ACKNOWLEDGEMENT

This report was prepared under DSR Project 55-23850, sponsored by the Manned Spacecraft Center of the National Aeronautics and Space Administration through Contract NAS 9-4065.

The publication of the report does not constitute approval by the National Aeronautics and Space Administration of the findings or the conclusions contained therein. It is published only for the exchange and stimulation of ideas.
Abstract

The digital guidance computer is the central control element in the Apollo control, guidance and navigation system. Efficient operation of the guidance computer during any mission phase requires the performance of many different functions occurring at approximately the same time. Some examples are the processing of input data in the form of velocity increments, gimbal angles, system status signals, astronaut keyboard commands and ground commands and producing output such as steering commands, control of mode and caution lamps, digital display updating and digital telemetry transmission. To illustrate the diversity of requirements with which this computer must cope, a specific phase of the Apollo mission is described in detail; i.e., the control of the spacecraft to accomplish a powered maneuver.

Navigation and Guidance

The two fundamental tasks of a guidance system are to maintain accurate knowledge of spacecraft position and velocity and to provide steering commands for required changes in course. In this section we shall discuss the computational aspects of navigation and guidance for major thrusting maneuvers of the Apollo spacecraft.

Navigation

For position and velocity determination the Apollo system includes inertial instruments capable of measuring thrust accelerations along three mutually orthogonal axes which are non-rotating. The Apollo guidance computer is then required to perform accurate integrations and gravity calculations on a real-time basis.

In Figure 1 is shown a functional diagram of the basic computations required of the navigation system. Incremental outputs from inertially stabilized integrating accelerometers, together with components of gravitational acceleration computed as functions of inertial position in a feedback loop, are summed to give the components of inertial velocity.

Figure 1. Navigation system

The gravity calculations may be performed in a straightforward manner. In Figure 2, the equations of motion for a vehicle moving in a spherical gravitational field are given together with a simple computation algorithm by means of which position and velocity are obtained as a first order difference equation calculation. Since velocity is updated by means of the average effective gravity over the interval of one time step, this technique has been termed the "average g" method.

Guidance

The task of providing steering commands for major thrusting maneuvers is frequently called
The guidance problem is always a boundary value problem subject to a variety of constraints of which fuel conservation, vehicle maneuverability and time are examples. Explicit solutions to the problem of guidance during periods of major thrusting require relatively complex calculations to be performed in flight on a time-critical basis.

Figure 2. Position and velocity computation

Velocity-to-be-Gained Method. During the Apollo mission, many of the major orbital transfer maneuvers can be accomplished conceptually by a single impulsive velocity change. For these cases an instantaneous velocity-to-be-gained vector based on conic orbits can be defined and the vehicle steered to null this vector. Refer to Figure 3 and let a vector \( \mathbf{v} \) be defined, corresponding to the present vehicle location \( \mathbf{r} \), as the instantaneous velocity required to satisfy a set of stated mission objectives. The velocity difference \( \mathbf{v} - \mathbf{v}_p \) between \( \mathbf{v} \) and the present vehicle velocity \( \mathbf{v}_p \) is then the instantaneous velocity-to-be-gained.

Two convenient guidance laws are immediately apparent which will assure that all three components of the vector \( \mathbf{v} - \mathbf{v}_p \) are simultaneously driven to zero. First, we may orient the vehicle to align the thrust acceleration vector \( \mathbf{a} \) with the direction of the velocity-to-be-gained vector. Alternatively, since a convenient expression can be developed for the time rate of change of the \( \mathbf{v} \) vector, we may direct the vector \( \mathbf{a} \) to cause the vector \( \mathbf{v} \) to be parallel to \( \mathbf{v}_p \) and oppositely directed. If the thrust acceleration magnitude is not sufficiently large it may not be possible to align the Vector \( \mathbf{v}_p \) with its derivative. However, with typical chemical rockets for which the burning time is relatively short, no difficulty has been encountered with this guidance logic.

A combination of these two techniques leads to a highly efficient steering law which compares favorably with calculus of variations optimum solutions. The scalar mixing parameter \( \gamma \) is chosen empirically to maximize fuel economy during this maneuver. A constant value of \( \gamma \) is usually sufficient for a particular mission phase; however, if required, it may be allowed to vary as a function of some convenient system variable.

A functional diagram illustrating the computation of the error signal required for control purposes is shown in Figure 4. The position, velocity

Figure 3. Velocity-to-be-gained methods

Figure 4. Velocity-to-be-gained steering
and gravitation vectors are computed as described above. The required impulsive velocity needed to achieve mission objectives is determined as a function of the position vector and used to calculate the velocity-to-be-gained. Convenient formulas for many targeting problems are given by Battin (2). Numerical differentiation of the required velocity vector and the accelerometer outputs, using values stored from the previous sample time, provides two important ingredients of the error signals. When properly scaled, the system output is a vector rate of command whose magnitude is proportional to the small angular differences between the actual and commanded thrust acceleration vectors whose direction defines the direction of vehicle rotation required to null the error. Near the end of the maneuver, when the velocity-to-be-gained is small, cross-product steering is terminated, the vehicle holds a constant attitude and engine cutoff is made on the basis of the magnitude of the vector $\mathbf{v}_g$.

**Initial Spacecraft Alignment.** The direction in space that the thrust vector should be oriented at the beginning of a powered flight maneuver is determined from the equation

$$\mathbf{a}_T = \mathbf{g} + (\mathbf{q} \cdot \mathbf{1}_g) \mathbf{1}_g$$

where $\mathbf{1}_g$ is a unit vector in the direction of the vector $\mathbf{v}_g$ and

$$\mathbf{q} = \sqrt{a_T^2 - (\mathbf{g})^2 + (\mathbf{1}_g \cdot \mathbf{g})^2}$$

The quantities $\mathbf{v}_g$ and $\mathbf{g}$ are both continuous functions through the ignition point and, thus, their computation can be started to align the vehicle initially prior to the firing of the engine.

**Inertial Measurement Unit**

For control, guidance and navigation during an accelerated maneuver, the Apollo system uses inertially stabilized instruments to measure thrust acceleration, an optical device to determine the specific orientation of this physical coordinate, system and a guidance computer to perform the numerical functions of data processing and exercising control over the vehicle orientation and rocket engines. Our primary concern in this paper is with the use of the computer in its central role as a control and processing element of the guidance system. Therefore, we shall give only a brief description of the over-all system hardware, referring the interested reader to the references (3), and concentrate in the next section on the characteristics of the Apollo Guidance Computer, AGC.

**Physical Characteristics**

The Apollo Inertial Measurement Unit, IMU, as shown schematically in Figure 5, is a three degree of freedom gimbal system utilizing integrating gyroscopes to detect angular deviations of the stable member with respect to inertial space, and to provide, along with their servo electronics, the establishment of a non-rotating member. On this stable member in an orthogonal triad are three accelerometers which are single degree of freedom pendulums with a digital pulse restraining system. Angle information as to the orientation of the computing coordinate frame with respect to the navigation base is derived from a two speed resolver system mounted on each axis of the IMU. This information is visually displayed to the navigator through a ball indicating system with resolver servo-controlled to follow the IMU resolvers. The same resolver system by means of a Coupling Data Unit, CDU, provides to the computer quantized angle increments corresponding to changes in gimbal angles. The CDU couples angle information to and from the guidance computer, performing both analog to digital and digital to analog conversion.

**IMU Alignment**

Since the Apollo IMU is normally not functioning during the long coasting periods, in-flight inertial system alignment against star references has been
provided before the start of each accelerated phase of the mission. For each such phase involving rocket burning or atmospheric drag, the trajectory and the thrust or drag lie fairly close to a fixed plane. The inner gimbal axis is then aligned approximately perpendicular to this plane. Since all required large maneuvers result mostly in inner gimbal motion, the difficulty of approaching gimbal lock associated with large middle gimbal angles is avoided. Finally, because large roll maneuvers are frequently required, the outer gimbal axis is mounted along or near the roll axis so that no restriction on roll maneuver ever exists.

In order to relate a star direction to the inertial system stable member orientation, a rigid structure mounted to the spacecraft called the navigation base is used to provide a common mounting structure for a star alignment telescope and the base of the inertial measurement gimbal system. Then by means of precision angle transducers on each of the axes of the telescope and on each of the axes of the inertial system gimbals, the indicated angles can be processed in the AGC to generate the star direction components in inertial system stable member coordinates. The use of an appropriate second star completes the full three-axis stable member orientation measurement. With this information the stable member orientation can then be changed under computer command, if desired, to the orientation optimum for use during the guidance maneuvers.

**Coarse Alignment**. IMU alignment is normally performed in two stages called "coarse align" and "fine align". The first step in coarse alignment is to provide the computer with a reasonably accurate knowledge of spacecraft attitude. For this purpose, the navigator sights sequentially two stars using the Scanning Telescope, SCT, which is a single-power, wide field of view instrument. The star image is sensed by the navigator who uses an optics hand controller to command the SCT prism such as to center the star on the reticle. By depressing a mark button when satisfactory tracking is achieved, the computer is signalled to read the SCT angles as transmitted by the optics CDU's. A second star direction at a reasonably large angle from the first is similarly measured. The navigator identifies the stars to the computer through the computer keyboard and the spacecraft attitude in three dimensions is thus determined. This orientation is maintained by an attitude hold autopilot.

In the second step of coarse alignment, the computer determines the desired IMU gimbal angles based upon its knowledge of spacecraft attitude and the guidance maneuver which will be next performed. These desired angles are sent to the IMU through the CDU to be matched by the IMU gimbal servos in response to error signals developed on the angle transducers on each gimbal axis. The IMU gimbal servos are then driven by the gyro stabilization error signals to hold the achieved orientation.

**Fine Alignment**. For fine alignment, two star directions are again measured by the navigator. However, this time he uses the Sextant, SXT, which is a 20-power, narrow field of view instrument in order to achieve necessary accuracy. When appropriately signalled, the computer simultaneously reads the SXT and IMU angles being transmitted via the CDU's. With these data the computer determines star directions in IMU stable member coordinates from which the spatial orientation of the IMU being held by gyro control can be calculated. From a knowledge of the desired attitude, the computer then determines the existing IMU attitude error and meters out the necessary number of gyro torquing pulses to precess the gyros and the IMU to correct the IMU alignment error. The two steps of fine alignment can be repeated if desired to obtain more precision when the torquing precession angle is large.

**Apollo Guidance Computer**

The Apollo Guidance Computer, AGC, is designed to handle a relatively large and diverse set of on-board data processing and control functions. Some of the special requirements for this computer include (1) real time solution of several problems simultaneously on a priority basis, (2) efficient two-way communication with the navigator, (3) capability of ground control through radio links, and (4) multiple signal interfaces of both a discrete and continuously variable type.
General Description

The memory section of the AGC has a memory cycle time of 12 microseconds and consists of a fixed (read only) portion of 36864 words together with an erasable portion of 2048 words. Each word in memory is 16 bits long (15 data bits and an odd parity bit). Data words are stored as signed 14-bit words using a one's complement convention. Instruction words consist of 3 order code bits and 12 address code bits.

Because of the short word length, the address portion of an instruction word does not always determine uniquely the address of a memory word. The ambiguity is removed by means of auxiliary addresses contained in so-called bank registers which are under program control.

The data words used in the AGC may be divided roughly into two classes: data words used for mathematical computations and data words used in the control of various subsystems. The latter class of variables can almost always be represented with 15 bits while the mathematical quantities require twice the desired 15-bit word length.

The sequence generator portion of the AGC provides the basic memory timing and the sequences of control pulses (microprograms) which constitute instructions. It also contains the priority interrupt circuitry and a scaling network which provides various pulse frequencies used by the computer and the rest of the guidance system. In addition there are a number of "involuntary" sequences, not under normal program control, which may break into the normal sequence of instructions. These are triggered either by external events or by certain overflows within the AGC and are used for counter incrementing and program interruption.

Counter incrementing may take place between any two instructions. External requests for incrementing a counter are stored in a counter priority circuit. At the end of every instruction a test is made to see if any incrementing requests exist. If not, the next instruction is executed directly. If a request is present, an incrementing memory cycle is executed to read the word stored in the counter register, increment or shift it and store the results back in the same location. All outstanding counter incrementing requests are processed before proceeding to the next instruction.

Program interruption also occurs between program steps. An interruption consists of storing the contents of the program counter and transferring control to a location fixed for each interrupt option. Interrupting programs may not be interrupted, but interrupt requests are not lost and are processed as soon as the earlier interrupted program is resumed.

Instruction Set

The three bits reserved for instruction codes can provide only eight possible operations. This number is extended through the use of so-called partial codes and an extend instruction. Partial codes are used to exploit the fact that a wider variety of instructions are applicable to erasable than to fixed memory. Since erasable memory is characterized by short addresses, the instruction field of a word may be correspondingly lengthened. The use of the extend instruction allows the instruction set of the AGC to be doubled. Its occurrence in a program signals that the following instruction code is to have an alternate interpretation.

Input-Output Interfaces

Information transfer between the AGC and other subsystems of various kinds. In one form, entire computer words are transferred into and out of the computer to provide pre-launch and in-flight radio links maintained between the computer and ground control. The down telemetry link operates at the relatively high rate of 50 AGC words or 800 bits per second. The up telemetry link effects a serial to parallel conversion of data with each bit received requiring a memory cycle. A maximum rate of 160 bits per second is permitted.

Incremental information transfer, as a means of analog data transmission, is used. In the conversion of gimbal angles and optics angles, an
intermediate transformation to incremental form is made in the CDU's, the input to which are electrical resolvers. The Apollo accelerometers are incremental by nature, producing a pulse output to the computer for each unit change in velocity. Incremental transfer is also used for angle commands from the computer to the gyros and the CDU's and for thrust control and certain display functions in the spacecraft. Pulses are sent in groups or “bursts” at a fixed rate.

Discrete signals are individual or small groups of binary digits used for discrete actions such as switch closures, mission phase changes, jet firings, display initiations and many other similar controlled events. The computer is the primary source of timing signals for all spacecraft systems furnishing in the neighborhood of twenty time pulse signals to various subsystems.

Inputs. Incremental and serial inputs to the AGC are received in counter registers as previously described. Pulses received by the computer cause short interruptions of the program sequence during which one of these registers is modified.

Discrete inputs to the computer may be interrupting or non-interrupting. Non-interrupting inputs are signals which can be interrogated by input-output channel instructions. Interrupting inputs cause the transfer of control to a particular address. When the appropriate action has been taken, the original program is then resumed at the point where it was interrupted. Programs operated during interrupt never exceed a few milliseconds in running time.

Outputs. Incremental output transmission is made by placing a number in an output counter register. The counter is then decremented at a fixed rate of 3200 times per second. Output pulses are generated concurrently until the number reaches zero. Pulse bursts are used in this way for gyro torquing. During an output pulse burst, a precision current source is gated on so that an amount of charge proportional to the desired angle change is forced through the torquing element of the gyro.

In another form of output transmission the number in the register controls the switching of a set of precision resistors in an operational amplifier network such that the amplifier output is proportional to that number. These analog signals are available as voltages for driving such equipment as attitude displays and steering gimbals for the rocket engine.

Discrete outputs are controlled either directly or indirectly by program. Typically, a discrete output is made by placing a one in the proper bit position of an output channel which in turn, sets a flip-flop.

Display and Keyboard

The Display and Keyboard, DSKY, shown in Figure 6, serves as the communication medium between the computer and the navigator. The principal part of the display is the set of three registers, each containing five decimal digits composed of electroluminescent segmented numerical lights. Five digits are used so that an AGC word of 15 bits can be displayed in one light register by five octal digits. Three registers are used because of the frequent need to display the three components of a vector.

Digits are entered into the computer from a keyboard of nineteen push buttons including the ten decimal digits, plus and minus and a number of auxiliary items. Each key depression causes a
computer interrupt. The key input channel is interrogated by the keyboard interrupt program, which also makes a request to the computer's executive program to process the character at the earliest opportunity.

In addition to the three light registers, the display has other digit displays labeled verb, noun, and program. The keyboard has keys labeled verb, noun, enter, and clear as well as three others. Commands and requests are made in the form of sentences each with an object and an action, such as "display velocity" or "load desired angle". The DSKY is designed to transmit such simple commands and requests made up of a limited vocabulary of 100 actions, or "verbs" and 100 objects, or "nouns". To command the computer, the operator depresses the verb key followed by two decimal digit keys. This enters the desired verb into the computer, where it is stored and also sent back to the DSKY to be displayed in the verb lights. The operator next enters the desired noun in similar fashion using the noun key, and it is displayed in the noun lights. When the verb and noun are specified, the enter key is depressed, whereupon the computer begins to take action on the command.

When the computer requests action from the operator, a verb and a noun are displayed in the lights and a relay is closed which causes the verb and noun lights to flash on and off in order to attract the operator's attention.

Utility Programs

Interpreter. Most of the AGC programs relevant to guidance and navigation are written in a pseudocode notation for economy of storage. This notation is encoded and stored in the AGC as a list of data words. An AGC program called the "interpreter" translates this list into a sequence of subroutine linkages. A pseudocode program consists of a string of operators and addresses with two 7-bit operators stored in one AGC word. Thus, the instruction set is expanded into a comprehensive mathematical language, which includes matrix and vector operations, using numbers of 28 bits and sign.

Executive. All AGC programs operate under control of the Executive routine except those which are executed in the interrupt mode. Executive controlled programs are called "jobs" as distinct from so-called "tasks", which are controlled by the Waitlist routine and completed during interrupt time. The functions of the Executive are to control priority of jobs and to permit time sharing of erasable storage. Jobs are usually initiated during interrupt by a task program or a keyboard program. The job is specified by its starting address and another number which gives it a priority ranking. As the job runs, it periodically checks to see if another job of higher priority is waiting to be executed. If so, control is transferred away until the first job again becomes the one with highest priority. No more than 20 milliseconds are permitted to elapse between these periodic priority checks.

When a job is geared to the occurrence of certain external events and must wait a period of time until an event occurs, it may be suspended or "put to sleep". The job's temporary storage is left intact through the period of inactivity. When the anticipated event occurs, the job is "awakened" by transfer of control to an address which may be different from its starting address. If a job of higher priority is in progress, the "awakening" will be postponed. When a job is finished, it transfers control to a terminating sequence which releases its temporary storage to be used by another job. Approximately ten jobs may be scheduled for execution or in partial stages of completion at any one time.

Waitlist. The function of the Waitlist routine is to provide timing control for other program sections. Waitlist tasks are run in the interrupt mode, and are restricted to a few milliseconds duration. If an interrupt program were to be longer, it could cause an excessive delay in other interrupts waiting to be serviced since one interrupt program inhibits all others until it calls for resumption of the main program. The Waitlist program derives its timing from one of the counter registers in the AGC. The counter priority state which controls this counter is driven by a periodic pulse train from the computer's clock and scalar such that it is incremented every 10 milliseconds. When the counter overflows, the interrupt occurs which calls the Waitlist program. Before the interrupting program resumes the normal program, it presets the counter so as to overflow after a desired number of 10-millisecond periods up to a limit of 12000 for
a maximum delay of 2 minutes. If the Waitlist is required to initiate a lengthy computation, the task will make an Executive routine call so that the computation is performed as a job during non-interrupted time.

**Digital Autopilot Control**

Two of the flight control problems, associated with major powered maneuvers of the Apollo spacecraft, will be discussed in this section. The first is control of the attitude of the vehicle while coasting in free space and the second is powered flight control of the attitude and flight path of the vehicle while thrusting.

**Coasting Flight Control**

During periods of coasting flight when there are no significant forces acting on the spacecraft, control over the vehicle involves attitude control only. The primary requirement for the attitude control system prior to thrusting is to maneuver the vehicle to its proper thrusting orientation.

The Apollo spacecraft effects attitude control with a reaction control system, RCS, which is also used for vernier translation control. The rockets are capable of reliable operation in pulses as short as 14 milliseconds. Sixteen of these engines are mounted on the sides of the service module in quadruple sets of 4 locations. They are normally fired in pairs to produce control couples. A variety of operational modes can be selected by the crew including attitude-hold and rate-command modes in addition to direct actuation of the reaction jets by the pilot through a three-axis hand controller.

In the primary mode, the Apollo Guidance Computer operates the jet solenoid valve drivers directly based on attitude error and attitude error rate information. As illustrated in Figure 7, the attitude reference is obtained directly from the CDU's while attitude rate must be computed in the AGC. As a function of attitude error and attitude error rate, nonlinear switching functions in the computer are employed to generate the necessary firing time intervals. A jet-selection logic is then used to select the individual jets to be fired. Simultaneously, attitude error signals are transmit-

![Figure 7. Coasting flight autopilot](image-url)
representing a rotation about the computed vector through an incremental angle equal to the selected maneuver rate times the iteration cycle period.

The second stage in the calculation is to develop a transformation matrix equal to the product of the matrix which relates initial spacecraft and stable member axes and the above determined incremental rotation matrix. This transformation is updated once per computation cycle. Desired CDU angles are also developed at each iteration cycle, compared with actual CDU angles, and the difference transformed into attitude errors. In order to minimize discontinuity, the desired CDU angles are interpolated between computation cycles.

**Powered Flight Control**

The function of the powered flight control system is to orient the vehicle thrust acceleration vector in response to commands generated by the guidance system. Since the thrust acceleration vector, on the average, oriented in the vicinity of the longitudinal axis of the vehicle, the powered flight control problem is primarily one of attitude control.

Immediately prior to sequence initiation of a major burn using the Apollo Service Propulsion System, SPS, the RCS holds the initial thrusting attitude in a narrow deadband. The preselected trim, which points the engine bell through the vehicle center of gravity, has been commanded and confirmed by the crew and the crew has accepted the thrusting parameters including time of ignition.

At a prescribed time before ignition, the navigator initiates ullage. At ignition time the RCS digital autopilot releases control of the vehicle to a thrust vector control, TVC, autopilot which then controls engine excursions. Ullage is terminated by the major program when successful thrust buildup is sensed.

During the thrust period the cross-product steer law commands a vehicle rate proportional to the angular separation of \( \hat{\mathbf{v}} \) and \( \hat{\mathbf{a}} \) (or \( \hat{\mathbf{v}} \)). The autopilot responds to attitude errors in pitch, yaw and roll which are generated as follows:

1. The steer law rate is transformed into equivalent commanded body pitch and yaw rates.
2. Successive CDU angle readings are differenced to derive gimbal angle rates.
3. The gimbal angle rates are transformed into body coordinates, thereby estimating current body rates.
4. The differences between commanded and current body rates are integrated yielding body attitude errors in pitch and yaw. The “roll” error is simply taken to be the difference between the present value and initial value of the outer gimbal angle, OGA. (With small middle gimbal angles OGA control is, in effect, roll control.)

The AGC treats the control of each of the three attitude errors as a separate problem. Three independent control signals are generated in accordance with the attitude errors. The implementation of roll control is achieved by reaction jets whose firing is controlled by phase-plane and jet-selection logic similar in concept to the RCS autopilot. The regulation of the outer gimbal angle to within \( \pm 5 \) degrees of a preset value is sufficient to prevent adverse cross-coupling between the pitch and yaw channels.

The TVC pitch/yaw autopilot programs must fulfill the primary requirement of vehicle stabilization in conjunction with the external guidance loop to provide satisfactorily small velocity pointing errors at thrust cutoff. The autopilot programs must also limit excursions in vehicle attitude and thrust vector in such a way as to minimize propellant usage, gimbal-servoclutch wear and crew malaise. Figure 8 shows a schematic block diagram of one channel (pitch and yaw) which can serve as a basis for describing the autopilot. For simplification it is assumed that the rate command, \( \omega \), has already been transformed into body coordinates. The role of the AGC in this autopilot is to perform a dynamic filtering operation on the sampled attitude error, \( \epsilon \), as required to generate a suitable sampled command to the gimbal-servo. A digital-to-analog converter changes the gimbal-servo command to an analog voltage which is held for each sample period.

One of the major obstacles to be overcome by the digital autopilot is the effect of an initial error
in the alignment of the thrust vector through the vehicle center of gravity. The digital filter has a
finite gain at d.c. and would demand a non-zero
attitude error input to produce an engine
misalignment. It is important to note that while this
steady state error produces a non-zero display to
the navigator on the attitude error needles, it does
not generally imply a steady state pointing error in
the velocity of the guided vehicle since the external
guidance loop will act to readjust the attitude com-
mand signal to the autopilot to compensate for this
attitude error. However, the pointing error could
be appreciable during short thruster firing periods when
there is insufficient time for the external guidance
loop to react to the thrust vector misalignment
before thrust cut-off. By the addition of a
tracking filter, the position of the center of
gravity is estimated every 1/2 second and a bias
signal fed back to provide actuator trimming. The
digital filter, whose primary responsibility is the
shaping of signals in order to avoid the addition of
electric bias into the slush and bending modes, is thus
relieved of maintaining an actuator offset signal.
After the transient period the attitude errors and
needle display will settle on the null positions.
At four seconds prior to engine cut-off the TVC
autopilot maintains constant attitude, damping out
terataes through most of the tail-off transient. At
2.5 seconds following the engine-off command TVC
operation ceases and the RCS autopilot is initiated
in the wide deadband mode.

Computer Operations for a Powered Maneuver

The Apollo mission program is divided into
functional sub-programs by designating major
modes by program numbers corresponding to the
various on board computational capabilities.
Generally speaking, the required sequences for the
flight to the moon encompass prelaunch, boost,
navigation, targeting, powered maneuvers, stable
member alignments and entry. The sub-programs
within these eight categories are identified,
respectively by the numbered intervals: P01-P07,
P10-P17, P20-P27, P30-P37, P40-P47, P50-P57,
and P60-P67. The navigator selects, by DSKY
entry, the program needed to perform the particular
mission phase at hand. In addition to specific
programs, a variety of special algorithms are
available, again at navigator selection, which display
useful information concerning the state of the vehicle
in space. For example, the apogee and perigee or
latitude, longitude and altitude can be computed.

Computer Program Description

The program P40 is called whenever the service
module propulsion system is used to effect a change
of orbit. The precise direction of thrust initiation
and the method of steering depends on previously
calculated target parameters. The targeting
problem of arriving at a given point in space at a
specified time is solved in P34. This program is
entered prior to P40 and allows the ignition time
and the transfer time interval to the target point to be loaded as DSKY inputs. The required impulsive velocity change, resulting perigee and the expected middle gimbal angle are displayed so that the crew may evaluate, in advance, the propellant usage and alignment adequacy for the maneuver as well as the final orbit safe perigee margin. Upon leaving P34, the program stores away, for later use, the crew approved times of ignition and transfer and the computed "offset target vector" to be used in the conic calculations for steering. The transition to P40 by DSKY input occurs at a time in advance of ignition sufficient to accomplish the busy crew checklist which precedes any major thrusting maneuver.

The primary purpose of program P40 is to control the guidance, navigation and control system during countdown, ignition, thrusting and thrust termination of an SPS maneuver. Before P40 can be selected, certain data must be provided for use by the control autopilots. These data are rate, deadband and jet usage, as well as SPS engine gimbal turn estimates and are loaded in a prescribed way as DSKY inputs. The CSM weight, inertias and engine torque, quantities also required by the autopilots, are computed on board and tracked during the thrusting maneuver. Their values are always available for inspection and readjustment.

Program P40 is selected by a keyboard entry at least five minutes before the estimated time of ignition. After a preliminary check made by the computer to determine any potential conflicts which might prevent this program being entered at the present time, the program lights on the DSKY will display 40 as the major program in progress. First, an internal flag is set to prevent any updating of the position and velocity vectors from being made by the coasting flight navigation program. The AGC then checks the status of the IMU to determine if the power is on or if the system is aligned to an orientation known by the computer. The computer will request the navigator to select an appropriate program if the IMU is off or not aligned to a known orientation. It is normally required that the IMU power be on for one hour prior to a thrusting maneuver.

After the vehicle and engine parameters have been satisfactorily set, the AGC then computes the initial thrust direction and the initial value of the velocity-to-be-gained vector. The three components of the velocity-to-be-gained vector are displayed in local vertical coordinates to the navigator who has the option to abort the program if he detects any gross errors in the computation.

From the initial thrust direction and engine bell trim angles, the AGC computes the preferred IMU orientation with the x-axis of the stable member in the direction of the computed attitude for thrust initiation. From this the gimbal angles are computed and displayed which would result if the present IMU orientation were held and the vehicle maneuvered to the preferred orientation, i.e., wings level and heads up as seen from the couch looking out along the x-axis. If the displayed middle gimbal angle is greater than 45 degrees, the navigator will select an IMU realignment program. Following the realignment procedures, the navigator may again select program P40.

In realigning, the crew is provided with two choices: 1) the preferred IMU orientation as calculated; and 2) a nominal orientation in which the z-axis of the stable member is directed toward the primary gravitation center, the y-axis is perpendicular to the plane defined by the present position and velocity vector, and the x-axis completes the orthogonal triad.

Assuming that the IMU is properly aligned, the AGC will extrapolate the position and velocity to a time 30 seconds prior to the predicted time of ignition and then select a routine to cause the vehicle to be maneuvered to the desired thrust attitude under computer control. After completion of the maneuver, the AGC requests the navigator to perform the engine gimbal drive test, a safety measure which he does via a keyboard entry. Following the test the gimbal is trimmed.

The computer now checks the time remaining before engine ignition. If the time is less than 45 seconds, an alarm is flashed to the navigator who then has the option of aborting the program. On the
other hand, with sufficient time to go, the AGC will display the time-to-ignition in minutes and seconds, the magnitude of the velocity-to-be-gained during the thrusting maneuver, and the measured change in velocity to the nearest 0.1 foot per second. This last quantity will, of course, be zero until ullage is started.

P40 next initiates a call to the waitlist program to begin the “average g” integration calculation at 30 seconds before the time of ignition. The navigator readies the service propulsion system by setting a main panel switch. Upon receipt of the +x translation hand controller discrete, the computer commands attitude jets on to begin the ullage maneuver. The navigator monitors the velocity change on the DSKY to ensure sufficient ullage is occurring. At 5 seconds prior to ignition, the computer signals the navigator to enable the main engine on. This is the final opportunity to abort the propulsion maneuver.

If the decision is made to continue, the computer commands the engine on when the time to ignition reaches zero and immediately changes the autopilot mode from coasting flight to powered flight. Ullage is terminated as soon as the velocity change monitor detects that the main engine has, indeed, ignited. The DSKY register, which has previously been displaying time to ignition, is changed so that the predicted time-to-go to engine cut-off is displayed.

During the burn the navigator monitors the DSKY registers to ensure that the time-to-go and the velocity-to-be-gained are actually decreasing and monitors the attitude ball indicator to ensure that the attitude error and attitude rates are within acceptable tolerances. When the computer determines that the targeting conditions have been met, an engine off signal will be sent to the SPS and attitude control again returned to the coasting flight autopilot.

At the end of the burn, the DSKY will display the residual values of velocity-to-be-gained in spacecraft coordinates. The navigator now has the option of manually trimming these velocity components by exercising the translation and rotation hand controllers.

In either case, when the maneuver is complete, the AGC will determine the new spacecraft orbital parameters, display them to the navigator and request the navigator to select either the idling program or some other major mission program.

Computer Program Mechanization

Any of the mission programs may be viewed as a chain of computational routines linked together by logical coding which sets and resets appropriate bits for flags, controls timing and sequencing, and produces DSKY displays. The numbered mission programs are initiated as jobs of specified priority. The job allows all types of interrupts to occur and reestablishes itself after the interrupt period. In fact, during its execution, the job itself must periodically check to determine if a higher priority job is waiting.

Program P40, begins as a job of priority 13 when the navigator performs Verb 37 Enter Noun 40 Enter. During the course of P40 several different jobs are begun and terminated, and some are left to recycle at a fixed rate. Usually the job signifies a computational routine which may be preparing display data or targeting parameters. Within itself, the job contains no intrinsic timing information. Since it is interruptable, the computation time interval may be of varying length. The precise timing structure of a program is established by a series of waitlist calls, or in the case of the autopilots, by use of the special interrupt clocks. Thus, for example, if a specific calculation is desired based on the measured gimbal angles at 30 seconds before the time of ignition, a waitlist call for that time may be set in P40 at any convenient point. At precisely this time, P40 will be interrupted and the program will begin at a new designated location in the interrupt mode. During this interval of a few milliseconds, the gimbal angles are read and perhaps a request made for a job of priority 15. After P40 resumes, it looks for higher priority jobs. Upon finding the new job of priority 15, a swap is made with P40. The new program continues until completion, after which P40 is reestablished.

For manned missions it is not necessary to time a program solely through the use of waitlist tasks.
since the navigator is an integral part of the guidance and navigation system. Numerous displays are provided for him to use in making decisions and value judgements. When a navigator response is requested, the mission program is effectively suspended or "put to sleep" and the verb-noun lights flash calling for DSKY inputs. The program is awakened by a navigator response.

The combination of several jobs with varying priorities, controlled in time by waitlist tasks and DSKY inputs, gives the effect of many computer activities being carried on almost simultaneously. In addition to this structure, other interrupt activities can proceed in the background. The Time 4 counter interrupt routine, T4RUPT, is initiated whenever the Time 4 counter overflows. Normally this counter is set to overflow every 120 milliseconds. Everytime this occurs, the T4RUPT routine is initiated and one or more of the following functions are performed:

1. Sampling and verification of the IMU mode of operation including turn-on.
2. Monitoring the telemetry rates.
3. Sampling of malfunction indications from the IMU.
4. Control of the relays of the DSKY for display of information, for commanding IMU and other spacecraft modes, and for control of indicator panel illumination.

The Time 4 counter serves to monitor the entire system in search of malfunctions. The Time 5 and Time 6 interrupts usually control digital autopilot timing and jet firing.

During a thrust maneuver, the computer may spend 20 to 25% of its time in the interrupt mode. For example, the TVC autopilot is cycled every 40 milliseconds and remains in interrupt for 8 milliseconds in each cycle. Additional interrupts which consume time are KEYRUPTS from the depression of DSKY buttons, MARKRUPTS from optics usage, UPRUPTS and DOWNRUPTS signifying up and down telemetry activity and interrupts generated by the hand controllers.

The above description is meant to serve as an aid in understanding how the procedures of P40 are implemented. For more detailed information, consider the illustration in Figure 9 where the various jobs and tasks are shown in graphical form. Program P40 is shown as a job of priority 13. During this job, the initial thrust direction and initial value of the velocity-to-be-gained vector are calculated and displayed in local vertical coordinates. The flashing display calls for navigator approval and P40 is "put to sleep". Upon awakening, the wings level attitude is computed and again displayed asking for DSKY action. When the program is signalled to proceed using Verb 33 Enter, P40 is suspended while the RCS autopilot directs the vehicle to the thrusting attitude by means of a new job of priority 23. The autopilot cycles at 100 milliseconds timed by the Time 5 clock. When the maneuver is complete, the navigator signals his approval and P40 again becomes the active program. The next step is a request by the computer to perform the engine gimbal drive test. If this option is selected by the navigator a waitlist call is placed for an immediate interrupt which will then occur within 10 milliseconds. The test proceeds as a sequence of waitlist tasks called once each second. In the meantime, P40 independently uses the waitlist as a delaying action to provide sufficient time for the test to be completed.

As the time of ignition approaches, P40 establishes a one second waitlist loop to count down to the firing time. This task, in turn, requests a job of priority 14 to display the time-to-ignition. P40 then extrapolates the position and velocity vectors to the time 30 seconds prior to ignition and places a waitlist call for the "average g{subscript}t" integration and steering equation computation to begin at that time. During the extrapolation, which is performed with priority 13, the time-to-go display, having priority 14, is periodically updated. P40 now ends as a job leaving the display function as the only computer activity except, of course, the interrupt controlled RCS autopilot.

At 30 seconds before ignition the "average g{subscript}t" integration is initialized by a job of priority 21 and a waitlist task is established to occur 5 seconds before ignition. In addition, a two second waitlist loop is begun for the purpose of reading the accelerometers. Each waitlist task in the cycle requests a job to perform the "average g{subscript}t" integration
Matrix update for RCS autopilot every 1 sec etc.

Keyboard response:
- Calculate initial VG initialization
- Maneuver initialization
- Display initialization

Interrupts control length of the RCS jet firings:
- 100 ms interrupts for RCS autopilot
- 120 ms interrupts for system maintenance

Legend:
- E = JOB ENDS
- S = JOB SLEEP
- W = JOB WAKE

Matrix update WL calls
WL calls for attitude maneuver jobs
Figure 9. Graphical description of program P40
with priority 20. The reading of the accelerometers, together with the integration, continues every two seconds throughout the maneuver until the program is terminated and a new program number selected.

At 5 seconds to go, a waitlist task is requested to occur at ignition. In addition, a fast reading accelerometer loop, based on 1/2 second waitlist calls, is initiated to monitor the main engine thrust buildup. The length of burn is now calculated by a job of priority 20. Although this has the same priority as "average \( \mathbf{g} \)" integration, no problem results since sufficient time exists for both jobs to be completed. During this final 5 second period, the time-to-go display job of priority 14 changes the display in order to flash a request for the navigator to enable the engine. A positive response brings the time-to-go back to the DSKY and all is prepared for ignition.

At ignition time, the engine bit is set on and control of the vehicle is transferred from the RCS to the TVC autopilot. Thereafter and until shutdown, the TVC autopilot will operate repetitively on 40 millisecond Time 5 interrupts.

Before entering the main portion of the burn, when the steering equations and autopilot will function together, two separate engine monitors are put into operation. The quick read accelerometer loop operates at 1/2 second waitlist calls and activates the TVC filters as soon as thrust is detected. The second monitor, operating as part of the "average \( \mathbf{g} \)" computation, observes the accumulated velocity change at a two second sample time. After a few passes, the engine is judged to be on and steady, and the steering equations are allowed to transmit guidance commands to the autopilot. For most of the burn, until the time-to-go to shutdown reaches -4 seconds the system remains in this guided mode. The timed events immediately before and after shutdown are not different conceptually from those described above and will not be elaborated on here.

In the case of a repetitive job like "average \( \mathbf{g} \)" there is an assumption that the computations involved will, in fact, be completed before the job is called again. For "average \( \mathbf{g} \)" this period is only 0.2 to 0.3 seconds. However, in the case of the steering equations, which are also exercised every two seconds, the solution of the required velocity vector problem cannot be completed within the stated time interval. In other words, "average \( \mathbf{g} \)" integration, cross-product steering, and the required velocity calculation together may take longer than the 2 seconds allowed which would conflict with the next "average \( \mathbf{g} \)" call. The problem of scheduling these crowded events is solved by calling the required velocity calculation only every other cycle when time is critical and using a less accurate extrapolated value.
