used in early *telegraph* systems.

An early form of digital communication was *Morse Code*, used to communicate alpha-numerical information as a series of “dots” and “dashes” over telegraph<sup>22</sup> systems. Each letter in the alphabet, and each numerical digit (0 through 9) was represented in Morse Code by a specific series of “dot” and “dash” symbols, a “dot” being a short pulse and a “dash” being a longer pulse. A similar code system called the *Continental Code* was used for early radio (“radiotelegraph”) communications.

As primitive as these codes were, they encapsulated many of the basic principles we find in modern digital serial communication systems. First, a system of codes was necessary in order to represent English letters and numerals by electrical pulses. Next, there needed to be some way to delineate the beginning and end of each character.

For example, consider the Continental Code encoding for the word **NOWHERE**. By placing an extra space (a pause in time) between characters, it is easy to represent individual characters in the message:

"NOWHERE "

— •	— — —	• — —	• • • •	•	• — •	•
N	O	W	H	E	R	E

---

<sup>22</sup>I do not expect any reader of this book to have firsthand knowledge of what a “telegraph” is, but I suspect some will have never heard of one until this point. Basically, a telegraph was a primitive electrical communication system stretching between cities using a keyswitch at the transmitting end to transmit on-and-off pulses and a “sounder” to make those pulses audible on the receiving end. Trained human operators worked these systems, one at the transmitting end (encoding English-written messages into a series of pulses) and one at the receiving end (translating those pulses into English letters).

If this space between characters were not present, it would be impossible to determine the message with certainty. By removing the spaces, we find multiple non-sensical interpretations are possible for the same string of “dots” and “dashes:”

*Same sequence of "dots" and "dashes,"  
with multiple interpretations!*

For that matter, it is even possible to confuse the meaning of the text string “NOWHERE” when the individual characters are properly interpreted. Does the string of characters say “NOWHERE,” or does it say “NOW HERE”?

This simple example illustrates the need for *delimiting* in serial data communication. Some means must be employed to distinguish individual groups of bits (generally called *frames* or *packets*) from one another, lest their meanings be lost. In the days when human operators sent and interpreted Morse and Continental code messages, the standard delimiter was an extra time delay (pause) between characters, and between words. This is not much different from the use of whitespace to delineate words, sentences, and paragraphs typed on a page. Sentences would certainly be confusing to read if not for spaces!

In later years, when *teletype* machines were designed to replace skilled Morse operators, the concept of frame delineation had to be addressed more rigorously. These machines consisted of a typewriter-style keyboard which marked either paper strips or pages with dots corresponding to a 5-bit code called the *Baudot code*. The paper strip or sheets were then read electrically and converted into a serial stream of on-and-off pulses which were then transmitted along standard telegraph circuit lines. A matching teletype machine at the receiving end would then convert the signal stream into printed characters (a telegram). Not only could unskilled operators use teletype machines, but the data rate far exceeded what the best human Morse operators could achieve<sup>23</sup>. However, these machines required special “start” and “stop” signals to synchronize the communication of each character, not being able to reliably interpret pauses like human operators could.

Interestingly, modern asynchronous<sup>24</sup> serial data communication relies on the same concept of

<sup>23</sup>A test message sent in 1924 between two teletype machines achieved a speed of 1920 characters per minute (32 characters per second), sending the sentence fragments “THE WESTERN ELECTRIC COMPANY”, “FRESHEST EGGS AT BOTTOM MARKET PRICES”, and “SHE IS HIS SISTER”.

<sup>24</sup>“Asynchronous” refers to the transmitting and receiving devices not having to be in perfect synchronization in order for data transfer to occur. Every industrial data communications standard I have ever seen is asynchronous rather than synchronous. In synchronous serial networks, a common “clock” signal maintains transmitting and receiving devices in a constant state of synchronization, so that data packets do not have to be preceded by “start” bits or followed by “stop” bits. Synchronous data communication networks are therefore more efficient (not having

“start” and “stop” bits to synchronize the transmission of data packets. Each new packet of serial data is preceded by some form of “start” signal, then the packet is sent, and followed up by some sort of “stop” signal. The receiving device(s) synchronize to the transmitter when the “start” signal is detected, and non-precision clocks keep the transmitting and receiving devices in step with each other over the short time duration of the data packet. So long as the transmitting and receiving clocks are close enough to the same frequency, and the data packet is short enough in its number of bits, the synchronization will be good enough for each and every bit of the message to be properly interpreted at the receiving end.

---

to include “extra” bits in the data stream) but also more complex. Most long-distance, heavy traffic digital networks (such as the “backbone” networks used for the Internet) are synchronous for this reason.

### 15.5.2 Physical encoding of bits

Telegraph systems were Boolean in nature: representing “dots” and “dashes” by one electrical state of the telegraph line, and pauses by another. When manually-actuated keyswitches were abandoned in favor of teletype machines, and Morse code abandoned in favor of the *Baudot* (5-bit) code for representing alphanumeric characters, the electrical nature of the telegraph (at least initially<sup>25</sup>) remained the same. The telegraph line would either be energized or not, corresponding to *marks* or *spaces* made on the teletype paper.

Many modern digital communication standards represent binary “1” and “0” values in exactly this way: a “1” is represented by a “mark” state and a “0” is represented by a “space” state. “Marks” and “spaces” in turn correspond to different voltage levels between the conductors of the network circuit. For example, the very common EIA/TIA-232 serial communications standard (once the most popular way of connecting peripheral devices to personal computers, formerly called RS-232) defines a “mark” (1) state as  $-3$  volts between the data wire and ground, and a “space” (0) state as  $+3$  volts between the data wire and ground. This is referred to as *Non-Return-to-Zero*<sup>26</sup> or NRZ encoding:

*Non-Return-to-Zero (NRZ) encoding*

An easy way to remember the difference between a “mark” and a “space” in this scheme is to recall the operation of old telegraph printing units, specifically how they created marks and spaces on moving paper strip. When the printing unit was energized (i.e. the transmitting key was pressed, sending current through the solenoid coil of the printer, corresponding to a “1” state), the printer’s iron armature would be pulled *down* to draw a mark on the paper strip. When de-energized (transmitting key released, stopping current in the telegraph line, corresponding to a “0” state), the printer’s armature would spring-return *up* from the paper to leave a blank space.

<sup>25</sup>Later versions of teletype systems employed audio tones instead of discrete electrical pulses so that many different channels of communication could be funneled along one telegraph line, each channel having its own unique audio tone frequency which could be filtered from other channels’ tones.

<sup>26</sup>This simply refers to the fact that the signal never settles at 0 volts.

This is not the only way to represent binary bits, though. An alternative method is to use an oscillating (square-wave) signal, counting *up* and *down* transitions (pulse edges) at specific times to represent 1 and 0 states. This is called *Manchester encoding*, and it is used in the 10 Mbps (10 million bits per second) version of *Ethernet* and in both the *FOUNDATION Fieldbus* “H1” and *Profibus* “PA” instrumentation network standards:

### Manchester encoding

Note how each binary bit (0 or 1) is represented by the *direction* of the voltage signal’s transition. A low-to-high transition represents a “1” state while a high-to-low transition represents a “0” state. Extra “reversal” transitions appear in the pulse stream only to set up the voltage level as needed for the next bit-representing transitions. The representation of bits by transitions rather than by static voltage levels guarantees the receiving device can naturally detect the clock frequency of the transmitted signal<sup>27</sup>. Manchester data is therefore referred to as *self-clocking*.

Interpreting a Manchester waveform is easier than it first appears. The key is identifying which transitions represent “clocked” bits and which transitions represent “reversals” prior to bits. If we identify the widest periods of the waveform, we know the transitions in these periods must represent real bits because there are no reversals. Another way to say this is the greatest time period found between successive transitions in a Manchester waveform *is* the clock period. Once we identify this clock period, we may step along the waveform at that same period width to distinguish clocked bits from reversals.

<sup>27</sup>This is most definitely *not* the case with NRZ encoding. To see the difference for yourself, imagine a continuous string of either “0” or “1” bits transmitted in NRZ encoding: it would be nothing but a straight-line DC signal. In Manchester encoding, it is *impossible* to have a straight-line DC signal for an indefinite length of time. Manchester signals *must* oscillate at a minimum frequency equal to the clock speed, thereby guaranteeing all receiving devices the ability to detect that clock speed and thereby synchronize themselves with it.

Yet another method for encoding binary 1 and 0 states is to use sine waves of different frequencies (“tone bursts”). This is referred to as *Frequency Shift Keying*, or *FSK*, and it is the method of encoding used in the HART “smart” instrument communications standard.

### *Frequency Shift Key (FSK) encoding*

In the HART standard – based on the Bell 202 standard used in telephone data exchange – two complete cycles at 2200 Hz represents a “0” bit (space), while one complete cycle at 1200 Hz represents a “1” bit (mark). This standard, along with a series of previous and subsequent modulation standards, was invented as a way to exchange digital data over telephone networks, which were built to communicate audio-frequency<sup>28</sup> AC signals and thus could not reliably communicate the square-wave signals associated with direct digital data. By assigning digital values to different audio frequencies, serial data could be communicated over telephone channels as a series of sine-wave tones.

The same principle of FSK allows HART-compatible instruments to communicate digital data over cables simultaneously carrying DC current (4 to 20 mA) signals representing control system data. Since each bit of FSK-encoded data consists of complete AC cycles (one full positive swing for every full negative swing), the superposition of AC tones does not affect the time-averaged value of the DC milliamp signal.

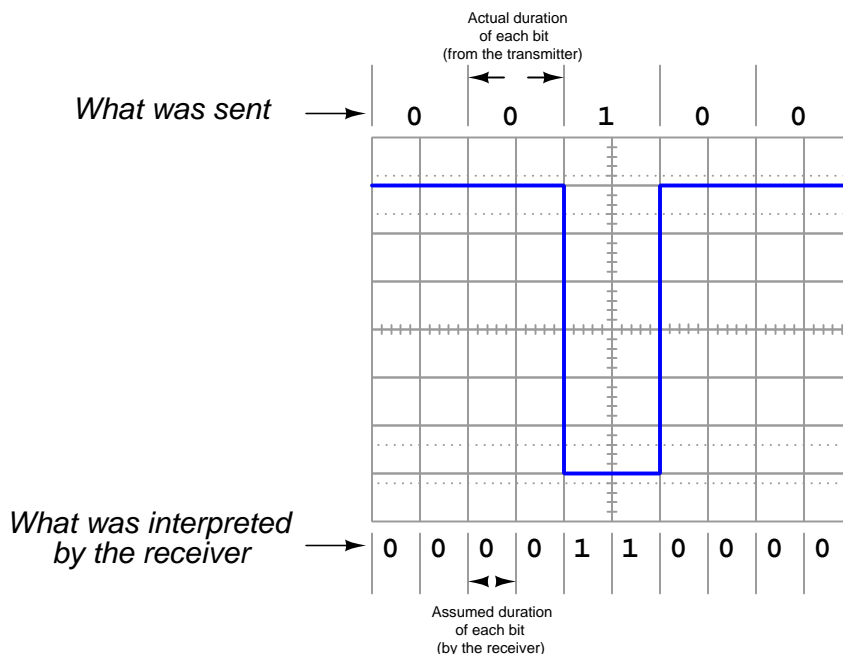

Other methods exist as well for encoding digital data along network cables, but these three are the most popular in industrial networks.

<sup>28</sup>It is relatively easy to build an apparatus that makes HART tone signals audible: simply connect a small audio speaker to the low-impedance side of an audio transformer (8 ohms) and then connect the high-impedance side of that transformer (typically 1000 ohms) to the HART signal source through a coupling capacitor (a few microfarads is sufficient). When HART communications are taking place, you can hear the FSK tones reproduced by the speaker, which sound something like the noises made by a fax machine as it communicates over a telephone line.

### 15.5.3 Communication speed

In order to successfully communicate digital data along a network, there must not only be a standard agreed upon between transmitting and receiving devices for encoding bits (NRZ, Manchester, FSK, etc.), but there must also be a standard in place for the *speed* at which those bits will be sent. This is especially true for NRZ and FSK encoding, where the “clock” speed is not explicitly present in the signal<sup>29</sup>.

For example, consider the confusion that could arise interpreting a NRZ signal if the transmitting device sends data at half the speed assumed by the receiving device:

Thus, one of the essential parameters in a serial data communication system is the *bit rate*, measured in *bits per second* (bps). Some communications standards have fixed bit rates, such as FOUNDATION Fieldbus H1 and Profibus PA, both standardized at exactly 31.25 kbps. Some, such as Ethernet, have a few pre-defined speeds (10 Mbps, 100 Mbps, 1 Gbps) defined by the specific transmitting and receiving hardware used. Others, such as EIA/TIA-232 may be arbitrarily set by the user at speeds ranging from 300 bps to over 115 kbps.

An older term sometimes used synonymously with bit rate is *baud rate*, however “bits per second” and “baud” are actually different things. “Baud” refers to the number of voltage (or current) alternations per second of time, whereas “bits per second” refers to the actual number of binary data bits communicated per second of time. Baud is useful when determining whether or not the bandwidth (the maximum frequency capacity) of a communications channel is sufficient for a certain communications purpose. For a string of alternating bits (e.g. 0101010101) using NRZ encoding,

<sup>29</sup>This is one of the advantages of Manchester encoding: it is a “self-clocking” signal.

the baud rate is equivalent<sup>30</sup> to the bit rate: exactly one voltage transition for each bit. For a string of unchanging bits (e.g. 000000000000 or 111111111111) using NRZ encoding, the baud rate is far less than the bit rate. In systems using Manchester encoding, the worst-case<sup>31</sup> baud rate will be exactly *twice* the bit rate, with two transitions (one up, one down) per bit. In some clever encoding schemes, it is possible to encode multiple bits per signal transition, such that the bit rate will actually be greater than the baud rate.

---

<sup>30</sup>This is likely why “bit rate” and “baud rate” became intermingled in digital networking parlance: the earliest serial data networks requiring speed configuration were NRZ in nature, where “bps” and “baud” are one and the same.

<sup>31</sup>For Manchester encoding, “worst-case” is a sequence of identical bit states, such as 111111111111, where the signal must make an extra (down) transition in order to be “ready” for each meaningful (up) transition representing the next “1” state.

### 15.5.4 Data frames

As mentioned earlier in this section, serial data is usually communicated *asynchronously* in industrial networks. This means the transmitting and receiving hardware need not be in perfect synchronization to reliably send and receive digital data. In order for this to work, data must be sent in “frames” or “packets” of fixed (maximum) length, each frame preceded by a special “start” signal and concluded with a special “stop” signal. As soon as the transmitting device issues the “start” signal, the receiving device synchronizes to that start time, and runs at the pre-determined clock speed to gather the successive bits of the message until the “stop” signal is received. So long as the internal clock circuits of the transmitting and receiving devices are running at *approximately* the same speed, the devices will be synchronized closely enough to exchange a short message without any bits being lost or corrupted. There is such a thing as a *synchronous* digital network, where all transmitting and receiving devices are locked into a common clock signal so they cannot stray out of step with each other. The obvious advantage of synchronous communication is that no time need be wasted on “start” and “stop” bits, since data transfer may proceed continuously rather than in packets. However, synchronous communication systems tend to be more complex due to the need to keep all devices in perfect synchronization, and thus we see synchronous systems used for long-distance, high-traffic digital networks such as those use for Internet “backbones” and not for short-distance industrial networks.

Like bit rate, the particular scheme of start and stop bits must also be agreed upon in order for two serial devices to communicate with each other. In some networks, this scheme is fixed and cannot be altered by the user. Ethernet is an example of this, where a sequence of 64 bits (an alternating string of “1” and “0” bits ending with a “1, 1”; this is the “preamble” and “start frame delimiter” or “SFD” bit groups) is used to mark the start of a frame and another group of bits specifies the length of the frame (letting the receiver know ahead of time when the frame will end). A graphic description of the IEEE 802.3 standard for Ethernet data frames is shown here, illustrating the lengths and functions of the bits comprising an Ethernet frame:

Other serial networks offer choices for the user to select regarding these parameters. One such example is EIA/TIA-232, where the user may specify not only the bit rate, but also how many bits will be used to mark the end of the data frame. It is imperative in such systems that *all* transmitting and receiving devices within a given network be configured exactly the same, so that they will all “agree” on how to send and receive data. A screenshot from a UNIX-based serial communication terminal program (called *minicom*<sup>32</sup>) shows these options:

In this particular screenshot, you can see the data rate options (extending from 300 bps all the way up to 230400 bps!), the number of data bits (from 5 to 8), and the number of stop bits (1 or 2), all configurable by the user. Of course, if this program were being used for communication of data between two personal computers, *both* of those computers would need these parameters set identically in order for the communication to take place. Otherwise, the two computers would not be in agreement on speed, number of data bits, and stop bits; their respective data frames simply would not match.

<sup>32</sup>An equivalent program for Microsoft Windows is *Hyperterminal*. A legacy application, available for both Microsoft Windows and UNIX operating systems, is the serial communications program called *kermit*.

To give an example of an EIA/TIA-232 data frame might look like as a series of voltage states, consider this waveform communicating a string of eight bits (01011001), using NRZ encoding. Here, a single “start” marks the beginning of the data frame, while two successive “stop” bits end it. Also note how the bit sequence is transmitted “backwards,” with the least-significant bit (LSB) sent first and the most-significant bit (MSB) sent last<sup>33</sup>:

*Serial bitstream for the digital byte 01011001,  
where the least-significant bit (LSB) is sent first*

Interestingly, the “mark” state (corresponding to a binary bit value of “1”) is the default state of the communications channel when no data is being passed. The “start” bit is actually a space (0). This is the standard encoding scheme for EIA/TIA-232, EIA/TIA-485, and some other NRZ serial communication standards.

One of the options you probably noticed in the “minicom” terminal program screenshot was something called *parity*. This is a simple form of error-checking used in many serial communication standards. The basic principle is quite simple: an extra bit is added at the end of the data frame (between the data and stop bits) to force the total number of “1” states to be either odd or even. For example, in the data stream just shown (10011010), there is an *even* number of “1” bits. If the serial device sending this eight-bit data group were configured for “odd” parity, it would append an additional “1” to the end of that frame to make the total number of “1” bits odd rather than even. If the next data group were 11001110 instead (already having an odd number of “1” bits), the transmitting device would have to attach a “0” parity bit on to the data frame in order to maintain an odd count of “1” bits.

Meanwhile, the receiving device is programmed to count up all the “1” bits in each data frame (including the parity bit), and check to see that the total number is still odd (if the receiving device is configured for odd parity just as the transmitting device, which the two should *always* be in agreement). Unlike the transmitting device which is tasked with *creating* the parity bit state, the receiving device is tasked with *reading* all the data bits plus the parity bit to check if the count is still as it should be. If any one bit somehow gets corrupted during transmission, the received frame will not have the correct parity, and the receiving device will “know” something has gone wrong. Parity

<sup>33</sup>This is standard in EIA/TIA-232 communications.

does not suggest *which* bit got corrupted, but it will indicate if there was a single-bit<sup>34</sup> corruption of data, which is better than no form of error-checking at all.

The following example shows how parity-checking would work to detect a transmission error in a 7-bit data word. Suppose a digital device asynchronously transmits the character “T” using ASCII encoding (“T” = 1010100), with one start bit, one stop bit, and “odd” parity. Since the “start” bit is customarily a 0 state (space), the data transmitted in reverse order (LSB first, MSB last), the parity bit transmitted after the data’s MSB, and the “stop” bit represented by a 1 state (mark), the entire frame will be the following sequence of bits: 0001010101. Viewed on an oscilloscope display where a negative voltage represents a “mark” and a positive voltage represents a “space,” the transmitted data frame will look like this:

Note how the parity bit in this particular frame has been generated by the transmitting device as a 0 state, because the parity type is set for “odd,” and the transmitting device realizes that the 7-bit data word already has an odd number of 1 bits in it and doesn’t need another “1” for the parity bit. The pulse waveform you see above is how this data frame will be transmitted onto the network.

<sup>34</sup>It should take only a moment or two of reflection to realize that such a parity check cannot detect an *even* number of corruptions, since flipping the states of any *two* or any *four* or any *six* (or even all eight!) bits will not alter the evenness/oddness of the bit count. So, parity is admittedly an imperfect error-detection scheme. However, it is certainly better than no error detection at all!

Now suppose this transmitted frame encounters a significant amount of electrical noise as it travels to the receiving device. If the frame reaches the receiver as shown in the next illustration, the receiving device will interpret the message incorrectly:

One of the bits has been corrupted by noise, such that the fifth transmitted data bit (which should be 1) is instead received as a 0. The receiving device, of course, has no knowledge of the noise present on the NRZ signal because all it “sees” is the “mark” or “space” states as interpreted by its input buffer circuitry. When the receiving device goes to count the number of 1 bits in the message (data plus parity bit, disregarding start and stop bits), however, it will count an even number of 1’s instead of an odd number of 1’s. Since the receiving device is also set for “odd” parity to match the transmitting device, it expects an odd number of 1’s in the received message. Thus, it “knows” there is a problem somewhere in this transmission, because the received parity is not odd as it should be.

Parity-checking does not tell us *which* bit is corrupted, but it does indicate that *something* has gone wrong in the transmission. If the receiving device is programmed to take action on receipt of a non-matching parity, it may reply with a request for the transmitting device to re-send the data as many times as necessary until the parity is correct.

If we look at the “minicom” terminal screenshot again to analyze the parity options, we see there are several to choose from:

The five options for parity in this program include *None*, *Even*, *Odd*, *Mark*, and *Space*. “No” parity is self-explanatory: the transmitting device does not attach an extra bit for parity at all, and the receiving device does not bother to check for it. Since the inclusion of a parity bit does add to the bulk of a data frame, it has the unfortunate effect of slowing down communications (more bit “traffic” occupying the channel than would otherwise need to be), thus the option to waive parity altogether for a more compact (faster) data frame. “Even” and “Odd” parity options work as previously described, with the transmitting device adding a parity bit to each frame to bring the total “1” bit count either to an even number or to an odd number (depending on the user’s configuration), and the receiving device checks for the same. “Mark” and “Space” are really of limited usefulness. In either of these two options, a parity bit is added, but the transmitting device does not bother to calculate the evenness or oddness of the data bits, rather simply making the parity bit always equal to 1 (“mark”) or 0 (“space”) as chosen by the user. The receiving device checks to see that the parity bit is always that value. These two options are of limited usefulness because the parity bit fails to reflect the status of the data being transmitted. The only corruption the receiving device can detect, therefore, is a corruption of the parity bit itself!

One will often find the communications parameters of a serial network such as this displayed in “shorthand” notation as seen at the top of the “minicom” terminal display: 38400 8N1. In this case, the terminal program is configured for a bit rate of 38400 bits per second, with a data field 8 bits long, no parity bit, and 1 stop bit. A serial device configured for a bit rate of 9600 bps, with a 7-bit data field, odd parity, and 2 stop bits would be represented as 9600 7O2.

Parity bits are not the only way to detect error, though. Some communication standards employ more sophisticated means. In the Ethernet (IEEE 802.3) standard, for example, each data frame is concluded with a *frame check sequence*, which is a collection of bits mathematically calculated by the transmitting device based on the content of the data. The algorithm is called a *cyclic*

*redundancy check*, or *CRC*, and is similar to the concept of “checksum” used by computers to check the integrity of data stored in hard disks and other “permanent” media. Like a parity algorithm, the CRC algorithm runs through a mathematical process whereby all the bits in the data field are counted, and a number is generated to reflect the statuses of those bits. The receiving device takes the received data field and performs the exact same mathematical algorithm, generating its own CRC value. If any of the data’s bits become corrupted during transmission, the two CRC values will not match, and the receiving device will know *something* has gone wrong.

Like parity, the CRC algorithm is not perfect. There exists a chance that just the right combination of errors may occur in transmission causing the CRC values at both ends to match even though the data is not identical, but this is highly unlikely (calculated to be one chance in  $10^{14}$ ). It is certainly better than having no error detection ability at all.

If the communications software in the receiving device is configured to take action on a detection of error, it may return a “request for re-transmission” to the transmitting device, so the corrupted message may be re-sent. This is analogous to a human being hearing a garbled transmission in a telephone conversation, and subsequently requesting the other person repeat what they just said.

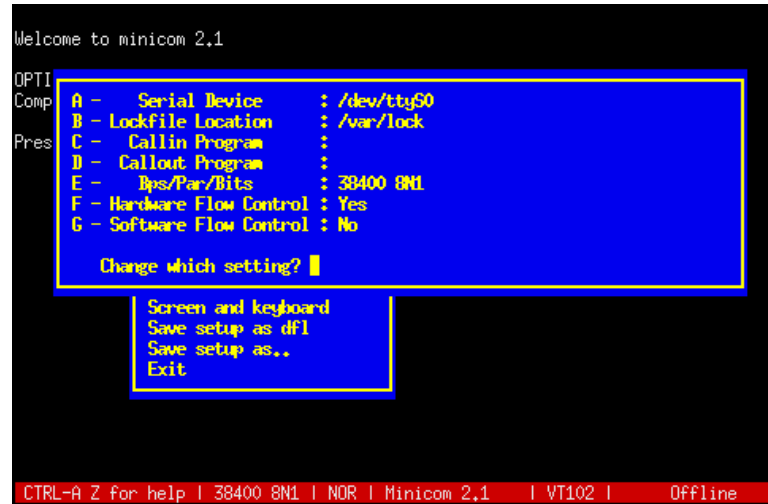

Another option often found in serial data communications settings is something called *flow control*, not to be confused with the actual control of fluid through a pipe. In the context of digital communications, “flow control” refers to the ability of a receiving device to request a reduction in speed or even a complete cessation of data transmission if the speed of the transmitted data is too fast for the receiving device to keep pace. An example common to personal computers is that of a mechanical printer: while the computer may be able to transmit data to be printed at a very rapid pace, the printer is limited by the speed of its printing mechanism. In order to make the printing process go more smoothly, printers are equipped with *buffer memory* to store portions of the print job received from the transmitting computer that have not had time to print yet. However, these buffers are of finite size, and may become overwhelmed on large print jobs. So, if and when a printer detects its buffer near full capacity, it may issue a command to the computer to freeze serial data transmission until the printer’s buffer has had some time to empty. In other words, the printer can send a message to the computer saying “Stop!” when its buffer is full, then later send another message saying “Resume” when its buffer is empty enough to resume filling. Thus, the receiving device has control over the flow of data necessary to manage its buffer resources.

Flow control in serial networks may take place in either *hardware* mode or *software* mode. “Hardware” mode refers to the existence of additional connector pins and cable conductors specifically designated for such “halt” and “resume” signals. “Software” mode refers to data codes communicated over the regular network channel telling the transmitting device to halt and resume. Software flow control is sometimes referred to as XON/XOFF in honor of the names given to these codes<sup>35</sup>. Hardware flow control is sometimes referred to as RTS/CTS in honor of the labels given to the serial port pins conveying these signals.

---

<sup>35</sup>The “XOFF” code tells the transmitting device to halt its serial data stream to give the receiving device a chance to “catch up.” In data terminal applications, the XOFF command may be issued by pressing the key combination <Ctrl><S>. This will “freeze” the stream of text data sent to the terminal by the host computer. The key combination <Ctrl><Q> sends the “XON” code, enabling the host computer to resume data transmission to the terminal.

The following screen shot shows options for flow control in the “minicom” terminal program:

```
Welcome to minicom 2.1

OPTI
Comp
Pres
A - Serial Device      : /dev/ttyS0
B - Lockfile Location  : /var/lock
C - Callin Program    :
D - Callout Program   :
E - Bps/Par/Bits      : 38400 8N1
F - Hardware Flow Control : Yes
G - Software Flow Control : No

Screen and keyboard
Save setup as df1
Save setup as..
Exit

CTRL-A Z for help | 38400 8N1 | NOR | Minicom 2.1 | VT102 | Offline
```

Here, you can see “hardware” flow control enabled and “software” flow control disabled. The enabling of “hardware” flow control means the serial communications cable must be equipped with the necessary lines to convey these handshaking signals (when needed) between devices. Software flow control tends to be the more popular option, the advantage of this of course being fewer conductors necessary in the serial data cable. The disadvantage of using software flow control over hardware is a slight inefficiency in data throughput, since the XON and XOFF commands require time to be transmitted serially over the same network as the rest of the data.

### 15.5.5 Channel arbitration

When two or more communication devices exchange data, the directions of their communication may be classified into one of two categories: *simplex* or *duplex*. A “simplex” network is one-way communication only. A sensor outputting digital data to a remotely-located indicator over a digital network would be an example of simplex communication, where the flow of information goes from sensor to indicator, and never the other direction. A public-address (PA) system is an analog example of a simplex communication system, since audio information only goes in one direction (from the person with the microphone to the audience).

“Duplex” communication refers to two-way data exchange. Voice telephony is an analog example of two-way (duplex) communication, where either person at the end of the connection can hear the other person talking. Duplex communication may be further subdivided into *half-duplex* and *full-duplex*, referring to whether or not the two-way communication may be simultaneous. In a “full-duplex” system, both devices may transmit data to each other simultaneously because they have separate channels (separate wires, or optical fibers, or radio frequencies) for their respective transmissions. In a “half-duplex” system, only one device may transmit at any time because the devices must share a common channel. A telephone system is an example of a full-duplex system, although it may be rather difficult for the people to understand each other when they are speaking over one another. A push-to-talk radio system (“walkie-talkie”) is an example of a half-duplex system, where each person must take turns talking.

Most industrial data networks are half-duplex, if only for the reason that most networks consist of more than two devices on a network segment. When more than two devices share a network, there are not enough data channels to allow *all* of the devices to simultaneously transmit and listen to each other. Thus, virtually any network supporting more than two devices will be half-duplex at best, and may even be limited to simplex operation in some cases.

In half-duplex systems, there must be some way for the respective devices to “know” when they are allowed to transmit. If multiple devices sharing one communications channel attempt to transmit simultaneously, their messages will “collide” in such a way that no device on the network will be able to interpret either message. The problem is analogous to two people simultaneously pressing the “talk” buttons on their two-way radio units: neither of the talking people can hear each other, and anyone else on the same channel hears the garbled amalgam of those two peoples’ superimposed transmissions. In order to avoid this scenario in a half-duplex network, there must be some strategy to coordinate transmissions so only one device “talks” at any given time. The problem of deciding “who” gets to “talk” at any given time is generally known as *channel arbitration*. Several strategies for addressing this problem have been developed in the data communications field, a few of which will be described in this subsection.

### Master-slave

Our first method works on the principle of having only one device on the network (the “master”) with permission to arbitrarily transmit data. All other devices on the network are “slaves,” which may only respond in direct answer to a query from the master. If the network happens to be simplex in nature, slave devices don’t even have the ability to transmit data – all they can do is “listen” and receive data from the one master device.

For example, in a half-duplex master-slave network, if one slave device has data that needs to be sent to another slave device, the first slave device must wait until it is prompted (“polled”) by the master device before it is allowed to transmit that data to the network. Once the data is transmitted, any and all slave devices may receive that transmission, since they all “listen” to the same communications channel.

An example of an industrial network using master-slave channel arbitration is HART *multidrop*, where multiple HART field instruments are parallel-connected on the same wire pair, and one device (usually a dedicated computer) serves as the master node, polling the field instruments one at a time for their data.

Another example of a master-slave industrial network is a *Modbus* network connecting a programmable logic controller (PLC) to multiple variable-frequency motor drives (VFDs). The master device (the PLC) initiates all communications, with the slave devices (the motor drives) at most replying to the PLC master (and in many cases not replying at all, but merely receiving data from the PLC in simplex mode).

Master-slave arbitration is simple and efficient, but suffers from one glaring weakness: if the master device happens to fail, all communication on the network halts. This means the ability of *any* device on the network to transmit information utterly depends on the proper function of *one* device, representing a high level of dependence on that one (master) device’s function.

Some master-slave networks address this problem by pre-assigning special “back-up” status to one or more slave devices. In the event that the master device fails and stops transmitting for a certain amount of time, the back-up device becomes “deputized” to act as the new master, taking over the role of the old master device by ensuring all slave devices are polled on schedule.

### Token-passing

Another method of arbitrating which device gets to transmit on a channel in a half-duplex network is the *token-passing* method. Here, a special data message called the “token” serves as temporary authorization for each device to transmit. Any device in possession of the token is allowed to act as a master device, transmitting at will. After a certain amount of time, that device must relinquish the token by transmitting the token message on the network, complete with the address of the next device. When that other device receives the token message, it switches into master mode and transmits at will. The strategy is not unlike a group of people situated at a table, where only one of them at a time holds some object universally agreed to grant speaking authority to the holder.

Token-passing ensures only one device is allowed to transmit at any given time, and it also solves the problem inherent to master-slave networks of what happens when the master device fails. If one of the devices on a token-passing network fails, its silence will be detected after the last token-holding device transmits the token message to the failed device. After some pre-arranged period of time, the last token-holding device may re-transmit the token message to the *next* device after the one that failed, re-establishing the pattern of token sharing and ensuring all devices get to “speak” their turn once more.

Examples of token-passing networks include the general-purpose Token Ring network standard (IEEE 802.5) and the defunct Token Bus (IEEE 802.4). Some proprietary industrial networks such as Honeywell’s TDC 3000 network (called the *Local Control Network*, or *LCN*) utilize token-passing arbitration.

Token-passing networks require a substantially greater amount of “intelligence” built into each network device than master-slave requires. The benefits, though, are greater reliability and a high level of bandwidth utilization. That being said, token-passing networks may suffer unique disadvantages of their own. For example, there is the question of what to do if such a network becomes severed, so that the one network is now divided into two segments. At the time of the break, only one device will possess the token, which means only one of the segments will possess any token at all. If this state of affairs holds for some time, it will mean the devices lucky enough to be in the segment that still has the token will continue communicating with each other, passing the token to one another over time as if nothing was wrong. The isolated segment, however, lacking any token at all, will remain silent even though all its devices are still in working order and the network cable connecting them together is still functional. In a case like this, the token-passing concept fares no better than a master-slave network. However, what if the designers of the token-passing network decide to program the devices to automatically generate a new token in the event of prolonged network silence, anticipating such a failure? If the network becomes severed and broken into multiple segments, the isolated segments will now generate their own tokens and resume communication between their respective devices, which is certainly better than complete silence as before. The problem now is, what happens if a technician locates the break in the network cable and re-connects it? Now, there will be *multiple* tokens on one network, and confusion will reign!

Another example of a potential token-passing weakness is to consider what would happen to such a network if the device in possession of the token failed before it had an opportunity to relinquish the token to another device. Now, the entire network will be silent, because no device possesses the token! Of course, the network designers could anticipate such a scenario and pre-program the devices to generate a new token after some amount of silence is detected, but then this raises the possibility of the previously-mentioned problem when a network becomes severed and multiple tokens arise in

an effort to maintain communication in those isolated network segments, then at some later time the network is re-connected and now multiple tokens create data collision problems.

## TDMA

A method of channel arbitration similar to token-passing is *TDMA*, or “Time Division Multiple Access.” Here, each device is assigned an absolute “time slot” in a repeating schedule when it alone is allowed to transmit. With token-passing, permission to transmit is granted to each device by the previous device as it relinquishes the token. With TDMA, permission to transmit is granted by an appointment on a fixed time schedule. TDMA is less time-efficient than token-passing because devices with no data to transmit still occupy the same amount of time in the schedule as when they have data to transmit. However, TDMA has the potential to be more tolerant of device failure and network segmentation than token-passing because neither the failure of a device nor segmentation of the network can prevent remaining devices from communicating with each other. If a device fails (becomes “silent”) in a TDMA network, that time slot simply goes unused while all other communication continues unabated. If the network becomes severed, each set of devices in the two segments will still follow their pre-programmed time schedule and therefore will still be able to communicate with each other.

Examples of TDMA networks include the *WirelessHART* and *ISA100.11a* radio instrumentation standards. The GSM cell phone network standard also includes TDMA as part of a larger strategy to manage access between multiple cell phones and cell towers. TDMA arbitration works very well for wireless (radio) networks where the communication channel is inherently unreliable due to physical obstacles. If a device on a TDMA wireless network falls out of range or becomes blocked, the rest of the network carries on without missing a step.

Practical TDMA networks are not quite as fault tolerant as the idealized vision of TDMA previously described. Real TDMA networks do depend on some “master” device to assign new time slots and also to maintain synchronization of all device clocks so that they do not “lose their place” in the schedule. If this master device fails, the TDMA network will lose the ability to accept new devices and will (eventually) lose synchronization.

In light of this fact, it might appear at first that TDMA is no better than master-slave arbitration, since both ultimately depend on one master device to manage communication between all other devices. However, TDMA does offer one significant benefit over master-slave, and that is more efficient use of time. In a master-slave network, the master must poll each and every device on the network to check if it has data to transmit. This polling requires additional network time beyond that required by the “slave” devices to report their data. In a TDMA network, the master device need only occupy time transmitting to the network when updating time-slot assignments and when broadcasting time synchronization messages. You can think of TDMA as being a “smarter” version of master-slave arbitration, where the devices need only be told once when they may transmit, rather than having to be told every single time when they may transmit.

## CSMA

A completely different method of channel arbitration is where any and all devices have permission to transmit when the network is silent. This is generally called *CSMA*, or “Carrier Sense Multiple Access.” There are no dedicated master and slave devices with CSMA, nor are devices permitted to transmit in a pre-determined order as with token-passing or in a pre-determined schedule as with TDMA. *Any* device on a CSMA network may “talk” in any order and at any time whenever the network is free. This is analogous to an informal conversation between peers, where anyone is permitted to break the silence.

Of course, such an egalitarian form of channel arbitration invites instances where two or more devices begin communicating simultaneously. This is called a *collision*, and must be addressed in some manner in order for any CSMA network to be practical.

Multiple methods exist to overcome this problem. Perhaps the most popular in terms of number of installed networks is *CSMA/CD* (“Carrier Sense Multiple Access with Collision Detection”), the strategy used in Ethernet. With CSMA/CD, all devices are not only able to sense an idle channel, but are also able to sense when they have “collided” with another transmitting device. In the event of a collision, the colliding devices both cease transmission, and set random time-delays to wait before re-transmission. The individual time delays are randomized to decrease the probability that a re-collision between the same devices will occur after the wait. This strategy is analogous to several peers in one group holding a conversation, where all people involved are equally free to begin speaking, and equally deferential to their peers if ever two or more accidentally begin speaking at the same time. Occasional collisions are normal in a CSMA/CD network, and should not be taken as an indication of trouble unless their frequency becomes severe.

A different method of addressing collisions is to pre-assign to each device on the network a priority number, which determines the order of re-transmission following a collision. This is called *CSMA/BA*, or “Carrier Sense Multiple Access with Bitwise Arbitration,” and it is analogous to several people of different social levels in one group holding a conversation. All are free to speak when the room is silent, but if two or more people accidentally begin speaking at the same time, the person of highest “rank” is allowed to continue while the “lower-rank” person(s) must wait. This is the strategy used in DeviceNet, an industrial network based on CAN technology, one of the more popular data networks used in automotive engine control systems.

Some CSMA networks lack the luxury of collision detection, and must therefore strive to prevent collisions rather than gracefully recover from them. Wireless digital networks are an example where collision detection is not an option, since a wireless (radio) device having a single antenna and a single channel cannot “hear” any other devices’ transmissions while it is transmitting, and therefore cannot detect a collision if one were to occur. A way to avoid collisions for such devices is to pre-assign each device on the network with a priority number, which determines how long each device is forced to wait after detecting a “quiet” network before it is allowed to transmit a new message. So long as no two devices on the network have the same “wait” time, there will be no collisions. This strategy is called *CSMA/CA*, or “Carrier Sense Multiple Access with Collision Avoidance,” and is the technique used for WLAN networks (the IEEE 802.11 specification). A consequence of collision avoidance, though, is unequal access to the network. Those devices with higher-priority (shorter wait times) will always have an advantage in transmitting their data over devices of lower priority. The degree of disparity in network access grows as more devices occupy the network. CSMA/CA is analogous to a group of shy people talking, each person afraid to speak at the same time as another,

and so each person waits a different amount of time following the conclusion of the last utterance before daring to speak. This sort of ultra-polite behavior may ensure no one accidentally interrupts another, but it also means the shiest person will hardly ever get a chance to speak.

One characteristic distinguishing all CSMA networks from master-slave, token-passing, and TDMA networks is a lack of *determinism*. “Determinism” is the ability to guarantee communication of a message within a specified maximum time. A master-slave or TDMA network following a repeating schedule guarantees that the time will not take longer than the period of the cycle. A token-passing network following a definite order guarantees that the time will not take longer than the number of devices times the maximum time each device may hold the token. A CSMA network, at least hypothetically, can prevent any device from transmitting its message if it keeps being blocked by other devices transmitting (the one highest-priority device in a CSMA/BA or CSMA/CA network being an exception of course). Determinism is important in industrial control systems where communication delays may adversely affect the stability of a control loop, and it is especially important in safety control systems where fast action is needed to avert catastrophe.

A potential problem in any digital network, but particularly networks employing CSMA arbitration, is something known as *jabbering*. If a network device happens to fail in such a way that it ceaselessly transmits a signal on the network, none of the other CSMA devices will ever be allowed to transmit because they continuously detect a “carrier” signal from the jabbering device<sup>36</sup>. Some Ethernet components sport *jabber latch* protection circuits designed to detect jabber and automatically cut off the offending device from the network, or employ “store-and-forward” buffering which is able to block jabbered data frames.

---

<sup>36</sup>I once encountered this very type of failure on the job, where a copper-to-fiber adapter on a personal computer’s Ethernet port jammed the entire network by constantly spewing a meaningless stream of data. Fortunately, indicator lights on all the channels of the communications equipment clearly showed where the offending device was on the network, allowing us to take it out of service for replacement.

### 15.5.6 The OSI Reference Model

Digital data communication may be described in many ways. For example, a connection formed between two computers to exchange a text document is a multi-layered activity, involving many steps to convert human language into electrical impulses for transmission, then re-convert those electrical impulses into human language again at the receiving end. Not surprisingly, there usually exist many different ways to perform this same task: different types of networks, different encodings, different communications and presentation software, etc.

To illustrate by analogy, think of all the actions and components necessary to transport items using an automobile. In order to move furniture from an apartment to a house, for example, you would require the following:

- An appropriate vehicle
- Addresses or directions for both locations
- A driver's license and knowledge of driving rules
- Fuel for the vehicle
- Knowledge of how to safely stack furniture for transport
- Knowledge of how the furniture is to be placed in the house

These details may seem trivial to mention, as human beings familiar with the common task of moving personal belongings from one location to another, but imagine having to describe every single action and component to someone from a primitive culture ignorant of vehicles, addresses, maps, driver's licenses, fuel, etc. One way to help describe all this complexity would be to assign different people to different layers of detail. For example, an automotive engineer could discuss the details of how engines burn fuel to do mechanical work (propelling the vehicle) while a furniture loader could describe how furniture is to be loaded and taken off the vehicle. A driving instructor could then explain all the procedures of safely driving the vehicle, while a city planner could explain the organization of streets and addresses in relation to a city map. Finally, an interior decorator could wax eloquent on the proper placement of furniture in the house. Each person would be describing a different aspect of the furniture move, each one of those aspects being important to the overall goal of moving furniture from one location to another.

Moreover, for each one of the aspects described by a specialist, there may exist several different alternatives. For example, there are many different models and designs of vehicle one might use for the job, and there may be different driving rules depending on where the two locations are for the move. Addresses and directions will *certainly* vary from city to city, and even within one city there will be alternative routes between the two locations. Finally, there is virtually no end to arrangements for furniture at the destination house, each one with its own functional and esthetic merits.

By the same token, the task of transporting digital data may be divided into similar categories. In order to move and process data from one computer to another, you need the following:

- An appropriate cable (or radio link) connecting the two computers
- Standardized electrical signals to represent bit states
- Addresses for each computer on the network
- Algorithms specifying how each computer takes turns “talking” on the common network
- Algorithms specifying how to organize packets of data to be sent and received serially
- Software to format the data on the transmitting end and interpret the data on the receiving end

Each of these aspects is important to the overall goal of creating, moving, and interpreting digital data between two or more computers, and there are many alternative methods (standards) for each aspect. We may represent 0 and 1 bits using NRZ (Non-Return to Zero) encoding, Manchester encoding, FSK modulation, etc.; the signals may be electrical or they may be optical or they may even be radio waves; the options for electrical cables and connector types are many. Bits may be framed differently as they are packaged for transmission, and arbitration between devices on the network managed in a variety of different ways. How we address multiple devices on a network so messages get routed to their proper destinations is important as well.

A scheme originally intended as a formal standard, but now widely regarded as a general model to describe the portions of other standards, helps us clarify the complexity of digital communications by dividing communication functions into seven distinct “layers.” Developed by the *ISO* (International Organization for Standards)<sup>37</sup> in 1983, the *OSI Reference Model* divides communication functions into the following categories, shown in this table with examples:

<b>Layer 7 Application</b>	This is where digital data takes on practical meaning in the context of some human or overall system function. <i>Examples: HTTP, FTP, HART, Modbus</i>
<b>Layer 6 Presentation</b>	This is where data gets converted between different formats. <i>Examples: ASCII, EBCDIC, MPEG, JPG, MP3</i>
<b>Layer 5 Session</b>	This is where "conversations" between digital devices are opened, closed, and otherwise managed for reliable data flow. <i>Examples: Sockets, NetBIOS</i>
<b>Layer 4 Transport</b>	This is where complete data transfer is handled, ensuring all data gets put together and error-checked before use. <i>Examples: TCP, UDP</i>
<b>Layer 3 Network</b>	This is where the system determines network-wide addresses, ensuring a means for data to get from one node to another. <i>Examples: IP, ARP</i>
<b>Layer 2 Data link</b>	This is where basic data transfer methods and sequences (frames) are defined within the smallest segment(s) of a network. <i>Examples: CSMA/CD, Token passing, Master/Slave</i>
<b>Layer 1 Physical</b>	This is where data bits are equated to electrical, optical, or other signals. Other physical details such as cable and connector types are also specified here. <i>Examples: EIA/TIA-232, 422, 485, Bell 202</i>

The vast majority of digital networking standards in existence address mere portions of the 7-layer model. Any one of the various Ethernet standards, for example, applies to layers 1 and 2, but none of the higher-level layers. In other words, Ethernet is a means of encoding digital information in electronic form and packaging that data in a standard format understandable to other Ethernet devices, but it provides no functionality beyond that. Ethernet does *not* specify how data will be routed over large-area networks, how to manage data-exchange sessions between computers (opening connections, initiating data transfer, closing connections), or how to format the data to represent real-world variables and media. Common industrial network standards such as EIA/TIA-232 and EIA/TIA-485 don’t even go that far, being limited mostly to layer 1 concerns (signal voltage levels, wiring, and in some cases types of electrical connectors). For example, EIA/TIA-485 does not specify

<sup>37</sup>If you are thinking the acronym should be “IOS” instead of “ISO,” you are thinking in terms of English. “ISO” is a non-English acronym!

how to address multiple devices connected to a common electrical network – all it does is specify what voltage levels represent “0” and “1” bits.

By contrast, some other industrial networking standards specify nothing about lower-level layers, instead focusing on high-level concerns. Modbus, for example, is concerned only with layer 7, and not with any of the lower-level layers<sup>38</sup>. This means if two or more industrial devices on a network (such as programmable logic controllers, or PLCs) use “Modbus” to communicate with each other, it refers only to the high-level programming codes designed to poll and interpret data within those devices. The actual cable connections, electrical signals, and communication techniques used in that “Modbus” network may vary widely. Anything from EIA/TIA-232 to Ethernet to a wireless network such as WLAN may be used to actually communicate the high-level Modbus instructions between PLCs.

Due to the fact that most industrial instrumentation networks span limited physical distances and require low latency (short time delays) in order to exchange process-critical data between devices, the most common layers of the OSI model seen in industrial networks are layers 1, 2, and 7. The middle layers become important when data leaves the plant site and must be routed along major communications networks such as the Internet. Inside an industrial facility, however, the networks must merely encode the data in some physical media (layer 1), package and address the data so it makes it to the appropriate device(s) (layer 2), and give that data contextual meaning (layer 7).

The following sections explore some common networking standards used for industrial instrumentation systems. The OSI Reference Model will be mentioned where appropriate.

## 15.6 EIA/TIA-232, 422, and 485 networks

Some of the simplest types of digital communication networks found in industry are defined by the EIA (Electronic Industry Alliance) and TIA (Telecommunications Industry Alliance) groups, under the numerical labels 232, 422, and 485. This section discusses these three network types.

---

<sup>38</sup>It should be noted here that some network standards incorporating the name “Modbus” actually do specify lower-level concerns. *Modbus Plus* is a layer 2 standard, for example.

### 15.6.1 EIA/TIA-232

The EIA/TIA-232C standard, formerly<sup>39</sup> known as *RS-232*, is a standard defining details found at layer 1 of the OSI Reference Model (voltage signaling, connector types) and some details found at layer 2 of the OSI model (asynchronous transfer, “flow control” or “handshaking” signals between transmitting and receiving devices). In the early days of personal computers, almost every PC had either a 9-pin or a 25-pin connector (and sometimes multiple of each!) dedicated to this form of digital communication. For a while, it was *the* way peripheral devices such as keyboards, printers, modems, and mice connected to personal computers. USB (Universal Serial Bus) has now all but replaced EIA/TIA-232 for personal computers, but it still lives on in the world of industrial devices.

EIA/TIA-232 networks are point-to-point, intended to connect only two devices<sup>40</sup>. The signaling is *single-ended* (also known as *unbalanced*), which means the respective voltage pulses are referenced to a common “ground” conductor, a single conductor used to transfer data in each direction:

EIA/TIA-232 specifies positive and negative voltages (with respect to the common ground conductor) for its NRZ signaling: any signal more negative than  $-3$  volts detected at the receiver is considered a “mark” (1) and any signal more positive than  $+3$  volts detected at the receiver is considered a “space” (0). EIA/TIA-232 transmitters are supposed to generate  $-5$  and  $+5$  volt signals (minimum amplitude) to ensure at least 2 volts of noise margin between transmitter and receiver. The voltage limits and NRZ encoding of EIA/TIA-232 comprise the OSI layer 1 elements of the standard.

<sup>39</sup>The designation of “RS-232” has been used for so many years that it still persists in modern writing and manufacturers’ documentation, despite the official status of the EIA/TIA label. The same is true for EIA/TIA-422 and EIA/TIA-485, which were formerly known as RS-422 and RS-485, respectively.

<sup>40</sup>“Daisy-chain” networks formed of more than two devices communicating via EIA/TIA-232 signals have been built, but they are rarely encountered, especially in industrial control applications.

Cable connectors are also specified in the EIA/TIA-232 standard, the most common being the DE-9<sup>41</sup> (nine-pin) connector. The “pinout” of a DE-9 connector for any *DTE* (Data Terminal Equipment) device at the end of an EIA/TIA-232 cable is shown here:

DE-9 cable connector

Pin number	Assignment	Abbreviation
1	Carrier Detect	CD
<b>2</b>	<b>Received Data</b>	<b>RD</b>
<b>3</b>	<b>Transmitted Data</b>	<b>TD</b>
4	Data Terminal Ready	DTR
<b>5</b>	<b>Signal Ground</b>	<b>Gnd</b>
6	Data Set Ready	DSR
7	Request To Send	RTS
8	Clear To Send	CTS
9	Ring Indicator	RI

Those terminals highlighted in **bold** font represent those connections absolutely essential for any EIA/TIA-232 link to function. The other terminals carry optional “handshaking” (“flow control”) signals<sup>42</sup> specified for the purpose of coordinating data transactions (these are the OSI layer 2 elements of the EIA/TIA-232 standard).

For *DCE* (Data Communications Equipment<sup>43</sup>) devices such as modems, which extend the EIA/TIA-232 signal path onward to other devices, the assignments of transmitting and receiving pins are swapped. For example, pin 2 is the Transmitted Data (TD) output while pin 3 is the Received Data (RD) input on a DCE device. This allows straight pin-to-pin cable connections between the DTE and DCE devices, so the transmit pin of the DTE device connects to the receive pin of the DCE, and vice-versa.

<sup>41</sup>Often (incorrectly) called a “DB-9” connector.

<sup>42</sup>The way hardware-based flow control works in the EIA/TIA-232 standard involves two lines labeled RTS (“Request To Send”) and CTS (“Clear To Send”) connecting the two devices together on a point-to-point serial network in addition to the TD (“Transmitted Data”) and RD (“Received Data”) and signal ground lines. Like the TD and RD terminals which must be “crossed over” between devices such that the TD of one device connects to the RD of the other device and vice-versa, the RTS and CTS terminals of the two devices must be similarly crossed. The RTS is an output line while the CTS is an input, on both devices. When a device is able to receive data, it activates its RTS output line to *request* data. A device is not permitted to transmit data on its TD line until it is *cleared* to send data by an active state on its CTS input line.

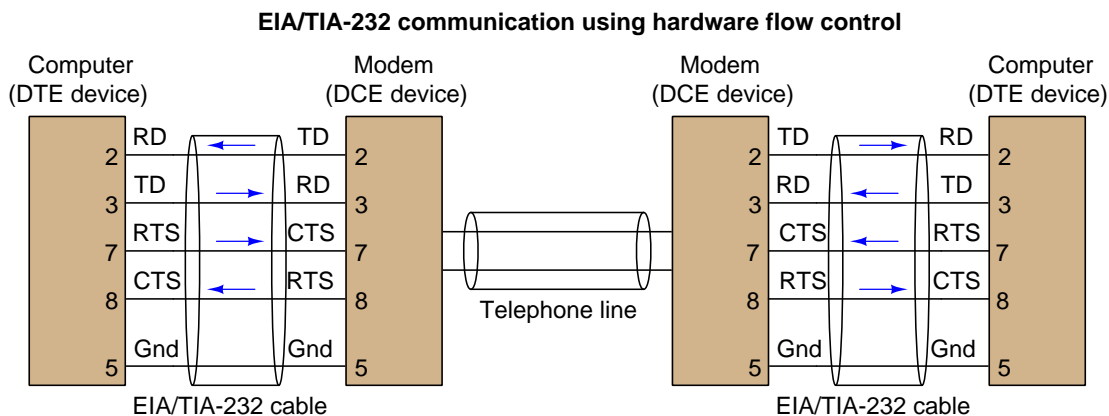

<sup>43</sup>Also known by the unwieldy acronym *DCTE* (Data Circuit Terminating Equipment). Just think of “DTE” devices as being at the very end (“terminal”) of the line, whereas “DCE” devices are somewhere in the middle, helping to exchange serial data between DTE devices.

The following diagram shows the minimum cable requirements for an EIA/TIA-232 serial communication link consisting of a pair of DTEs connecting through a pair of DCEs. This minimal point-to-point network assumes the devices are configured for either *software* flow control (i.e. digital codes send over the TD/RD lines requesting the transmitting device to halt and resume) or no flow control at all:

In order to utilize hardware flow control, the EIA/TIA-232 cable(s) must include two additional conductors connecting the RTS and CTS pins between devices to enable them to signal each other with voltage-level states declaring when they are ready to receive more data:

Improper flow control configuration is a common commissioning problem in new serial networks. If the devices are configured for hardware handshaking (i.e. necessitating RTS and CTS lines in the connecting cables) or those devices simply default to hardware handshaking as new, but cables lacking RTS-to-CTS lines are used between these devices, the devices will never communicate because their respective (floating) CTS inputs will remain in the idle state and therefore the devices “think” they do not have permission to send data. *Hardware flow control necessitates serial cables with at least five conductors, while software flow control needs only three (TD, RD, and Ground).*

If one desires to directly connect two DTE devices together using EIA/TIA-232, a special cable called a *null modem* must be used, which swaps the connections between pins 2 and 3 of each device. A “null modem” connection is necessary for the transmit pin of each DTE device to connect to the receive pin of the other DTE device:

The concept of a “null modem” is not unique to EIA/TIA-232 circuits<sup>44</sup>. Any communications standard where the devices have separate “transmit” and “receive” channels will require a “null modem” connection with transmit and receive channels swapped to be able to communicate directly without the benefit of interconnecting DCE devices. Four-wire EIA/TIA-485 and Ethernet over twisted-pair wiring are two other examples of digital communication standards where a “null” style cable is required for two DTE devices to directly connect.

EIA/TIA-232 networks may be simple, but they tend to be rather limited both in data bit rate and distance, those two parameters being inversely related. References to the EIA/TIA-232 standard repeatedly cite a maximum data rate of 19.2 kbps at 50 feet cable rate. Experimental tests<sup>45</sup> suggest greater rate/distance combinations may be possible in optimum conditions (low cable capacitance, minimum noise, good grounding). Since EIA/TIA-232 was developed to connect peripheral devices to computers (typically within the physical span of one room), and at modest speeds, neither of these limitations were significant to its intended application.

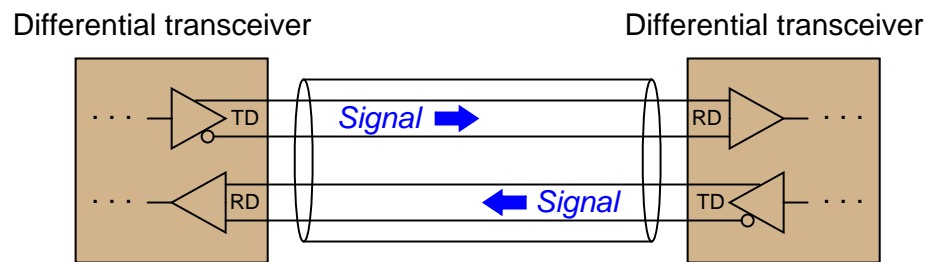

<sup>44</sup>In fact, the concept is not unique to digital systems at all. Try talking to someone using a telephone handset held upside-down, with the speaker near your mouth and the microphone near your ear, and you will immediately understand the necessity of having “transmit” and “receive” channels swapped from one end of a network to the other!

<sup>45</sup>Once I experimented with the fastest data rate I could “push” an EIA/TIA-232 network to, using a “flat” (untwisted, unshielded pair) cable less than ten feet long, and it was 192 kbps with occasional data corruptions. Park, Mackay, and Wright, in their book *Practical Data Communications for Instrumentation and Control* document cable lengths as long as 20 meters at 115 kbps for EIA/TIA-232, and 50 meters (over 150 feet!) at 19.2 kbps: over three times better than the advertised EIA/TIA-232 standard.

### 15.6.2 EIA/TIA-422 and EIA/TIA-485

The next two network standards<sup>46</sup> are less comprehensive than EIA/TIA-232, specifying only the electrical characteristics of signaling without any regard for connector types or any layer 2 (handshaking) considerations. Within these domains, the 422 and 485 standards differ significantly from 232, their designs intended to optimize both maximum cable length and maximum data rate.

To begin with, the electrical signaling used for both EIA/TIA-422 and EIA/TIA-485 is *differential* rather than single-ended (*balanced* rather than unbalanced). This means a dedicated *pair* of wires is used for each communications channel rather than a single wire whose voltage is referenced to a common ground point as is the case with EIA/TIA-232:

Using dedicated wire pairs instead of single conductors sharing a common ground means that EIA/TIA-422 and EIA/TIA-485 networks enjoy much greater immunity to induced noise than EIA/TIA-232. Noise induced via electrostatic coupling along the length of a network cable tends to be fairly equal (i.e. common-mode) on all non-grounded conductors of that cable, but since the receivers in EIA/TIA-422 and EIA/TIA-485 networks response only to differential voltages (not common-mode voltages), induced noise is ignored.

<sup>46</sup>Former labels for EIA/TIA-422 and EIA/TIA-485 were RS-422 and RS-485, respectively. These older labels persist even today, to the extent that some people will not recognize what you are referring to if you say “EIA/TIA-422” or “EIA/TIA-485.”

The advantage differential signaling enjoys over single-ended signaling may be understood by graphical comparison. The first illustration shows how electrical noise imposed on the ungrounded conductor of a simplex communications cable becomes superimposed on the digital data signal, detected at the receiving end. Noise is modeled here as a voltage source in series along the ungrounded conductor, near the receiving end. In reality, it is more likely to be distributed along the bulk of the cable length:

If the superimposed noise voltage detected at the receiver has sufficient peak-to-peak amplitude to push the signal voltage above or below critical threshold levels, the receiver will interpret this as a change of digital state and cause corruptions in the data stream.

By contrast, any noise superimposed on ungrounded conductors in a differential signaling circuit cancel at the receiver, because the close proximity of those two conductors ensures any induced noise will be the same. Since the receiver responds only to *differential* voltage between its two inputs, this common-mode noise cancels, revealing a “clean” data signal at the end:

Both EIA/TIA-422 and EIA/TIA-485 systems use differential signaling, allowing them to operate over much longer cable lengths at much greater cable speeds than EIA/TIA-232 which is single-ended. Other high-speed network standards including Ethernet and USB (Universal Serial Bus) use differential signaling as well.

EIA/TIA-422 is a *simplex* (one-way) communications standard, whereas EIA/TIA-485 is a *duplex* (two-way) standard. Both support more than two devices on a network segment. With EIA/TIA-422, this means one transmitter and multiple receivers. With EIA/TIA-485, this may include multiple *transceivers* (devices capable of both transmitting and receiving at different times: half-duplex). Four wires are necessary to connect two such devices when full-duplex (simultaneous two-way communication) is required, and full-duplex is only practical between two devices (as shown in the previous illustration).

EIA/TIA-422 and EIA/TIA-485 specify positive and negative voltage differences (measured between each dedicated wire pair) for its signaling, both for transmitting devices as well as receiving devices. A receiver must recognize any signal more negative than  $-200$  millivolts as a “mark” (1) and any signal more positive than  $+200$  millivolts as a “space” (0). These voltage thresholds are much lower than those specified for EIA/TIA-232 ( $\pm 3$  volts) due to the relative lack of noise on differential signal lines compared to ground-referenced signal lines. Simply put, less noise voltage on the lines means the signal doesn’t have to be as strong to “swamp” that noise and be reliably detected at the receiver. EIA/TIA-422 transmitters (“drivers”) are supposed to generate  $-2$  and  $+2$  volt signals (minimum amplitude) to ensure at least  $1.8$  volts of noise margin between transmitter and receiver. EIA/TIA-485 drivers are allowed a smaller noise margin, with the minimum signal levels being  $-1.5$  volts and  $+1.5$  volts.

The maximum recommended cable length for both EIA/TIA-422 and EIA/TIA-485 networks is  $1200$  meters, which is greater than half a mile<sup>47</sup>. The maximum data rate is inversely dependent on cable length (just as it is for EIA/TIA-232), but substantially greater owing to the noise immunity of differential signaling. With the long cable lengths and higher data rates made possible by differential signaling, some applications may require *terminating resistors* to eliminate reflected signals. Experiments conducted by Texas Instruments demonstrate acceptable signal integrity at  $200$  kbps over a cable  $100$  feet long with no termination resistors. With a termination resistor at the receiver input (for simplex data transmission) in place on the same  $100$  foot cable, a data rate of  $1$  Mbps was achieved.

---

<sup>47</sup> $1200$  meters is the figure commonly cited in technical literature. However, Park, Mackay, and Wright, in their book *Practical Data Communications for Instrumentation and Control* document EIA/TIA-422 and EIA/TIA-485 networks operating with cable lengths up to  $5$  km (over  $16000$  feet!) at data rates of  $1200$  bps. Undoubtedly, such systems were installed with care, using high-quality cable and good wiring practices to minimize cable capacitance and noise.

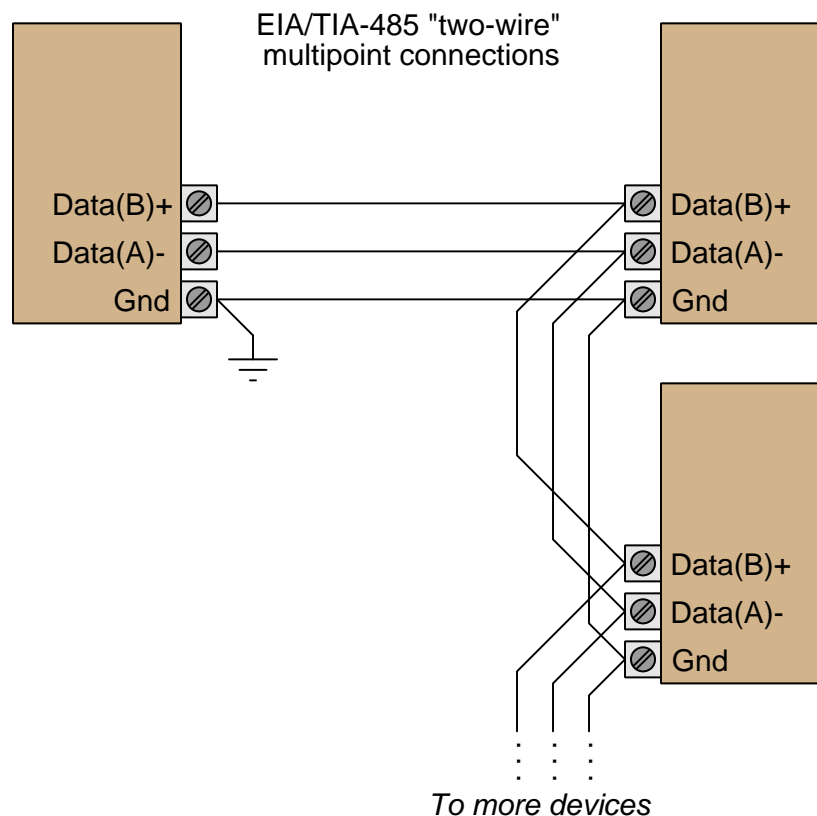

Due to the lack of standardization for cable connectors in EIA/TIA-422 and EIA/TIA-485 networks, there are no established pin numbers or labels for the differential transmit and receive conductors. A common convention seen in industrial devices, though, are the labels “A” and “B”, alternative labeled “−” and “+” or “A−” and “B+” in honor of their idle-state polarities (the “mark” or “1” state). In a 4-wire EIA/TIA-485 network, where full-duplex operation is possible, the terminals and connections will look something like this:

The good news with regard to 422/485 terminal labeling is that you will not harm the electronics by accidentally connecting the wires with incorrect polarity. If, for example, you cannot get a 422/485 receiver to acknowledge data sent by a 422/485 transmitter, you may try swapping the polarity (A/B, or +/− connections) without risking harm to the device and see if that fixes the problem.

Note the use of a ground conductor connecting both devices together. Even though the data signaling is differential and therefore does not theoretically require a common ground connection (since common-mode voltage is ignored), a ground connection helps ensure the common-mode voltage does not become excessive, since *real* receiver circuits have practical limits on the amount of common-mode voltage they can tolerate.

A popular connection scheme for EIA/TIA-485 half-duplex operation is where the Transmitted Data (TD) and Received Data (RD) terminal pairs are combined, so that two-way communication may occur over one pair of wires. With such devices, it is customary to label the terminals simply as “Data” (A– and B+):

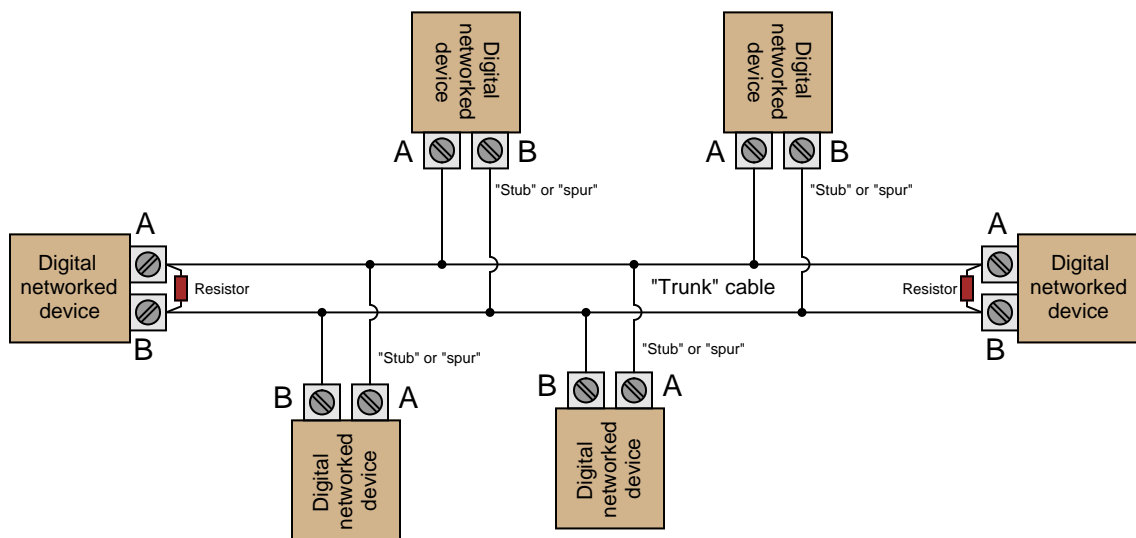

The possibility of half-duplex operation raises the question of channel arbitration and device addressing, but since the EIA/TIA-485 standard does not specify anything outside of layer 1 concerns, these matters are left to other networking standards to fulfill. In other words, EIA/TIA-485 is not a complete data communications standard, but merely serves as the layer 1 component of other standards such as Allen-Bradley's *Data Highway* (DH), Opto 22's *Optomux*, and others.

Given the potential for high-speed communication along lengthy runs of cable using EIA/TIA-422 or EIA/TIA-485, the potential necessity of terminating resistors to prevent signal “reflection” is very real. Networks operating with short cables, and/or slow data rates, may work just fine without termination resistors<sup>48</sup>. However, the effects of reflected signals grows more pronounced as the reflection time (time-of-flight for the signal to travel “round-trip” from one end of the cable to the other and back) approaches a substantial fraction of the bit time.

<sup>48</sup>In fact, a great many EIA/TIA-485 networks in industry operate “unterminated” with no problems at all.

No network should have more than two termination resistors, one at each (far) end, and care should be taken to limit the lengths of all cable “stubs” or “spurs” branching off of the main “trunk” cable:

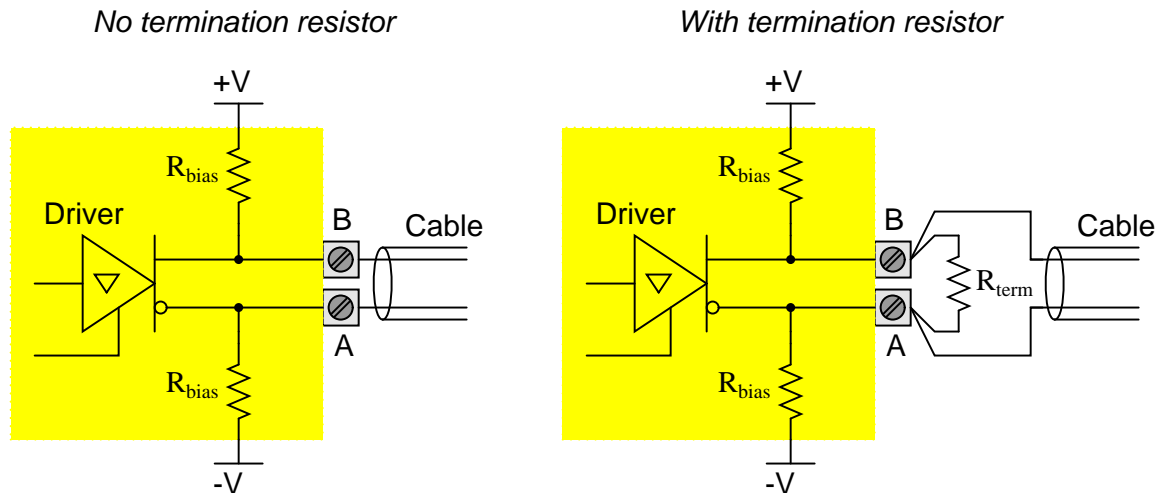

The proper value for these resistors, of course, is equality with the characteristic impedance<sup>49</sup> of the cable itself. A termination resistor value greater than the cable’s surge impedance will still allow positive reflections of limited amplitude, while a termination resistor value less than the cable’s surge impedance will still allow negative reflections of limited amplitude.

However, the inclusion of resistive loads to an EIA/TIA-422 or EIA/TIA-485 network may cause other problems. Many devices use a pair of internal *biasing resistors* to establish the “mark” state necessary for idle conditions, connecting the “A” terminal to the negative supply voltage rail through a resistor and the “B” terminal to the positive supply voltage rail through another resistor. Connecting a terminating resistor between terminals “A” and “B” will alter the voltage levels normally provided by these biasing resistors, consequently causing problems.

<sup>49</sup>For detailed explanation of how and why this is necessary, refer to section 5.10 beginning on page 475.

The following schematic diagram shows the equivalent circuit of an EIA/TIA-485 transceiver device, with and without a terminating resistor connected:

When the driver is in high-impedance (High-Z) mode, the “idle” state of the wire pair will be established by the bias resistors (equal to the supply voltage so long as there is no loading). However, a terminating resistor will act as a DC load to this biasing network, causing a substantial reduction of the “idle” state voltage toward 0 volts. Recall that  $-200$  millivolts was the receiving threshold value for a “mark” state in both EIA/TIA-422 and EIA/TIA-485 standards (terminal “A” negative and terminal “B” positive). If the presence of a terminating resistor<sup>50</sup> reduces the idle state voltage to less than 200 millivolts absolute, the receiver(s) will not be able to reliably read the network’s idle state and communication errors will result.

Thus, we see that the inclusion of any terminating resistors must be accompanied by an analysis of the devices’ bias resistor networks if we are to ensure robust network operation. It is foolhardy to simply attach terminating resistors to an EIA/TIA-422 or EIA/TIA-485 network without considering their combined effect on biasing.

<sup>50</sup>Actually *two* terminating resistors in parallel, since one will be at each end of the cable! The actual DC biasing network will be more complicated as well if more than one device has its own set of internal bias resistors.

## 15.7 Ethernet networks

An engineer named Bob Metcalfe conceived the idea of Ethernet in 1973, while working for the Xerox research center in Palo Alto, California. His fundamental invention was the CSMA/CD method of channel arbitration, allowing multiple devices to share a common channel of communication while recovering gracefully from inevitable “collisions.” In Metcalfe’s vision, all of the “network intelligence” would be built directly into “controller” devices situated between the DTE devices (computers, terminals, printers, etc.) and a completely passive coaxial cable network. Unlike some other networks in operation at the time, Metcalfe’s did not rely on additional devices to help coordinate communications between DTE devices. The coaxial cable linking DTE devices together would be completely passive and “dumb,” performing no task but the conduction of broadcast signals between all devices. In that sense, it served the same purpose as the “luminiferous ether” once believed to fill empty space: conducting electromagnetic waves between separated points.

The CSMA/CD (“Carrier Sense Multiple Access with Collision Detection”) method of bus arbitration works by giving each Ethernet device the ability to sense an idle channel as well as sense if it happens to “collide” with another transmitting device. In the event of a collision, the colliding devices both cease transmission, and set random time-delays to wait before re-transmission. The individual time delays are randomized to decrease the probability that a re-collision between the same devices will occur after the wait. This strategy is analogous to several peers in one group holding a conversation, where all people involved are equally free to begin speaking, and equally deferential to their peers if ever two or more accidentally begin speaking at the same time. Occasional collisions are perfectly normal in an Ethernet network, and should not be taken as an indication of trouble unless their frequency becomes severe.

Metcalfe’s original network design operated at a data rate of 2.94 Mbps, impressive for its time. By 1980, the three American computer companies DEC (Digital Equipment Corporation), Intel, and Xerox had collaborated to revise the Ethernet design to a speed of 10 Mbps, and released a standard called the *DIX Ethernet* standard (the acronym “DIX” representing the first letter of each company’s name). Later, the IEEE Local and Metropolitan Networks Standards Committee codified the DIX Ethernet standard under the numeric label 802.3. At the present time there exist many “supplemental” standards underneath the basic 802.3 definition, a few of them listed here:

- 802.3a-1985 *10BASE2 “thin” Ethernet*
- 802.3d-1987 *FOIRL fiber-optic link*
- 802.3i-1990 *10BASE-T twisted-pair cable Ethernet*
- 802.3u-1995 *100BASE-T “Fast” Ethernet and Auto-Negotiation*
- 802.3x-1997 *Full-Duplex standard*
- 802.3ab-1999 *1000BASE-T “Gigabit” Ethernet over twisted-pair cable*

The IEEE 802.3 standard is limited to layers 1 and 2 of the OSI Reference Model: the “Physical” and “Data link” layers. In the physical layer (1), the various supplements describe all the different ways in which bits are electrically or optically represented, as well as permissible cable and connector types. In the data link layer (2), the IEEE standard describes how devices are addressed (each one with a unique identifier known as a *MAC address*, consisting of a 48-bit binary number usually

divided into six bytes, each byte written as a two-character hexadecimal number), the CSMA/CD channel arbitration protocol, and also how data frames are organized for Ethernet transmissions.

### 15.7.1 Repeaters (hubs)

Bob Metcalfe's original design for Ethernet consisted of DTE devices connected to a common coaxial cable through the use of "tee" connectors, like this:

This cabling arrangement suffered several problems. First, it was inconvenient to run through an office building, since each DTE device needed to be coupled rather closely to the main "trunk." Short cable segments (called *stubs*, *spurs*, or *drops*) joining the main trunk line to each DTE device could not be too long, or else they would cause multiple signal reflections to occur in the main line. Secondly, the signal strength decreased with each "tee" connector: every time the signal branched, it would lose power. Thirdly, the need for termination resistors at the far ends of the "ether" cable opened up the possibility that those terminators might fail, fall off, or be forgotten during installation or maintenance<sup>51</sup>.

<sup>51</sup>These very same problems may arise in FOUNDATION Fieldbus networks, for the exact same reason: the cabling is passive (for increased reliability). This makes FOUNDATION Fieldbus instrument systems challenging to properly install for most applications (except in really simple cases where the cable route is straightforward), which in my mind is its single greatest weakness at the time of this writing (2009). I strongly suspect Ethernet's history will repeat itself in FOUNDATION Fieldbus at some later date: a system of reliable "hub" devices will be introduced so that these problems may be averted, and installations made much simpler.

As Ethernet evolved as a practical networking standard, one of the many improvements added to its design was the concept of a *repeating hub*. A “repeater” is an active device designed to re-broadcast a signal, usually to overcome inevitable power losses incurred as that signal propagates along a cable. Repeaters are common in the telecommunications industry, where telephone, television, and computer signals must travel hundreds or thousands of miles between points of transmission and reception. A “repeating hub” is a repeater with multiple ports for many cables to plug into, where any signal entering on any cable is repeated to *all* ports on the device. Thus, a repeating hub (or simply “hub”) allows multiple Ethernet devices to interconnect with no degradation in signal quality:

Not only do hubs improve system performance by boosting signals' voltage levels, but they also eliminate the need for termination resistors in the network. With a hub-based system, each and every cable terminates at either a DTE or DCE device, which is (now) designed with the proper termination resistance built-in to their internal transceiver circuitry. This means each and every Ethernet cable is automatically terminated with the proper impedance simply by plugging it in to the Ethernet port of *any* device. “Stub” or “spur” cables with their length restrictions are also a thing of the past, since no cable ever splits or branches in a hub-based network system.

Hubs are considered “layer 1” devices, because they operate purely on the physical layer of Ethernet: all they do is receive Ethernet signals and re-broadcast those signals in boosted form to all other devices plugged into the hub. As a piece of interconnecting hardware, a hub is considered a DCE (Data Communications Equipment), as opposed to the end-of-cable devices such as computers and printers which are DTEs (Data Terminal Equipment).

Repeating hubs may be connected together to form larger networks<sup>52</sup>:

Since hubs are merely “layer 1” devices, mindlessly boosting and re-broadcasting signals received to their ports, their presence does not mitigate collisions between transmitting devices. As far as collisions between those devices is concerned, they might as well be directly connected together on a single piece of coaxial cable. One way to express this concept is to say that all portions of the network are part of the same *collision domain*. In other words, any devices on this network are able to collide with each other, because all transmissions are sensed by all the devices. This is analogous to a small room with several people in it: the room is small enough that everyone can hear everyone else talking, which means only one person in that room is able to speak at a time.

---

<sup>52</sup>There are practical limits as to how many hubs may be “daisy-chained” together in this manner, just as there are practical limits to how long a twisted-pair cable may be (up to 100 meters). If too many hubs are cascaded, the inevitable time delays caused by the process of repeating those electrical impulses will cause problems in the network. Also, I have neglected to specify the use of *crossover* cables to connect hubs to other hubs – this is a topic to be covered later in this book!

### 15.7.2 Ethernet cabling

Along with hubs came another form of Ethernet cable and connector: *unshielded, twisted pair* (UTP) wiring and *RJ-45* “flat” connectors. These cables use multiple twisted pairs of wires instead of the coaxial cable specified in Metcalfe’s original Ethernet. The purpose of using twisted-wire pairs is to reduce magnetic signal coupling (for more information, refer to section 8.3.6 beginning on page 625).

For 10 Mbps Ethernet over UTP cable (called 10BASE-T) and for 100 Mbps Ethernet (called 100BASE-TX), only two<sup>53</sup> out of four available wire pairs are used:

Pin number	Assignment	Abbreviation
1	Transmit Data (+)	TD+
2	Transmit Data (–)	TD–
3	Receive Data (+)	RD+
4	(not used)	
5	(not used)	
6	Receive Data (–)	RD–
7	(not used)	
8	(not used)	

It should be noted that 1000 Mbps (“Gigabit”) Ethernet over twisted-wire pairs does in fact use all four pairs in an eight-wire cable, a departure from traditional UTP Ethernet cable wiring:

Pin number	Assignment	Abbreviation
1	Pair “A” (+)	BLDA+
2	Pair “A” (–)	BLDA–
3	Pair “B” (+)	BLDB+
4	Pair “C” (+)	BLDC+
5	Pair “C” (–)	BLDC–
6	Pair “B” (–)	BLDB–
7	Pair “D” (+)	BLDD+
8	Pair “D” (–)	BLDD–

<sup>53</sup>With only half the available wire pairs used in a standard 10 Mbps or 100 Mbps Ethernet cable, this opens the possibility of routing *two* Ethernet channels over a single four-pair UTP cable and RJ-45 connector. Although this is non-standard wiring, it may be a useful way to “squeeze” more use out of existing cables in certain applications. In fact, “splitter” devices are sold to allow two RJ-45-tipped cables to be plugged into a single RJ-45 socket such that one four-pair cable will then support two Ethernet pathways.

Along with UTP cables and RJ-45 connectors came a significant alteration to the basic electrical scheme of Ethernet. Metcalfe's original design used a simple coaxial cable as the "ether" connecting devices together. Such cables had only two conductors, meaning each device needed to transmit *and* receive data over the same two conductors. With UTP cable's four pairs of conductors, transmission and reception of signals occurs over different wire pairs<sup>54</sup>. This means connections made between Ethernet devices must employ a "swap" between TD and RD wire pairs in order for communication to take place, so that the "receiver" circuitry of one device connects to the "transmitter" circuitry of the other, and vice-versa. This is precisely the same characteristic inherent to EIA/TIA-232 and four-wire EIA/TIA-485 networks, where separate wire pairs are dedicated to "transmit" and "receive" functions.

In a typical Ethernet system, the interconnecting hubs perform this transmit/receive swap. Hubs are considered DCE devices, while computers and other end-of-the-line devices are considered DTE devices. This means the pin assignments of DTE and DCE devices must be different in order to ensure the transmit/receive pin swap necessary for straight-through cables to work. This also means if someone ever wishes to directly connect two Ethernet DTE devices together without the benefit of a hub in between, a special *crossover* cable must be used for the connection, identical in function to the *null modem* cable used to connect two EIA/TIA-232 DTE devices together:

<sup>54</sup>This means modern Ethernet is capable of full-duplex communication between two devices, whereas the original coaxial-based Ethernet was only capable of half-duplex communication.

Furthermore, the same problem exists when multiple hubs are connected to form larger networks. Since each hub is a DCE device, a straight-through cable connecting two hubs together will pass transmitted signals from one hub directly to the “transmit” pins of the other hub, not the “receive” pins as it needs to. Consequently, a “crossover” cable should be used to connect two Ethernet hubs together in order to avoid this problem:

Some early Ethernet hubs provided a different solution to the “crossover” problem, and that was a crossover *switch* built into the hub, allowing a person to manually switch the transmit and receive wire pairs with the push of a button. In this next photograph of a four-port Ethernet hub, you can see the “Normal/Uplink” pushbutton on the right-hand side of the front panel, controlling the furthest-right port of the hub. This switch is supposed to be placed in the “Normal” position if the device plugged into that port is a DTE device, and placed in the “Uplink” position if the device is a DCE device (e.g. another hub):

Note the LED indicator lights by each port on the hub. One LED indicates whether or not the cable is active (when a powered Ethernet DTE device is plugged into that port of the hub), while the other LED indicates traffic on the cable (by blinking). These LEDs are very helpful for identifying a crossover problem. This hub even has an LED indicating the occurrence of collisions (the “Col” LED just below the main power LED), giving simple visual indication of collision frequency.

Newer Ethernet DTE and DCE devices use auto-sensing technology to perform any necessary transmit/receive pin swaps, rendering crossover cables and crossover pushbuttons unnecessary for either DTE-to-DTE or hub-to-hub connections. Auto-sensing is a standard feature of 1000BASE-T (“Gigabit” Ethernet).

### 15.7.3 Switching hubs

The next evolutionary step in Ethernet network connections is the introduction of a *switching hub*, or simply *switch*. A “switch” looks exactly like a repeating hub, but it contains intelligence to route transmitted signals only to specific ports, rather than broadcasting every received data frame to all ports. What enables this to happen is the information contained in each Ethernet frame transmitted by DTE devices:

Note that part of the frame includes both a source address and a destination address. These refer to the 48-bit “MAC” addresses uniquely identifying each and every Ethernet device. A switching hub “learns” the identities of all devices plugged into each of its ports by remembering the “source” addresses received through those ports. When a switch receives an Ethernet frame with a destination address it recognizes as residing on one of its ports, it *only* repeats that frame to that specific port, and not to the other ports. In other words, an Ethernet switch does not mindlessly broadcast all messages to all of its ports the way an Ethernet hub does. The switch’s targeted direction of messages reduces the amount of “traffic” seen at the other ports, and also avoids unnecessary collisions because messages only get sent to their intended destinations.

If a switch receives a data frame with an unrecognized destination address, it defaults to basic “hub” behavior by broadcasting that frame to all ports. If a device plugged into one of that switch’s ports replies to that data frame, the MAC address of that device is noted for future traffic direction to that port.

The presence of a switching hub in a larger network has the effect of dividing that network into separate collision domains, so that a collision occurring in one domain does not “spill over” into another domain where it would delay communication between those devices:

Of course, collisions between these two domains may still occur, for instance if a device in the first domain tries to transmit to a device in the second domain at the exact same time that a device in the second domain attempts to transmit to a device in the first.

With this added intelligence, switching hubs are considered “layer 2” devices, since they operate not just at the physical layer of electrical impulses, but also at the next layer of device addressing. Since switching hubs add benefit beyond repeating hubs without any drawbacks<sup>55</sup>, most people elect to use switches whenever possible.

---

<sup>55</sup>Even the cost difference is negligible. It should be noted, though, that switches may exhibit unintended behavior if a cable is unplugged from one of the ports and re-plugged into a different port. Since switches internally map ports to device addresses, swapping a device from one port to another will “confuse” the switch until it re-initializes the port identities. Re-initialization may be forced by cycling power to the switch, if the switch does not do so on its own.

## 15.8 Internet Protocol (IP)

I remember first learning about the world-wide Internet, and wondering what it actually *looked like*. The first vision entering my mind when people told me about a computer network spanning nearly all of the United States and many other parts of the world was that of a thick cable strung along telephone poles and buried underground, with a big sign on it saying “Internet.” I also remember well the shock of learning that although the Internet made use of several high-capacity networks (called *backbones*) connecting large data centers in different cities, the real “magic” of the Internet did not reside in any particular cable or link. Instead, what made the Internet so widespread and accessible was actually a *protocol* allowing for the free exchange of data along and between disparate systems. This “protocol” allowed digital data to be packaged in such a way that it could be sent along nearly any kind of communications link (from copper wires to fiber-optic to radio waves) – and indeed along multiple pathways between the same two points – while arriving at the destination intact. Thus, the Internet was akin to a random patchwork of existing communications pathways pressed into coordinated service by the sharing of a common “language.” In this section, we will investigate the protocol at the heart of the Internet, appropriately called *Internet Protocol*, or *IP*.

Physical network standards such as Ethernet only define aspects relevant to lower layers of the OSI Reference Model. While these details are essential for communication to occur, they are not enough on their own to support a wide-spread communications system. For this reason, network standards such as EIA/TIA-485 and Ethernet almost always comprise the lower layer(s) of a more complex communications protocol capable of managing higher-order addresses, message integrity, “sessions” between computers, and a host of other details.

Internet Protocol (IP) manages network addresses and data handling over a much larger physical domain than Ethernet is able to. The basic principle of IP is that large digital messages may be broken down into smaller pieces, then each piece buffered with additional data bits to form *packets* specifying (among other things) how the pieces are to be directed to their proper destination(s). The completed packets are then transmitted individually and received individually, where they may be reassembled at the receiver to form the original message in its entirety. An analogy for this process is an author with a printed paper manuscript for a book, who needs to get her manuscript to a print shop across town. Unfortunately, the mail service in this town cannot transport the bulky manuscript in one piece, so the author divides the manuscript into 10-page bundles and mails each of these bundles in its own package to the print shop. The individual packages may not make it to the print shop on the same day, or even in the correct order, but the addressing on each package directs the postal service to deliver each of them to the proper location.

This strategy for transmitting large digital messages is at the heart of the Internet: data sent from one computer to another over the Internet is first broken down into packets, which are then routed over a variety of pathways to their destination. The packets need not take the same route to their destination, nor do they even need to travel along the same *kinds* of networks. The receiving computer must then reassemble those packets in the proper order to re-create the original data. This “packetization” of data allows multiple messages to be interleaved on a network (i.e. the network’s bandwidth being alternately used to convey pieces of completely different messages, rather than being reserved for one whole message at a time) as well as permitting alternate routes that the message may take in order to traverse large physical distances. In a web-shaped network where multiple pathways exist between any two points, the ability to direct packets of data along alternate routes increases the reliability of that network: failure of any one routing node or communications pathway does not necessarily prevent data from reaching its final destination. This fault tolerance

was one of the design criteria for what came to be the Internet when it was first developed by the United States' Department of Defense.

Interestingly, the task of portioning a large block of digital data into packet-sized pieces, and then re-assembling those pieces together in the proper order to form the original data block, is *not* the task of IP, but rather the task of some higher-level protocol such as TCP (Transmission Control Protocol). Internet Protocol (IP) merely specifies how the individual packets are to be marked and routed to their proper destination(s)<sup>56</sup>. To use the manuscript analogy again, IP is the postal service with its system of mailing addresses, postage stamps, and labeling conventions, while TCP (or some other higher-level protocol) is the author and publisher who divide the manuscript into smaller bundles and then reassemble those bundles into the original manuscript, respectively. For this reason, IP is not a complete solution for large-scale network communication on its own. This is why the Internet's central protocol is referred to as TCP/IP, the two protocols working together to ensure coordinated and reliable communication of packetized data over wide areas.

---

<sup>56</sup>When packets travel between different kinds of networks, the “gateway” devices at those transition points may need to *fragment* large IP packets into smaller IP packets and then re-assemble those fragments at the other end. This fragmentation and reassembly *is* a function of Internet Protocol, but it happens at the packet level. The task of portioning a large data block into packet-sized pieces at the very start and then reassembling those packets into a facsimile of the original data at the very end, however, is beyond the scope of IP.

### 15.8.1 IP addresses

IP is a “layer 3” technology, being concerned with network-wide addresses for routing information between two different locations. IP is not concerned with the details of communication along any particular wire or fiber-optic cable. It is not “aware” of how bits are represented electrically, or what kind of connectors are used to couple cables together. IP is only concerned with “networks” in the broad sense of the word, as abstract collections of computers that are *somehow* (it doesn’t care exactly how) connected to each other.

Networking equipment (DCE) designed to pay attention to IP addresses for routing purposes are called, not surprisingly, *routers*. Their purpose is to direct packets to their appropriate destinations in the shortest amount of time.

In order for the Internet Protocol to specify where packets are coming from and where they are going to, each source and destination must be marked with its own *IP address*. IP version 4 (IPv4) uses 32-bit addresses, usually expressed as four octets (four bytes) written using decimal numbers. For example:

IP address 00000000 00000000 00000000 00000000 is written as 0.0.0.0

IP address 11111111 11111111 11111111 11111111 is written as 255.255.255.255

IP address 10101001 11111010 00101101 00000011 is written as 169.250.45.3

In order for two inter-connected computers to exchange data using Internet Protocol, each one must have a unique IP address:

At first, this may seem redundant. Doesn’t each and every Ethernet device already have its own unique “MAC address” 48 bits in length to distinguish it from every other Ethernet device in existence? If so, why add *another* set of identifying addresses to the system?

This is true – Ethernet devices are already uniquely addressed – but those MAC addresses serve different purposes than IP addresses. Recall that Ethernet is a standard only at layers 1 and 2, and is not “aware” of any higher-level concerns. Ethernet MAC addresses are useful to switching hubs and other Ethernet DCE devices tasked with management of Ethernet data frames, but those MAC addresses – unique as they may be – have little relevance in the greater picture of IP where we must fragment and reassemble messages over very large-scale networks. More importantly, the reason we need IP addresses is to be able to use interconnecting networks other than Ethernet. For example, two computers may be connected to each other with a simple EIA/TIA-232 cable (or even using radio transceiver units for a “wireless” connection) instead of Ethernet, but still use Internet

Protocol to route packets to their destinations<sup>57</sup>. By having its own dedicated addressing scheme, IP ensures computers can send and receive data packets with no regard to *physical interconnection details, channel arbitration methods, or anything else in between*. In a sense, IP is the “glue” that holds disparate networks together, and makes something like a world-wide Internet possible when so many different network types exist to connect digital devices together. If we attempted to use Ethernet MAC addresses for the same purpose, *the entire Internet would have to consist solely of Ethernet networks!*

A helpful analogy is to think of Ethernet MAC addresses like Social Security numbers for United States citizens, while IP addresses are like street addresses used to route mail. Each US citizen should have their own unique Social Security number, shared by no one else. This number is used for many purposes, including identification on Federal tax documents, to help route specific information (such as income records and Social Security payments) to the proper people. Despite the uniqueness of these numbers, though, people still need separate mailing addresses in order to receive mail through the postal service and other package distribution agencies. The mailing address serves a different purpose than the Social Security “address” each US citizen possesses. Furthermore, the existence of separate mailing addresses ensures even non-citizens living in the United States (e.g. foreign students, ambassadors, etc.) who have no Social Security numbers still have a way to send and receive mail. The mapping of device MAC addresses to IP addresses is handled by a protocol called *ARP* (Address Resolution Protocol) discussed later in this chapter.

### The “ping” utility

Computers enabled to communicate using Internet Protocol (IP) are equipped with a utility program named **ping** useful for detecting the presence of other IP-enabled computers connected to the same network. The classic format of this program is execution by typing the word “ping” at the computer’s command-line interface followed by the IP address of the other computer you wish to detect the presence of. For example, if I wished to check for the presence of a computer on the network with an IP address of 133.82.201.5, I would type this command at my computer’s command line and press the “Enter” key:

```
ping 133.82.201.5
```

The **ping** utility works by sending a very short digital message<sup>58</sup> to the specified IP address, requesting a reply from that computer (usually with multiple attempts). The **ping** command as implemented on the Microsoft Windows (XP) operating system typically makes four attempts before quitting. Some other operating systems’ implementation of **ping** continue indefinitely until halted by the user with the “Control-C” keystroke interrupt combination.

---

<sup>57</sup>In fact, this is precisely the state of affairs if you use a *dial-up* telephone connection to link your personal computer with the Internet. If you use dial-up, your PC may not use Ethernet at all to make the connection to your telephone provider’s network, but rather it might use EIA/TIA-232 or USB to a modem (modulator/demodulator) device, which turns those bits into modulated waveforms transmittable over a voice-quality analog telephone line.

<sup>58</sup>The “ping” command is technically defined as an “Echo Request” command, which is part of the *Internet Control Message Protocol* (ICMP) suite.

When diagnosing problems with IP-enabled network devices, few utilities are as immediately useful as **ping**. Networking professionals commonly use the word “ping” as a verb, as in “I tried to *ping* that computer, but it gave no response.” There are many reasons why a computer might fail to respond to a **ping** query, but a successful **ping** attempt proves several things:

- The destination device is powered up and its IP functionality is working
- All network devices (DCE) between your computer and the destination device are communicating
- All cables necessary for the communication of data between your computer and the destination are functional
- Both your computer and the destination device are on the same *subnet* (this topic covered in more detail later)

Since **ping** requires the first three layers of the OSI model to properly function (Physical, Data Link, and Network layers), using this as a diagnostic test neatly identifies where in the OSI model a problem exists. If two computers are not communicating with each other as they should but the **ping** utility works between them, the communication fault must lie within one of the upper OSI layers (e.g. Transport, Session, Presentation, or Application). Thus, we see the **ping** utility as a tool for “divide-and-conquer” style troubleshooting, where we may prove good connections between certain devices and thereby narrow the scope of the problem by elimination.

### IPv4 address ranges

Given the addressing purpose of Internet Protocol (to designate addresses over an extremely large collection of digital communication devices), addresses must be chosen with care. IP version 4 uses a 32-bit field to designate addresses, limiting its address capacity to  $2^{32}$  unique addresses. As large as this number is, it is not enough to uniquely identify all Internet-capable devices worldwide. The inventors of IP did not dream their Internet would grow to the proportions it has today. Let this be a lesson to all those involved with computers: the future is usually bigger than you think! A variety of clever techniques has been developed to deal with this shortage of IP addresses. One of them is to dynamically assign addresses to Internet-connected computers *only when they are turned on*. This is how most personal Internet connections work: when you power up your personal computer to connect to the Internet, your service provider assigns you a temporary IP address through a protocol called DHCP (Dynamic Host Configuration Protocol). Your provider then forces you to relinquish this temporary IP address when you shut down your computer, so someone else may use it for theirs.

The *Internet Corporation for Assigned Names and Numbers*, or *ICANN*, is the organization responsible<sup>59</sup> for assigning IP addresses to Internet users worldwide (among other tasks). This group has designated certain IP address ranges specific to internal (i.e. *Local Area Network*, or *LAN*) network devices, which shall never be used “publicly” to address devices on the world-wide Internet. These specially-designated “private” LAN address ranges are as follows:

10.0.0.0 to 10.255.255.255

172.16.0.0 to 172.31.255.255

192.168.0.0 to 192.168.255.255

Additionally, all computers have their own special *loopback* IP address, used to send IP message packets to itself for certain purposes (including diagnostics): 127.0.0.1. This IP address is completely *virtual*, not associated with any network hardware at all<sup>60</sup>. Therefore, the **ping** command executed on any computer should *always* be able to detect address 127.0.0.1, regardless of the status or even existence of actual network hardware (cards or interfaces) on that computer. Failure of the **ping** command to detect the loopback address is a sign that the computer’s operating system is not configured to use Internet Protocol.

A computer’s loopback address may have uses other than diagnostic. Some computer applications are network-oriented by nature, and rely on IP addresses even if the application is performing some local function rather than a function between computers on an actual network. The *X-windows* graphic-user interface (GUI) system popularly used on UNIX operating systems is an example of this, referencing the loopback address to form a connection between client and server applications running on the same computer.

---

<sup>59</sup>Prior to ICANN’s formation in 1999, the *Internet Assigned Numbers Authority*, or *IANA* was responsible for these functions. This effort was headed by a man named Jon Postel, who died in 1998.

<sup>60</sup>The term “loopback” refers to an old trick used by network technicians to diagnose suspect serial port connections on a computer. Using a short piece of copper wire (or even a paperclip) to “jumper” pins 2 and 3 on an EIA/TIA-232 serial port, any serial data transmitted (out of pin 3) would be immediately received (in pin 2), allowing the serial data to “loop back” to the computer where it could be read. This simple test, if passed, would prove the computer’s low-level communication software and hardware was working properly and that any networking problems must lie elsewhere.

### 15.8.2 Subnetworks and subnet masks

IP (version 4) addresses are used in conjunction with something called *subnet masks*<sup>61</sup> to divide IP networks into “subnetworks.” A “subnetwork” is a range of IP-addressed devices allowed to communicate with each other. You may think of the subnet mask to be a sort of “filter” used to identify IP addresses belonging to the proper range.

The subnet mask works as a bitwise filter, identifying those bits in the IP address defining the subnetwork. For example, if the subnet mask on a computer is set to 255.0.0.0 (binary 11111111 00000000 00000000 00000000), it means the first 8 bits of the IP address define the subnetwork, and thus the computer is only allowed to communicate with another computer belonging to the same subnetwork (i.e. having the same first octet in its IP address).

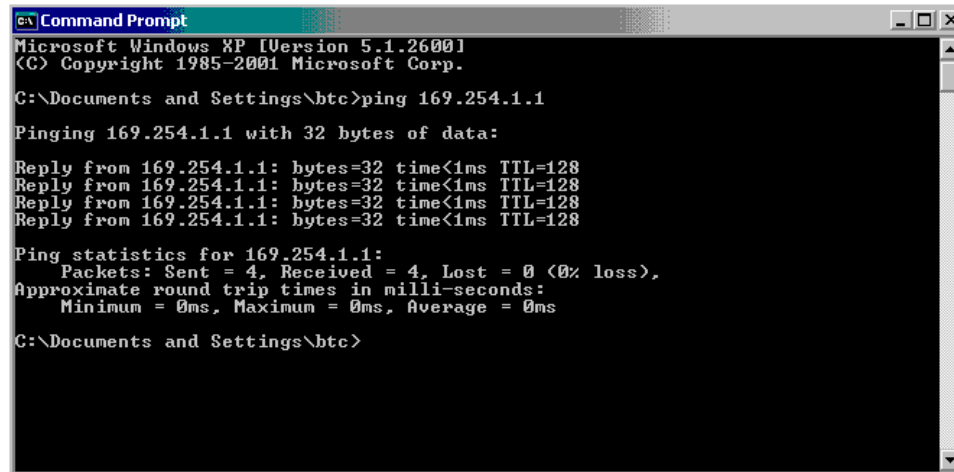

A set of examples showing two interconnected computers with differing IP addresses (and in some cases, different masks) illustrates how this works<sup>62</sup>. In the first example, two computers with IP addresses differing in the last two octets are able to communicate because their subnets are the same (169.254):

<sup>61</sup>Also called “netmasks” or simply “masks.”

<sup>62</sup>These are real test cases I performed between two computers connected on a 10 Mbps Ethernet network. The error messages are those generated by the `ping` utility when communication was attempted between mis-matched computers.

We may check to see the IP addresses and subnet masks are correct by using the `ping` command. A screenshot of `ping` being used on a personal computer running the Microsoft Windows XP operating system is shown here:

```
C:\Documents and Settings\btc>ping 169.254.1.1

Pinging 169.254.1.1 with 32 bytes of data:

Reply from 169.254.1.1: bytes=32 time<1ms TTL=128
Reply from 169.254.1.1: bytes=32 time<1ms TTL=128
Reply from 169.254.1.1: bytes=32 time<1ms TTL=128
Reply from 169.254.1.1: bytes=32 time<1ms TTL=128

Ping statistics for 169.254.1.1:
    Packets: Sent = 4, Received = 4, Lost = 0 (0% loss),
    Approximate round trip times in milli-seconds:
        Minimum = 0ms, Maximum = 0ms, Average = 0ms

C:\Documents and Settings\btc>
```

In the next example, we see two computers with the same mask value, but with different address values in the octets designated by their masks. In other words, these two computers belong to different subnets: one to 167.254 and the other to 169.254, and as a result they are not allowed to communicate with each other using Internet Protocol. The resulting error messages generated by the `ping` utility are shown in this diagram:

In the last example, we see two computers having different mask values as well as different IP addresses. The subnet of the left-hand computer is 169.254.10 while the subnet of the right-hand computer is 169.254:

The computer on the left may only communicate with IP addresses matching in the first three octets (169.254.10). Seeing that the destination address for the second computer does not match in its third octet, **ping** returns a “Destination host unreachable” error message when executed from the left-hand computer.

When the computer on the right attempts to communicate with (“ping”) the computer on the left, it is allowed to transmit to that computer because its mask only screens for agreement in the first two octets (169.254), which happen to match. However, the computer on the left is not allowed to transmit to the computer on the right because of its more restrictive subnet, and so **ping** running on the right-hand computer returns a “Request timed out” error message because it never receives a reply from the left-hand computer to any of its queries.

With just two computers connected by a single cable, the concept of subnetworks and masks seems useless, and indeed it is on this small of a scale. However, “subnetting” is a useful technique for managing high traffic loads on large networked systems using IP addresses, and so it is commonly seen in many local area networks (LANs) such as those found at industry and commercial sites.

While many IPv4-compliant computers designate both the IP address and the subnet mask values as sets of “dotted-decimal” numbers with each decimal (0-255) representing an “octet” of eight bits in the 32-bit IPv4 address space (e.g. IP = 169.254.5.1 and Mask = 255.255.0.0), a more modern designation for subnets is to append the device’s IP address with a forward slash character and a decimal number specifying how many bits are used to specify the subnet.

To illustrate by example, consider a computer having the IP address 169.254.5.1 and a mask value of 255.255.0.0 (thus specifying that it belongs to the subnetwork 169.254), we could alternatively state that computer’s IP address as 169.254.5.1/16. The “16” means that the first sixteen bits of its IP address define its subnet. To cite another example, a computer with an IP address of 192.168.35.100 and a subnet mask of 255.255.255.0 could have its address alternatively written as 192.168.35.100/24. The “24” tells us the first 24 bits (first three octets) of the IP address define its subnetwork: this computer belongs to the subnetwork 192.168.35.

The `ping` diagnostic utility program may be used to search for unknown IP addresses on a known subnet. This may be done by “pinging” to the *broadcast address* for that subnet: an IP address formed by the known subnet numbers, followed by all binary 1’s filling the unknown bit spaces. For example, you could use `ping` to search for devices on the subnet `156.71` (subnet mask `255.255.0.0`) by using the following command:

```
ping 156.71.255.255
```

### 15.8.3 Routing tables

Devices on an IP-compliant network need to know how to best route IP data packets from one location to another. In the case of special *router* devices managing traffic on the Internet, optimum packet routes are determined by a number of different criteria (e.g. degree of congestion in a route, the fewest number of “hops” from one router to another, geographical distance, etc.), updated continually by sophisticated algorithms operating within the routers. Data for these optimum routes are stored in lists called *routing tables*.

Personal computers also have routing tables, which may be modified by the user. An application where you may need to modify the routing table of a personal computer is the case of enabling that computer to communicate with a brand-new device installed on the industrial network, whose subnetwork ID differs from the other devices on that network. Many network-ready industrial instruments are shipped from the manufacturer with default subnets of 192.168.1. It is quite possible that the subnet of the industrial network you intend to have the device operate on is different from this default factory-configuration. This in itself is not necessarily a problem, as IP addresses and subnet mask values of IP-enabled devices are always user-configurable. However, if the only method of configuring this new device is by communicating to it through an IP network connection, you are faced with a Catch-22: how do you communicate with it to alter its subnet, when its subnet prevents you from communicating with it?

One solution to this Catch-22 dilemma is to temporarily use a personal computer with a subnet matching the new device to configure that new device, then disconnecting the device from the personal computer after it has been configured for the new subnetwork, and subsequently plugging the device into the industrial network where it will function.

Another solution is to use one of the personal computers already residing on the industrial network to configure the new device, and specially enabling that one computer to talk to the device’s default subnet. In this way, the new device may be plugged into the industrial network, configured for a new IP address and subnet while on that network, where it will subsequently communicate with existing devices on the proper subnet. This may be done through the `route` command-line utility. At a command prompt (just like when using the `ping` command), type “route” followed by arguments telling it to add the device’s default address and subnet mask to the computer’s routing table. Supposing our new device has a default IP address of 192.168.1.10 and a default mask of 255.255.255.0, our `route` command would need to be entered as follows:

```
route add 192.168.1.10 mask 255.255.255.0
```

After issuing this command to the personal computer, it may be used to communicate with the new device to change its IP address and subnet mask values to match devices on the industrial network.

### 15.8.4 IP version 6

The next version of IP (version 6, or IPv6) uses 128-bit addresses, giving  $2^{128}$  address possibilities (in excess of  $3.4 \times 10^{38}$ ), in stark contrast to IPv4's paltry  $2^{32}$  address space. To put this enormous quantity into perspective, there are enough IPv6 addresses to designate nearly 57 *billion* of them for each and every gram of the Earth's mass<sup>63</sup>. While IPv4 addresses are typically written as four octets in decimal form (e.g. 169.254.10.5), this notation would be very cumbersome for writing IPv6 addresses. Thus, IPv6 addresses are written as a set of eight hexadecimal numbers (up to four characters per number) separated by colons, such as 4ffd:522:c441:d2:93b2:f5a:8:101f. The phase-in of IPv6 to replace IPv4 has already started for certain portions of the Internet, but the full transition to IPv6 is expected to take many years. The IPv6 "loopback" virtual address for computers is 0:0:0:0:0:0:0:1, or more simply<sup>64</sup> written as ::1.

Note the "shorthand" notation used in the previous IPv6 addresses to eliminate extra characters: some of the 16-bit segments are truncated to less than four hexadecimal characters if the preceding (more-significant) characters are zero. Thus, you see :522: instead of :0522:, and :d2: instead of :00d2:. The loopback address of ::1 is the ultimate shorthand notation, collapsing all prior segments (which are all zero) into a pair of back-to-back colons.

IP version 6 supports subnetworks just as IPv4 does, but instead of denoting subnet masks in the same colon-delimited fashion as IPv6 addresses, IPv6 subnet masks are simply specified by the number of "1" bits beginning from the first (MSB). The rationale here is that subnet mask bits should be contiguous<sup>65</sup>, with no zero bits separating one bits. This being the case, the subnet mask for any practical IP range may be specified as a simple number of 1's from the MSB down to the LSB<sup>66</sup>.

It should be noted that an updated version of the `ping` command (called `ping6`) is available to help diagnose IPv6 systems.

---

<sup>63</sup>According to Douglas Giancoli's *Physics for Scientists and Engineers* textbook, the mass of the Earth is  $5.98 \times 10^{24}$  kg, or  $5.98 \times 10^{27}$  grams. Dividing  $2^{128}$  (the number of unique IPv6 addresses) by the Earth's mass in grams yields the number of available IPv6 address per gram of Earth mass. Furthermore, if we assume a grain of sand has a mass of about 1 milligram, and that the Earth is modeled as a very large collection of sand grains (not quite the truth, but good enough for a dramatic illustration!), we arrive at 57 *million* IPv6 addresses per grain of sand on Earth.

<sup>64</sup>The fully-written loopback address is actually 0000:0000:0000:0000:0000:0000:0000:0001.

<sup>65</sup>While it is possible to use non-contiguous subnet mask values, the practice is frowned upon by most system administrators.

<sup>66</sup>Indeed, subnet masks for IPv4 can be specified in this manner as well, not just IPv6 subnet masks.

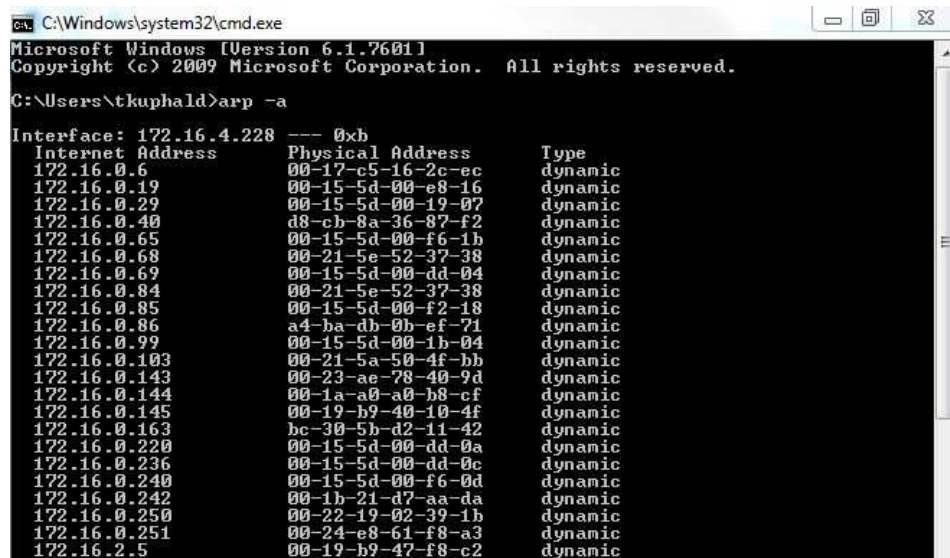

### 15.8.5 ARP

While Internet Protocol (IP) provides a universal addressing standard for devices operating on large-scale digital networks, individual devices usually possess MAC addresses unique to each device. As mentioned in a previous section, IP addresses are to MAC addresses as mailing addresses are to Social Security numbers: the IP address serves to route information sent over the network, while MAC addresses identify the individual devices themselves. Any digital network system dealing with both types of addresses must somehow “map” each MAC address to a corresponding IP address, and this is handled by a protocol called *Address Resolution Protocol*, or *ARP*.

Every node running the ARP protocol on a digital network maintains a table of equivalent addresses, MAC to IP. This table is called the *ARP cache*, the contents of which may be displayed by running the following command on the device’s command-line interface:

```
arp -a
```

The `arp -a` command instructs the machine to print *all* (-a) ARP cache entries to the screen for your viewing. This, of course, only displays what that machine happens to know at that time. If the ARP cache has not been updated recently, addressing data found in the ARP cache may be out of date or even missing. Here is a partial screenshot of the `arp -a` command run on a Microsoft Windows computer, showing each IP (“internet”) address in the ARP cache and its corresponding MAC (“physical”) address:

```

```

One way to update the ARP cache on a machine with a command-line interface is to first issue a broadcast<sup>67</sup> ping request. Responses from active nodes on the network will populate the machine’s

<sup>67</sup>The “ping” command is often used to test the response of a single IP node on a network, by issuing the command followed by the IP address of interest (e.g. `ping 192.168.35.70`). By contrast, a “broadcast” ping request attempts to contact a range of IP addresses within a subnet. For example, if we wished to ping all the IP addresses beginning with 192.168.35, we would issue the command with all 1’s in the last octet of the IP address field (e.g. `ping 192.168.35.255`).

ARP cache with address information, after which you may run the `arp -a` command to display those cache entries.

### 15.8.6 DNS

The acronym *DNS* actually stands for two related things: *Domain Name System* and *Domain Name Server*. The first meaning of “DNS” refers to the system of exchanging numerical IP addresses with alphanumeric *Uniform Resource Locators (URLs)* which are easier for human beings to remember. When you use web browser software to navigate to a web site on the Internet, you have the option of entering the URL *name* of that site (e.g. `www.google.com`) or a numerical IP address (e.g. `75.125.53.104`). Special computers connected to the Internet called *Domain Name Servers*, and *Domain Name Resolvers (DNRs)* use the *Address Resolution Protocol (ARP)* to convert your target web site name to its actual IP address so that a connection may be made between that computer and yours.

ICANN, the same organization responsible for allotting IP addresses, also maintains databases for all registered domain names.

### 15.8.7 Command-line diagnostic utilities

In addition to `ping` and `arp`, another utility program useful for troubleshooting network connections from a Microsoft Windows computer’s command line interface<sup>68</sup> is `ipconfig`. When executed, `ipconfig` returns a listing of all available (configured and operating) network interfaces on that computer:

```
C:\Documents and Settings\hbc>ipconfig

Windows IP Configuration

Ethernet adapter Local Area Connection:

    Connection-specific DNS Suffix  . : 
    IP Address. . . . . : 169.254.1.2
    Subnet Mask . . . . . : 255.255.0.0
    Default Gateway . . . . . : 

Ethernet adapter Wireless Network Connection:

    Media State . . . . . : Media disconnected

C:\Documents and Settings\hbc>
```

---

<sup>68</sup>In UNIX-based operating systems the program used to access the command line is often called `terminal` or `xterm`. In Microsoft Windows systems it is simply called `cmd`.

The equivalent command for UNIX operating systems is `ifconfig`, shown in this screenshot:

```
root@Renegade2:/home# ifconfig
eth0      Link encap:Ethernet  HWaddr 00:13:20:08:ec:e6
          inet addr:192.168.0.64 Bcast:192.168.0.255 Mask:255.255.255.0
          inet6 addr: fe80::213:20ff:fe08:ece6/64 Scope:Link
          UP BROADCAST RUNNING MULTICAST  MTU:1500  Metric:1
          RX packets:170901 errors:0 dropped:0 overruns:0 frame:0
          TX packets:107550 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:1000
          RX bytes:212178154 (212.1 MB)  TX bytes:14005068 (14.0 MB)

eth1      Link encap:Ethernet  HWaddr 00:0e:35:a2:1b:7f
          inet6 addr: fe80::20e:35ff:fea2:1b7f/64 Scope:Link
          UP BROADCAST MULTICAST  MTU:1500  Metric:1
          RX packets:441 errors:0 dropped:0 overruns:0 frame:0
          TX packets:570 errors:0 dropped:6 overruns:0 carrier:0
          collisions:0 txqueuelen:1000
          RX bytes:0 (0.0 B)  TX bytes:0 (0.0 B)
          Interrupt:18 Base address:0x2000 Memory:48005000-48005fff

lo        Link encap:Local Loopback
          inet addr:127.0.0.1 Mask:255.0.0.0
          inet6 addr: ::1/128 Scope:Host
          UP LOOPBACK RUNNING  MTU:16436  Metric:1
          RX packets:8 errors:0 dropped:0 overruns:0 frame:0
          TX packets:8 errors:0 dropped:0 overruns:0 carrier:0
          collisions:0 txqueuelen:0
          RX bytes:516 (516.0 B)  TX bytes:516 (516.0 B)

root@Renegade2:/home#
```

Some of the more interesting details contained in the output from `ifconfig` are the IPv6 addresses (in addition to IPv4 addresses), Ethernet MAC addresses (listed as “hardware addresses” or *HWaddr*), Ethernet performance data (e.g. number of collisions), IP performance data (e.g. number of IP packets received and transmitted), and details on the “loopback” address (IPv4 127.0.0.1 or IPv6 ::1).

A utility intended to reveal the DNS name of a computer given its IP address, or visa versa, is `nslookup`. The same command works on Microsoft Windows and UNIX operating systems alike. Here, we see the UNIX version used to identify four IP addresses of the popular Google search engine web site, followed by the Microsoft Windows version:

```
root@Renegade2:/home# nslookup www.google.com
Server:          192.168.0.1
Address:         192.168.0.1#53

Non-authoritative answer:
www.google.com canonical name = www.l.google.com.
Name:   www.l.google.com
Address: 74.125.53.103
Name:   www.l.google.com
Address: 74.125.53.147
Name:   www.l.google.com
Address: 74.125.53.99
Name:   www.l.google.com
Address: 74.125.53.104
```

```

```

Another utility used to explore network connections is **tracert** (spelled **tracert** on Microsoft Windows operating systems). This utility sends a test packet to the designated destination address, returning information on all the “hops” the IP packet takes between computers along the network to reach its destination and the amount of time taken to make the trip. Execution of **tracert** on a UNIX computer and **tracert** on a Microsoft Windows computer are shown here:

```
root@Renegade2:/home# traceroute www.google.com
traceroute to www.google.com (74.125.53.147), 30 hops max, 40 byte packets

## 15.9 Transmission Control Protocol (TCP) and User Datagram Protocol (UDP)

At the next OSI Reference Model layer (layer 4) is a set of protocols specifying how reliable communication “connections” should be established between devices on a digital network. Rather than specifying addresses for routing data packets on a large network (OSI layer 3), layer 4 works on the level of virtual data “ports” at the transmitting and receiving devices. The purpose of these virtual ports is to manage multiple types of data transactions to and from the same IP address, such as in the case of a personal computer accessing a web page (using HTTP) and sending an email message (using SMTP) at the same time. An analogy to help understand the role of ports is to think of multiple packages delivered to different people at a common address such as a business office. The mailing address for the office is analogous to the IP address of a computer exchanging data over a network: it is how other computers on the network “find” that computer. The personal or department names written on the different packages are analogous to virtual ports on the computer: “places” within that node where specific messages are directed once they arrive.

*Transmission Control Protocol (TCP)* and *User Datagram Protocol (UDP)* are two methods used to manage data flow through “ports” on a DTE device, with TCP being the more complex and robust of the two. Both TCP and UDP rely on IP addressing to specify which devices send and receive data, which is why you will often see these protocols listed in conjunction with IP (e.g. TCP/IP and UDP/IP). TCP and UDP are both useless on their own: a protocol specifying port locations without an IP address would be as meaningless as a package placed in the general mail system with just a name but with no street address. Conversely, IP anticipates the presence of a higher-level protocol such as TCP or UDP by reserving a portion of its “datagram” (packet) bit space for a “protocol” field<sup>69</sup> to specify which high-level protocol generated the data in the IP packet.

TCP is a complex protocol specifying not only which virtual “ports” will be used at the sending and receiving devices, but also how data integrity will be guaranteed. Data communicated via TCP are sent in blocks of bits called *segments*. In the same way that the IP algorithm encapsulates data into self-contained “packets” with the necessary routing data to ensure proper delivery to the destination, the TCP algorithm encapsulates data with “header” bits specifying such details as sequence number, acknowledgment identification, checksum (for error-detection), urgency of the message, and optional data. TCP takes responsibility for ensuring both devices on the network are ready to exchange data, breaks the data block into segments of an appropriate size to be encapsulated inside IP packets on the transmitting end, checks each segment for corruption (using the CRC method) upon receipt, reassembles those segments into the whole data block at the receiving end, and terminates the connection between devices upon completion. If a TCP segment successfully arrives at the receiving device, the TCP protocol running at the receiving device acknowledges this to the transmitting device. If the transmitting device fails to receive an acknowledgment within a specified time, it automatically re-sends the segment. If a TCP segment arrives corrupted, the TCP protocol running at the receiving device requests a re-send from the transmitting device. TCP thus fulfills the task of the author and publisher in the manuscript analogy, handling the disassembly and reassembly of the manuscript. In rigorously checking the integrity of the data transfer, TCP’s functionality is akin to sending each manuscript package via *certified mail* where the author may

---

<sup>69</sup>Both IPv4 and IPv6 reserve eight bits for this purpose.

track the successful delivery of each and every package.

Another feature of TCP is end-to-end *flow control*, enabling the receiving device to halt the incoming data stream for any reason, for example if its buffer memory becomes full. This is analogous to the XON/XOFF control signals used in simple serial communication protocols such as EIA/TIA-232. In the case of large networks, TCP flow control manages the flow of data segments even when the communication paths are dynamic and liable to change.

If IP (Internet Protocol) is the “glue” that holds the Internet together, TCP (Transmission Control Protocol) is what makes that glue strong enough to be practically useful. Without TCP, data communication over the wildly disparate physical networks that comprise the world-wide Internet would be far less reliable.

UDP is a much simpler protocol, lacking not only the segment sequencing of TCP but also lacking many of the data-integrity features of TCP. Unlike TCP, the UDP algorithm does not sequence the data block into numbered segments at the transmitting end or reassemble those numbered segments at the receiving end, instead relegating this task to whatever application software is responsible for generating and using the data. Likewise, UDP does not error-check each segment and request re-transmissions for corrupted or lost segments, once again relegating these tasks to the application software running in the receiving computer. It is quite common to see UDP applied in industrial settings, where communication takes place over much smaller networks than the world-wide Internet, and where the IP data packets themselves tend to be much smaller as well. Another reason UDP is more common in industrial applications is that it is easier to implement in the “embedded” computer hardware at the heart of many industrial devices. The TCP algorithm requires greater computational power and memory capacity than the UDP algorithm, and so it is much easier to engineer a single-chip computer (i.e. microcontroller) to implement UDP than it would be to implement TCP.

Information-technology professionals accustomed to the world of the Internet may find the use of UDP rather than TCP in industrial networks alarming. However, there are good reasons why industrial data networks do not necessarily need all the data-integrity features of TCP. For example, many industrial control networks consist of seamless Ethernet networks, with no routers (only hubs and/or switches) between source and destination devices. With no routers to go through, all IP packets communicated between any two specified devices are guaranteed to take the exact same data path rather than being directed along alternate, dynamic routes. The relative stability and consistency of communication paths in such industrial networks greatly simplifies the task of packet-reassembly at the receiving end, and makes packet corruption less likely. In fact, many industrial device messages are short enough to be communicated as single IP packets, with no need for fragmentation or re-assembly at all!

A noteworthy exception to the use of UDP in industrial applications is FOUNDATION Fieldbus HSE (High-Speed Ethernet), which uses TCP rather than UDP to ensure reliable transmission of data from source to destination. Here, the designers of FOUNDATION Fieldbus HSE opted for the increased data integrity offered by TCP rather than use UDP as may other industrial IP-based network protocols do.

Using another utility program on a personal computer called `netstat` (available for both Microsoft Windows and UNIX operating systems) to check active connections<sup>70</sup>, we see the various IP addresses and their respective port numbers (shown by the digits following the colon after the IP address) as a list, organized by TCP connections and UDP connections:

```
C:\Documents and Settings\htc>netstat -an
Active Connections

```

Proto	Local Address	Foreign Address	State

An interesting distinction between TCP and UDP is evident in this screenshot. Note how each of the TCP connections has an associated “state” (either LISTENING or ESTABLISHED), while none of the UDP connections has a state associated with it. Recall that TCP is responsible for initiating and terminating the connection between network devices, and as such each TCP connection must have a descriptive state. UDP, on the other hand, is nowhere near as formal as TCP in establishing connections or ensuring data transfer integrity, and so there are no “states” to associate with any of the UDP connections shown. Data arriving over a UDP connection simply shows up unannounced, like an impolite guest. Data arriving over a TCP connection is more like a guest who announces in advance when they will arrive, and also says “good bye” to the host as they depart.

Many different port numbers have been standardized for different applications at OSI Reference Model layers above 4 (above that of TCP or UDP). Port 25, for example, is always used for SMTP (Simple Mail Transfer Protocol) applications. Port 80 is used by HTTP (HyperText Transport Protocol), a layer-7 protocol used to view Internet “web” pages. Port 443 is used by HTTPS, an encrypted (secure) version of HTTP. Port 107 is used by TELNET applications, a protocol whose purpose it is to establish command-line connections between computers for remote administrative work. Port 22 is used by SSH, a protocol similar to TELNET but with significantly enhanced security. Port 502 is designated for use with Modbus messages communicated over TCP/IP.

<sup>70</sup>In this particular case, I typed `netstat -an` to specify *all* (a) ports with *numerical* (n) IP addresses and port numbers shown.

## 15.10 The HART digital/analog hybrid standard

A technological advance introduced in the late 1980's was *HART*, an acronym standing for **H**ighway **A**ddressable **R**emote **T**ransmitter. The purpose of the HART standard was to create a way for instruments to digitally communicate with one another over the same two wires used to convey a 4-20 mA analog instrument signal. In other words, HART is a *hybrid* communication standard, with one variable (channel) of information communicated by the analog value of a 4-20 mA DC signal, and another channel for digital communication whereby many other variables could be communicated using pulses of current to represent binary bit values of 0 and 1. Those digital current pulses are *superimposed* upon the analog DC current signal, such that the same two wires carry both analog and digital data simultaneously.

### 15.10.1 Basic concept of HART

Looking at a standard loop-powered (2-wire) process transmitter circuit, we see the transmitter, a DC power supply (voltage source), and usually a 250 ohm resistor to create a 1 to 5 volt signal readable by any voltage-sensing indicator, controller, or recorder:

The transmitter's primary function in this circuit is to regulate current to a value representative of the measured process variable (e.g. pressure, temperature, flow, etc.) using a range of 4 to 20 mA, while the DC voltage source provides power for the transmitter to operate. Loop-powered instruments are very common in industrial instrumentation because they allow both power and (analog) data to be conveyed on the same pair of wires.

With the advent of microprocessor-based process transmitters, it became possible for instrument technicians to digitally configure parameters inside the transmitter (e.g. range values, damping values) and also query the transmitter for self-diagnostic alarms. In order to make full use of this digital functionality, though, there had to be some way to *communicate* digital data to and from the process transmitter over the same two wires used to convey the 4-20 mA analog signal. Otherwise, the only way to access this rich array of digital data inside the transmitter would be to connect a communicator device to some data port located on the transmitter itself, which is inconvenient due to the nature of how these transmitters are used in industry (located in dirty places, often hard to access while carrying a personal computer or other communication device).

Thus the *HART* communication protocol was born to address this need. HART communicates digital data along the loop conductors in the form of AC signals (audio-frequency tones) *superimposed* on the 4-20 mA DC current signal. A modem built into the smart transmitter translates these AC signals into binary bits, and vice-versa. Now, instrument technicians could “talk” with the new microprocessor-based transmitters simply by connecting a HART communications device at any point along the two-wire cable, even at the far end where the cable terminates at the control system hardware (panel-mounted controller, PLC, DCS, etc.).

Being able to communicate digital data over the same wire pair as the DC power and analog signal opens a whole new range of possibilities. Now, the field-mounted transmitter can communicate self-diagnostic information, status reports, alarms, and even multiple process variables to the control system in addition to the original analog signal representing the (main) process variable. With digital communication, the only data limitation is speed (data rate), not quantity. The control system may even communicate information *to* the transmitter using the same digital protocol, using this digital data channel to switch between different measurement range sets, activating special features (e.g. square-root characterization, damping, etc.), automatically and remotely.

With HART, the traditional series-connected circuit configuration of transmitter, DC power supply, and resistor remains unchanged. A HART-enabled transmitter, though, is equipped with a built-in digital microcontroller managing its functions, and this miniature computer is able to send and receive digital data as AC signals (current pulses in sending mode, voltage pulses in receiving mode) superimposed on the same two wires carrying the 4 to 20 mA analog signal and DC power. Any other computer device equipped with a HART modem, the necessary configuration software, and an appropriate device description<sup>71</sup> for that particular instrument may communicate with the HART transmitter if connected in parallel with the transmitter's loop power terminals:

This external computer – through the use of HART data transmission – now has the ability to monitor details of the transmitter's operation, configure the transmitter, update its measurement ranges, and perform a host of additional functions.

<sup>71</sup>A *Device Description*, or *DD* (DD) file, is analogous to a “driver” file used to instruct a personal computer how to communicate with a printer, scanner, or any other complex peripheral device. In this case, the file instructs the HART configuration computer on how it should access parameters inside the field instrument's microcontroller. Without an appropriate DD file loaded on the configuration computer, many of the field instrument's parameters may be inaccessible.

The connection between the HART modem and the HART-enabled transmitter need not be made directly at the transmitter's terminals. *Any* set of points in the circuit electrically parallel to the transmitter's terminals are permissible as connection points for the HART modem. This flexibility is a great advantage in loop circuits spanning long distances, enabling the technician to connect their HART configuration equipment at the most physically convenient location:

A convenient alternative to a personal computer and HART modem is a special hand-held device called a *HART communicator*. Two different models of HART communicator are shown in the following photographs, a Rosemount model 268 on the left and an Emerson model 375 on the right:

HART communicators are battery-powered, portable devices built specifically for configuring HART-enabled field instruments. Like personal computers, they must be updated with DD files<sup>72</sup> to be able to communicate with the latest models of HART-enabled field instruments.

Perhaps the single greatest disadvantage of HART data communication is its slow speed. Not only is the bit rate slow by modern standards – only 1200 bits per second – but the encoding of HART data is laden with “overhead” bits<sup>73</sup> required to synchronize devices, specify device addresses on a network, check for errors, and other functions necessary for making HART a reliable data-communications protocol. As a result, the typical time required for a complete HART transaction (one device requesting data, and the other device replying) is half a second! This means on average no more than two complete messages per second may be communicated by HART. This limits the use of HART data communication to non-routine purposes (e.g. error messages sent by field

<sup>72</sup>A “DD” file, or *Device Descriptor* file, is akin to a *driver* file used in a personal computer to allow it to communicate data with some peripheral device such as a printer. DD files basically tell the HART communicator how it needs to access specific data points within the HART field instrument.

<sup>73</sup>Every byte (8 bits) of actual HART data is sent as an asynchronous serial frame with a start bit, parity bit, and stop bit, so that 11 bits’ worth of time are necessary to communicate 8 bits of real data. These “byte frames” are then packaged into larger message units called HART *telegrams* (similar to Ethernet data frames) which include bits for synchronizing receiving devices, specifying device addresses, specifying the length of the data payload, communicating device status, etc.

instruments, range changes made by technicians) rather than continuous process measurement and control in all but the slowest process applications.

HART technology has breathed new life into the venerable 4-20 mA analog instrumentation signal standard. It has allowed new features and capabilities to be added on to existing analog signal loops without having to upgrade wiring or change all the instruments in the loop. Some of the features of HART are listed here:

- Diagnostic data may be transmitted by the field device (self-test results, out-of-limit alarms, preventive maintenance alerts, etc.)
- Field instruments may be re-ranged remotely through the use of HART communicators
- Technicians may use HART communicators to force field instruments into different “manual” modes for diagnostic purposes (e.g. forcing a transmitter to output a fixed current so as to check calibration of other loop components, manually stroking a valve equipped with a HART-capable positioner)
- Field instruments may be programmed with identification data (e.g. tag numbers corresponding to plant-wide instrument loop documentation)

It should be mentioned that HART communication over 4-20 mA signal wires is a legacy technology. At the time of this writing (2011), HART protocol is still the most popular form of wired digital field instrument communication in industrial use. However, more modern digital standards such as Profibus and FOUNDATION Fieldbus deliver all the benefits of HART technology and more. It seems that wired-HART will remain in wide industrial use for many years to come, but it is really just the beginning of digital field instrument technology and does not represent the state of the art. For more information regarding modern “fieldbus” digital instrumentation, refer to chapter 16 on the FOUNDATION Fieldbus standard beginning on page 1133.

An important addition to the HART standard introduced with version 7 is *wireless* (radio) communication capability. This portion of the standard describes how HART data may be communicated via radio waves instead of audio-frequency AC signal bursts superimposed on DC signal wires. Here, HART is the sole method of exchanging process data between field instruments rather than a secondary method to a 4-20 mA DC analog signal. Communicating over radio waves eliminates the theoretical speed barrier faced by wired-HART (1200 bits per second) while still permitting HART-compliant computer software and field communicator devices to work with these wireless instruments. For more information regarding the *WirelessHART* standard, refer to section 17.2 beginning on page 1232.

### 15.10.2 HART physical layer

The HART standard was developed with existing installations in mind. The signals had to be robust enough to travel over twisted-pair cables of very long length and unknown characteristic impedance. This meant that the data communication rate for the digital data had to be very slow, even by 1980's standards, in order to avoid problems created by reflections along unterminated cabling. The HART standard is concerned only with three layers of the OSI Reference model: layer 1 (FSK modulation,  $\pm 0.5$  mA transmitter signaling), layer 2 (Master-slave arbitration, data frame organization), and layer 7 (specific commands to read and write device data). Layers 3 through 6 of the OSI model are irrelevant to the HART standard.

Digital data is encoded in HART using the Bell 202 modem standard: two audio-frequency “tones” (1200 Hz and 2200 Hz) are used to represent the binary states of “1” and “0,” respectively, transmitted at a rate of 1200 bits per second. This is known as *frequency-shift keying*, or *FSK*. The physical representation of these two frequencies is an AC current of 1 mA peak-to-peak superimposed on the 4-20 mA DC signal. Thus, when a HART-compatible device “talks” digitally on a two-wire loop circuit, it produces tone bursts of AC current at 1.2 kHz and 2.2 kHz. The receiving HART device “listens” for these AC current frequencies and interprets them as binary bits. The following photograph shows a HART waveform captured by a digital oscilloscope:

Each “1” bit in this HART waveform is a single cycle of 1200 Hz tone, while each “0” bit is a double-cycle of 2200 Hz tone. The waveform shown here is an alternating series of “1” and “0” bits.

An important consideration in HART current loops is that the total loop resistance (precision resistor values plus wire resistance) must fall within a certain range: 250 ohms to 1100 ohms. Most 4-20 mA loops (containing a single 250 ohm resistor for converting 4-20 mA to 1-5 V) measure in at just over 250 ohms total resistance, and work quite well with HART. Even loops containing two 250 ohm precision resistors meet this requirement. Where technicians often encounter problems is when they set up a loop-powered HART transmitter on the test bench with a lab-style power supply and *no* 250 ohm resistor anywhere in the circuit:

The HART transmitter may be modeled as two parallel current sources: one DC and one AC. The DC current source provides the 4-20 mA regulation necessary to represent the process measurement as an analog current value. The AC current source turns on and off as necessary to “inject” the 1 mA P-P audio-frequency HART signal along the two wires. Inside the transmitter is also a HART modem for interpreting AC voltage tones as HART data packets. Thus, data transmission takes place through the AC current source, and data reception takes place through a voltage-sensitive modem, all inside the transmitter, all “talking” along the same two wires that carry the DC 4-20 mA signal.

For ease of connection in the field, HART devices are designed to be connected in parallel with each other. This eliminates the need to break the loop and interrupt the DC current signal every time we wish to connect a HART communicator device to communicate with the transmitter. A typical HART communicator may be modeled as an AC voltage source<sup>74</sup> (along with another HART voltage-sensitive modem for receiving HART data). Connected in parallel with the HART transmitter, the complete circuit looks something like this:

With all these sources in the same circuit, it is advisable to use the *Superposition Theorem* for analysis. This involves “turning off” all but one source at a time to see what the effect is for each source, then superimposing the results to see what all the sources do when all are working simultaneously.

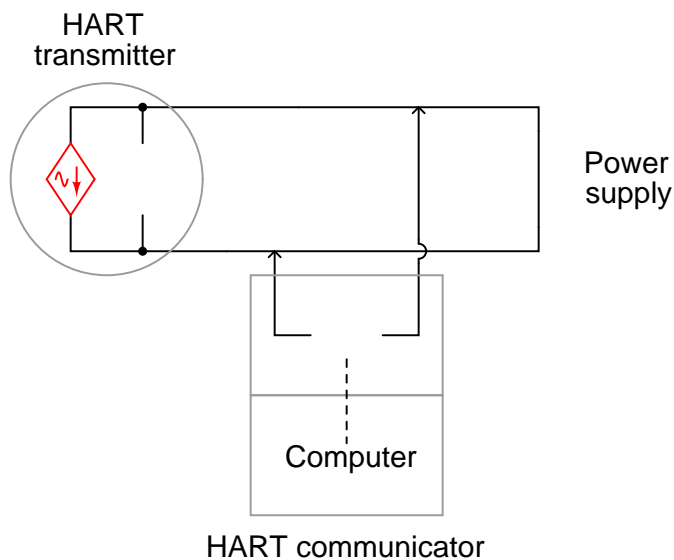

---

<sup>74</sup>The HART standard specifies “master” devices in a HART network transmit AC voltage signals, while “slave” devices transmit AC current signals.

We really only need to consider the effects of either AC source to see what the problem is in this circuit with no loop resistance. Consider the situation where the transmitter is sending HART data to the communicator. The AC current source inside the transmitter will be active, injecting its 1 mA P-P audio-frequency signal onto the two wires of the circuit. The AC voltage source in the communicator will disconnect itself from the network, allowing the communicator to “listen” to the transmitter’s data.

To apply the Superposition Theorem, we replace all the other sources with their own equivalent internal resistances (voltage sources become “shorts,” and current sources become “opens”). The HART communicator will be modeled as an “open” even though it is technically a voltage source because it must turn itself off (i.e. switch to high-impedance mode) in order for any field device to communicate to it:

The HART communicator is “listening” for those audio tone signals sent by the transmitter’s AC source, but it “hears” nothing because the DC power supply’s equivalent short-circuit prevents any significant AC voltage from developing across the two wires. This is what happens when there is no loop resistance: no HART device is able to receive data sent by any other HART device.

The solution to this dilemma is to install a resistance of at least 250 ohms but not greater than 1100 ohms between the DC power source and all other HART devices, like this:

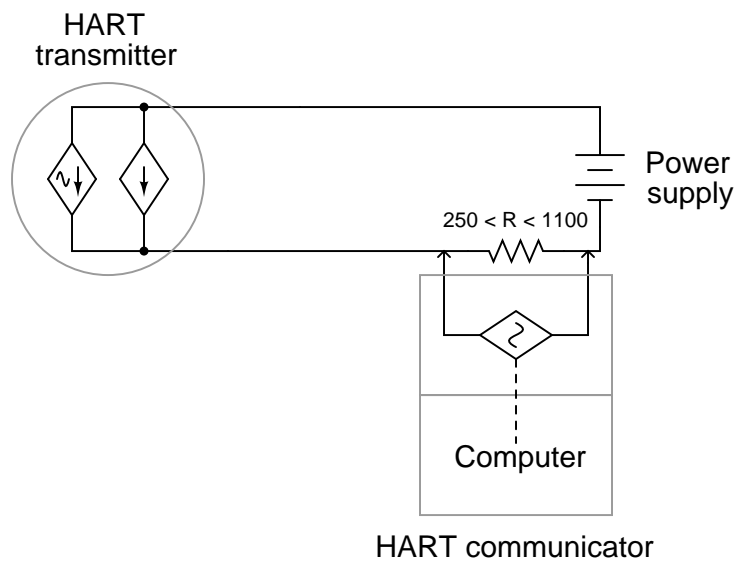

Loop resistance must be at least 250 ohms to allow the 1 mA P-P AC signal to develop enough voltage to be reliably detected by the HART modem in the listening device. The upper limit (1100 ohms) is not a function of HART communication so much as it is a function of the DC voltage drop, and the need to maintain a minimum DC terminal voltage at the transmitter for its own operation. If there is too much loop resistance, the transmitter will become “starved” of voltage and act erratically. In fact, even 1100 ohms of loop resistance may be too much if the DC power supply voltage is modest.

Loop resistance is also necessary for the HART transmitter to receive data signals transmitted by the HART communicator. If we analyze the circuit when the HART communicator's voltage source is active (replacing the DC power supply with a short and the transmitter current sources with opens), we get this result:

Without the loop resistance in place, the DC power supply would “short out” the communicator’s AC voltage signal just as effectively as it shorted out the transmitter’s AC current signal. The presence of a loop resistor in the circuit prevents the DC power supply from “loading” the AC voltage signal by the communicator. This AC voltage is seen in the diagram as being directly in parallel with the transmitter, where its internal HART modem receives the audio tones and processes the data packets.

Manufacturers' instructions generally recommend HART communicator devices be connected directly in parallel with the HART field instrument, as shown in the previous schematic diagrams. However, it is also perfectly valid to connect the communicator device directly in parallel with the loop resistor like this:

Connected directly in parallel with the loop resistor, the communicator is able to receive transmissions from the HART transmitter just fine, as the DC power source acts as a dead short to the AC current HART signal and passes it through to the transmitter.

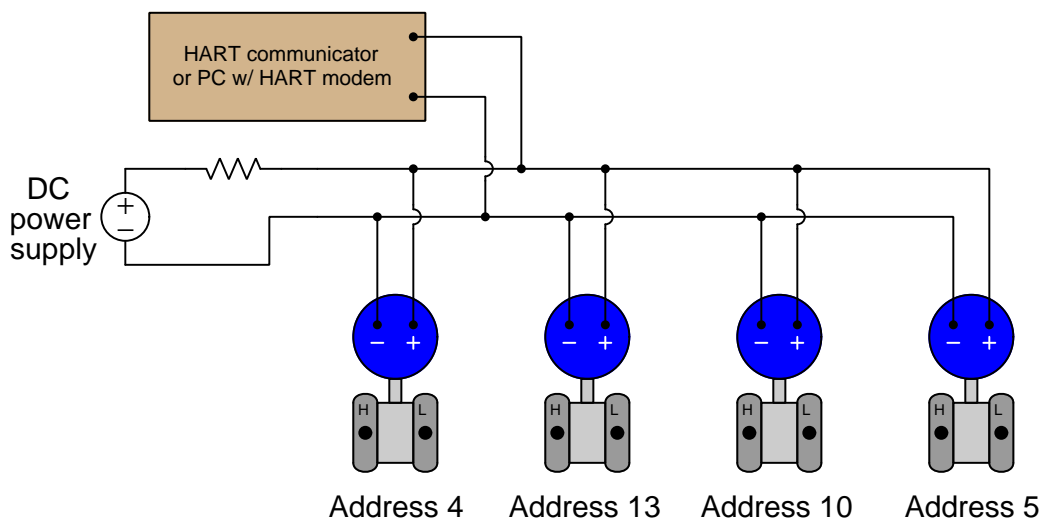

This is nice to know, as it is often easier to achieve an alligator-clip connection across the leads of a resistor than it is to clip in parallel with the loop wires when at a terminal strip or at the controller end of the loop circuit.

### 15.10.3 HART multidrop mode

The HART standard also supports a mode of operation that is totally digital, and capable of supporting multiple HART instruments on the same pair of wires. This is known as *multidrop mode*, where field instruments are slaves and the communicator (or control system) is the master.

Every HART instrument has an *address* number, which is typically set to a value of zero (0). A network address is a number used to distinguish one device from another on a broadcast network, so messages broadcast across the network may be directed to specific destinations. When a HART instrument operates in digital/analog hybrid mode, where it must have its own dedicated wire pair for communicating the 4-20 mA DC signal between it and an indicator or controller, there is no need for a digital address. An address becomes necessary only when multiple devices are connected to the same network wiring, and there arises a need to digitally distinguish one device from another on the same network.

This is a functionality the designers of HART intended from the beginning, although it is rarely used in industry. Multiple HART instruments may be connected directly in parallel with one another along the same wire pair, and information exchanged between those instruments and a host system, if the HART address numbers are set to non-zero values (between 1 and 15):

Setting an instrument's HART address to a non-zero value is all that is necessary to engage multidrop mode. The address numbers themselves are irrelevant, as long as they fall within the range of 1 to 15 and are unique within that network. Once a HART instrument is configured for multi-drop mode (i.e. given a non-zero HART address), its current becomes fixed at 4 mA and no longer varies with the process variable measurement.

The major disadvantage of using HART instruments in multidrop mode is its slow speed. Due to HART's slow data rate (1200 bits per second), it may take several seconds to access a particular instrument's data on a multidropped network. For some applications such as temperature measurement, this slow response time may be acceptable. For inherently faster processes such as liquid flow control, it would not be nearly fast enough to provide up-to-date information for the control system to act upon.

#### 15.10.4 HART multi-variable transmitters and burst mode

Some “smart” instruments have the ability to report multiple process variables. A good example of this is Coriolis-effect flowmeters, which by their very nature simultaneously measure the density, flow rate, and temperature of the fluid passing through them. A single pair of wires can only convey *one* 4-20 mA analog signal, but that same pair of wires may convey *multiple* digital signals using HART protocol.

If the host system receiving the transmitter’s signal(s) is HART-ready, it may digitally poll the transmitters for all variables. If, however, the host system does not “talk” using the HART protocol, some other means must be found to decode the wealth of digital data digitally offered by the multi-variable transmitter. One such device is Rosemount’s model 333 HART “Tri-Loop” demultiplexer shown in the following photograph:

This device uses a feature of HART called *burst mode* where one HART instrument repeatedly transmits information rather than waiting to be polled by a master HART device (such as a control system or a hand-held communicator)<sup>75</sup>. The Rosemount 333 receives these bursts of data, converting as many as three digitally-encoded HART variables into independent 4-20 mA analog output signals, which any suitable analog indicator or controller device may then receive.

It should be noted that the same caveat applicable to multidrop HART systems (i.e. slow speed) applies to multi-variable HART communication as well. Even though burst mode eliminates the need for master-device communications and therefore occupies less time than normal (polled) HART communication, typical wait times for HART data may still be too long for some industrial process applications. Typical HART burst rate is approximately three HART “telegram” packets per second, as opposed to two complete transmissions per second in the case of polled HART where

<sup>75</sup>Truth be told, HART instruments configured to operate in burst mode are still able to respond to queries from a master device, just not as often. Between bursts, the HART slave device waits a short time to allow any master devices on the network to poll. When polled, the slave device will respond as it normally would, then resumes its bursts of unpolled data once again. This means that normal master/slave communication with a HART instrument set for burst mode will occur at a slower pace than if the instrument is set for normal mode.

the master requests data and the slave replies. If we configure a process transmitter to burst-communicate three different variables, for example, the update rate for each one of those variables will be approximately once per second (three variables communicated at a total rate of three HART telegrams per second), which is simply too slow for many industrial applications (e.g. closed-loop liquid flow control). In applications where speed is not a concern, however, HART communication is a very practical solution for acquiring multiple channels of data from one instrument over a single pair of wires.

## 15.11 Modbus

Developed by the Modicon company (the original manufacturer of the *Programmable Logic Controller*, or *PLC*) in 1979 for use in its industrial control products, *Modbus* is a protocol designed specifically for exchanging process data between industrial control devices. The Modbus standard does not specify any details of physical networking, and thus may be deployed on many different types of physical networks. In other words, Modbus primarily falls within layer 7 of the OSI Reference Model (the so-called “Application Layer”) and therefore is compatible<sup>76</sup> with any lower-level communication protocols including EIA/TIA-232, EIA/TIA-485, Ethernet (the latter via TCP/IP), and a special token-passing network also developed by Modicon called *Modbus Plus*. The Modbus standard primarily defines the *meaning* of various Modbus commands, the addressing scheme used to place data within devices, and the formatting of the data.

Modbus consists of a set of standardized digital codes intended to read data from and write data to industrial devices. A Modbus-compliant industrial device has been programmed to understand these codes and respond to them appropriately when received. The simplest Modbus codes read and write single bits of data in the device’s memory, for example the status of a PLC input channel, PLC output channel, or status bit within a PLC program. Other Modbus codes operate on 16-bit words of data, useful for reading and writing counter and timer accumulated values, operands for mathematical instructions, converted analog signals, etc.

Early implementations of Modbus used EIA/TIA-485 as the network physical layer, which is strictly a layer 1 protocol. This meant that Modbus needed to specify a channel arbitration scheme in order to negotiate communications with multiple devices on a network. The arbitration chosen was master/slave, where one PLC functioned as the master Modbus device and all other devices functioned as Modbus slaves.

Interestingly, this vestige of master/slave arbitration survives to this day, even when Modbus commands are communicated via networks with their own differing arbitration methods. For example, Modbus commands communicated over Ethernet still reference “slave” addresses even though the Ethernet network those messages are sent over uses CSMA/CD arbitration. In other words, there is a hint of OSI layer 2 embedded within Modbus messages that still dictates which Modbus devices may issue commands and which must obey commands.

---

<sup>76</sup>These Modbus data frames may be communicated directly in serial form, or “wrapped” in TCP segments and IP packets and Ethernet frames, or otherwise contained in any form of packet-based protocol as needed to transport the data from one device to another. Thus, Modbus does not “care” how the data is communicated, just what the data means for the end-device.

### 15.11.1 Modbus overview

We may begin our exploration of Modbus by first considering an example of a PLC-controlled motor system that does *not* employ Modbus. Here, the PLC sends individually-wired Forward, Reverse, and Stop, and speed-control command signals to a variable-frequency drive (VFD) which then sends three-phase power of varying frequency to an electric motor to do some useful task:

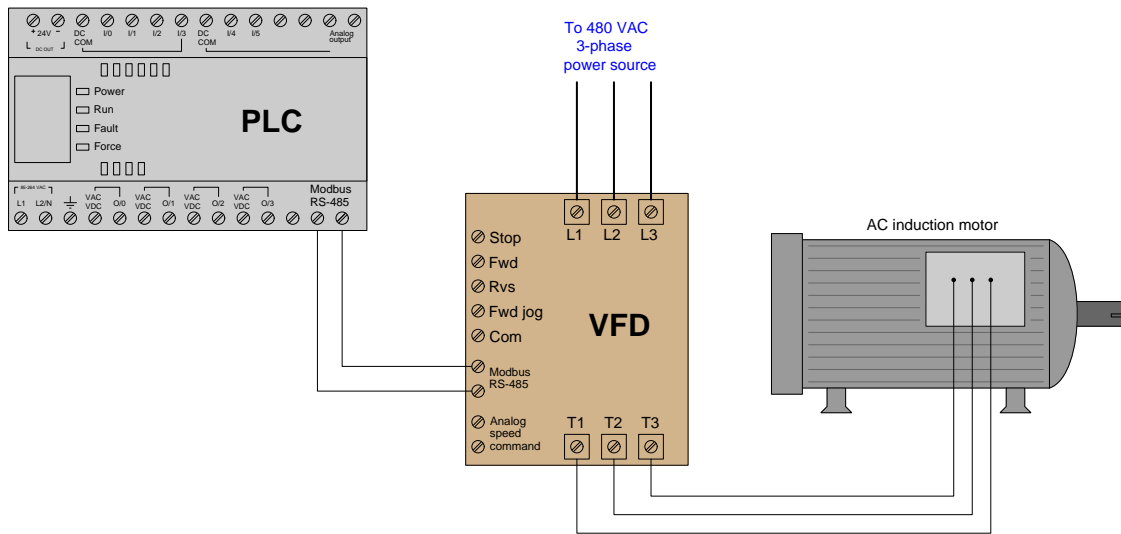

The discrete commands (e.g. Stop, Forward, Reverse) are nothing more than on/off contact closures provided by the PLC's output channels to the VFD's input terminals. When the PLC commands the VFD to run in the Reverse direction, it simply activates output channel 0/1 which closes a relay contact inside the PLC to connect the VFD's "Rvs" terminal to the VFD's "Com" terminal. The VFD detects this electrical continuity, and responds by running the motor in its reverse direction. Motor speed is commanded by an analog voltage signal (typically 0 to 10 volts DC) output by the PLC, with 0 volts representing zero speed and 10 volts representing full speed. The VFD receives this analog voltage signal and responds to it by outputting the appropriate frequency of three-phase AC power to the induction motor.

While this system is certainly functional, it may be improved upon through the use of Modbus.

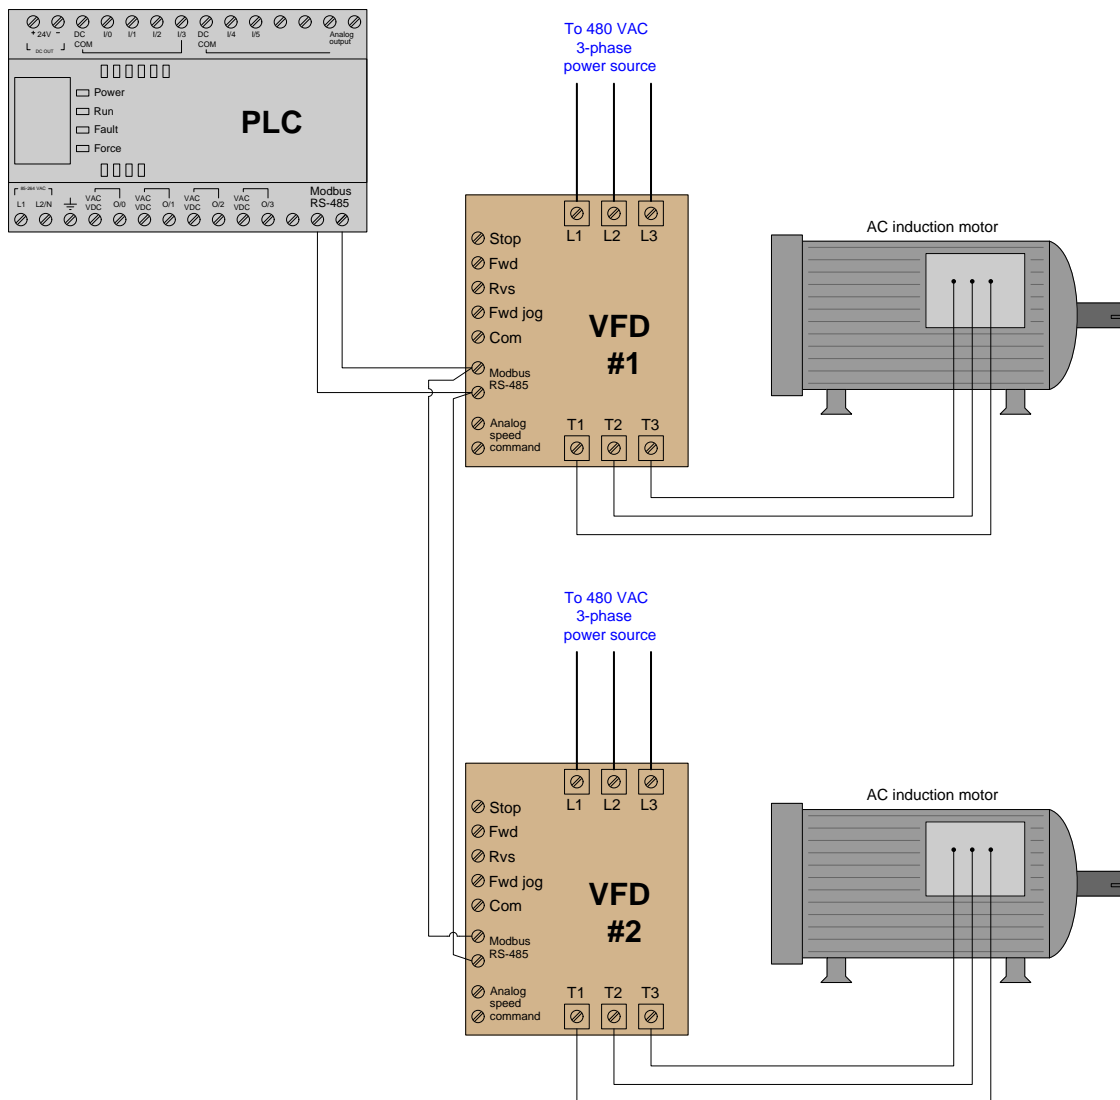

Now consider this updated motor control system, where the only connecting wires between the PLC and VFD is a single two-conductor cable between the Modbus/RS-485 terminals of both devices. The PLC functions as a Modbus master device while the VFD functions as a Modbus slave:

By using appropriate Modbus commands transmitted to the VFD, the PLC is able to issue all the same commands (e.g. Stop, Forward, Reverse, speed control) as before but using far fewer wires. For example Modbus command code 05 writes a single bit of data to the receiving device, allowing the PLC to send discrete-signal commands to the VFD one at a time. When the PLC commands the VFD to run in the Reverse direction, it issues a 05 command followed by a “1” data bit addressed to the appropriate memory location inside the VFD reserved for the “Reverse” command bit. When the PLC commands the VFD to change motor speed, it issues an 06 Modbus code (“write register”) followed by a 16-bit number representing the desired motor speed and the appropriate address within the VFD reserved for speed command.

Not only can the PLC issue all the same commands as before, but it may also *read* data from the VFD which it could not do before. For example, if the VFD provides a memory location for storing fault codes (e.g. motor overcurrent, bus undervoltage, etc.), the PLC may be programmed to issue an 03 Modbus code to read a single register (16 bit binary number) from that memory location within the VFD, and thereby monitor the status of the VFD to alert human technicians of potential problems, and/or to modify its own controlling of the motor.

Another advantage of the Modbus communication standard is that it is designed to address multiple devices on the same network. This means our hypothetical PLC is not limited to controlling and monitoring just one motor, but *up to 247 separate Modbus slave devices* on the same two-wire communication cable! The following illustration shows how this might work for multiple motors:

Each VFD is given its own Modbus network *slave address*, so that the PLC is able to distinguish between the two drives when communicating on the same wire pair. Every Modbus code transmitted by the PLC contains this address as a single byte (8 bits) of data in order to make the receiving VFD aware that the code applies to it and not to any other Modbus device on the network. In
